Rhythm control aims to restore and keep sinus rhythm. The CCS suggests it for most stable patients whose AF began recently and suggests considering it, rather than rate control, for newly diagnosed AF. Sinus rhythm can be restored by electrical cardioversion under procedural sedation, which works in about 90% of cases, or with drugs, most often IV procainamide in Canadian emergency departments. Antiarrhythmic drugs help keep sinus rhythm, and **catheter ablation**, which isolates the areas that trigger AF, is used after drugs fail or as a first choice in selected patients with symptoms (Andrade et al., 2020).

Because cardioversion can dislodge a clot, the CCS sets anticoagulation rules. If AF has lasted more than 48 hours, most stable patients should receive at least 3 weeks of therapeutic anticoagulation before a planned cardioversion, unless a transesophageal echocardiogram rules out a clot. Cardioversion without that preparation is reserved for AF with a clear onset within 12 hours and no recent stroke or transient ischemic attack, or for AF of 12 to 48 hours in a patient with a CHADS2 score of 0 or 1. Anticoagulation is started as early as possible, ideally before the procedure, and continued for at least 4 weeks afterward; after that, the CHADS-65 algorithm decides (Andrade et al., 2020).

In the emergency department, AF that directly causes hypotension, acute coronary syndrome or pulmonary edema needs immediate electrical cardioversion, while AF triggered by another illness, such as sepsis, is managed by treating that illness. Most patients go home, with follow-up ideally within a week (Andrade et al., 2020). New AF can also follow surgery (Chapter 7; Clinical Judgment box).

Nursing Care and Teaching

The nurse counts the apical and radial pulses for a full minute and records any pulse deficit (section 16.2), and asks about palpitations, fatigue, breathlessness, dizziness and chest pain. Heart rate and blood pressure are checked before rate-control drugs, and values outside the ordered limits are reported. For patients on anticoagulants, the nurse watches for bleeding, assesses fall risk (Chapter 8), checks for drug interactions and follows kidney function. The nurse teaches stroke warning signs using Heart and Stroke's FAST message (Chapter 31) and the need to call 9-1-1 at once. Patients learn what to do about a missed dose and never to stop an anticoagulant without talking to the prescriber. AF is most common in older adults, who are also more likely to have reduced kidney function, several medications and falls, so their medication lists need close review.

CLINICAL JUDGMENT

New Atrial Fibrillation After Surgery

Names and details are fictional; this is a composite story.

Rosa Medeiros, 72, is on day 2 after a total hip replacement. At 0300 she calls the nurse, saying her heart is "fluttering." Her pulse is irregular at about 140 per minute, and her blood pressure has fallen from 132/78 mm Hg at midnight to 96/60 mm Hg. She is alert but anxious.

- **Recognize cues:** new palpitations; irregular rapid pulse; falling blood pressure; recent major surgery. The nurse also checks oxygen saturation, respiratory rate, temperature, pain, urine output, the wound and dressing, and her skin colour, looking at lips and nail beds as well as skin.
- **Analyze cues:** the pattern suggests new AF with rapid ventricular response. Possible triggers after surgery include pain, low blood volume or bleeding, low potassium or magnesium, hypoxemia, infection and pulmonary embolism (Chapter 15).
- **Prioritize hypotheses:** the first concern is falling cardiac output from the fast rate; bleeding as a cause or a contributor must be ruled out.
- **Generate solutions:** call the physician or rapid response team now using SBAR (Chapter 6); place her on a cardiac monitor; obtain a 12-lead ECG; anticipate electrolytes, a complete blood count and other tests; prepare IV access.
- **Take action:** stay with Ms. Medeiros, keep her in bed, give oxygen if saturation is below target, treat pain as ordered and give rate-control drugs as ordered with blood pressure checks.
- **Evaluate outcomes:** heart rate, blood pressure, rhythm, mental status and urine output. If she becomes hypotensive with confusion or chest pain, she needs urgent cardioversion. The team will weigh her stroke risk against her bleeding risk after surgery before choosing anticoagulation.

MEDICATIONS

Drugs for Rate and Rhythm

These drugs are named here without doses; always check the order, the Canadian product monograph and employer policy.

- **Beta-blockers (metoprolol, bisoprolol):** slow the heart rate in AF and other tachycardias. Check heart rate and blood pressure before each dose; watch for bradycardia, hypotension, dizziness and worsening heart failure.
- **Nondihydropyridine calcium channel blockers (diltiazem, verapamil):** slow AV node conduction. Watch for hypotension and bradycardia; used with caution when the ejection fraction is low (Andrade et al., 2020).
- **Digoxin:** slows AV node conduction. Watch for toxicity: poor appetite, nausea, vomiting, blurred or yellow vision, confusion, a slow pulse and new PVCs. Low potassium or magnesium, high calcium, kidney impairment and older age raise the risk (Pharmascience, 2022).
- **Amiodarone:** an antiarrhythmic with a long half-life. Monitoring includes thyroid function, liver enzymes, chest X-ray and lung function, eye symptoms and the QTc. It raises digoxin levels and increases the effect of warfarin (JAMP Pharma Corporation, 2022).
- **Adenosine:** ends many SVTs; given only with cardiac monitoring and resuscitation equipment available. Warn the patient about brief flushing, breathlessness and chest pressure (Fresenius Kabi Canada, 2016).

- **Atropine:** raises the heart rate in symptomatic bradycardia (Wigginton et al., 2025).

16.7 Heart Blocks, Pacemakers and Implantable Devices

Atrioventricular Blocks

In an **AV block**, impulses from the atria are delayed or stopped on their way to the ventricles. The 2018 ACC/AHA/HRS guideline describes four main patterns (Kusumoto et al., 2019):

- **First-degree AV block:** every P wave is conducted, but the PR interval is longer than 0.20 seconds (200 milliseconds). Because no beat is actually blocked, the guideline notes that "AV delay" is the more accurate term (Figure 16.16).
- **Second-degree AV block, Mobitz I (Wenckebach):** the PR interval grows longer from beat to beat until one P wave is not conducted and a QRS is dropped; then the cycle starts again (Figure 16.17).
- **Second-degree AV block, Mobitz II:** the PR interval stays the same, but now and then a P wave is suddenly not followed by a QRS. When every second P wave is blocked (2:1 block), the type cannot be told from the strip (Figure 16.18).
- **Third-degree (complete) AV block:** no impulses reach the ventricles. P waves and QRS complexes each keep their own rhythm with no relationship between them (AV dissociation), and a slow escape rhythm keeps the ventricles beating (Figure 16.19).

Figure 16.16 Rhythm strip showing first-degree AV block: every P wave is followed by a QRS complex, but the PR interval (marked) is longer than 0.20 seconds. (credit: “Rhythm strip: PR interval prolonged, first-degree AV block” by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

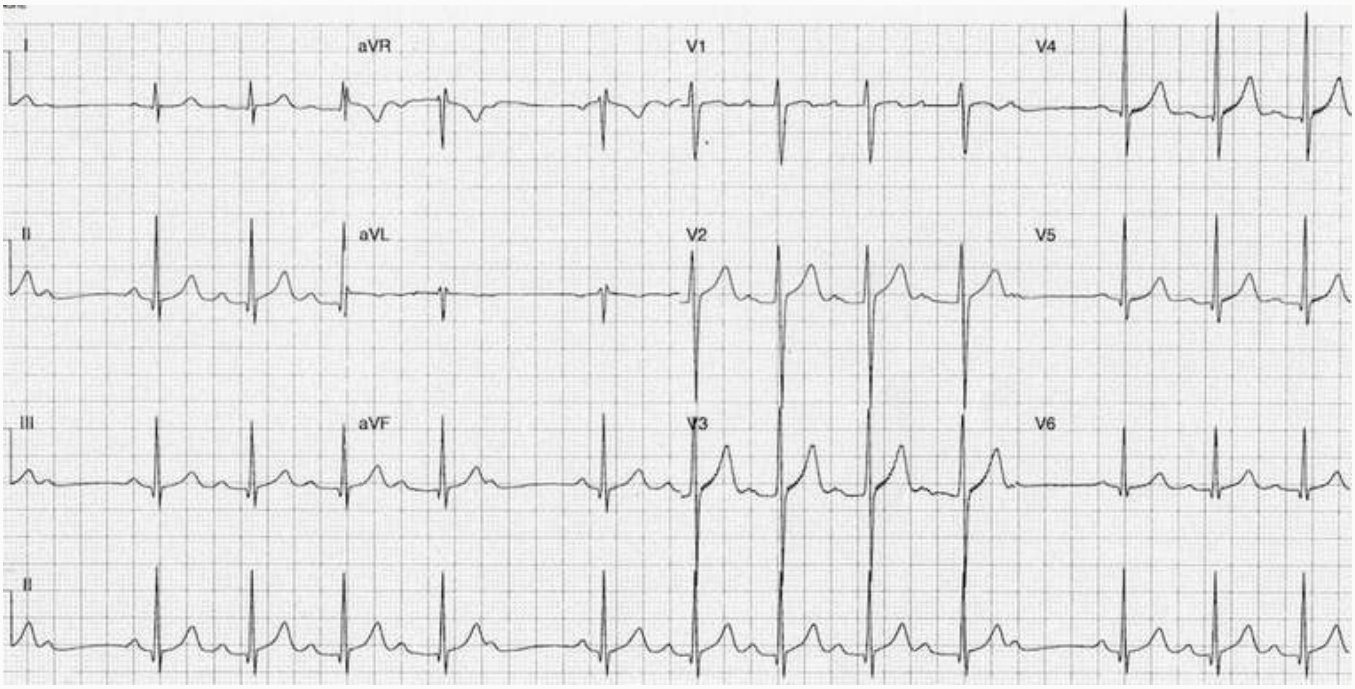

Figure 16.17 A 12-lead ECG showing second-degree AV block, Mobitz I (Wenckebach): the PR interval lengthens from beat to beat until a P wave is not conducted and a QRS complex is dropped. (credit: "Mobitz I AV block" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

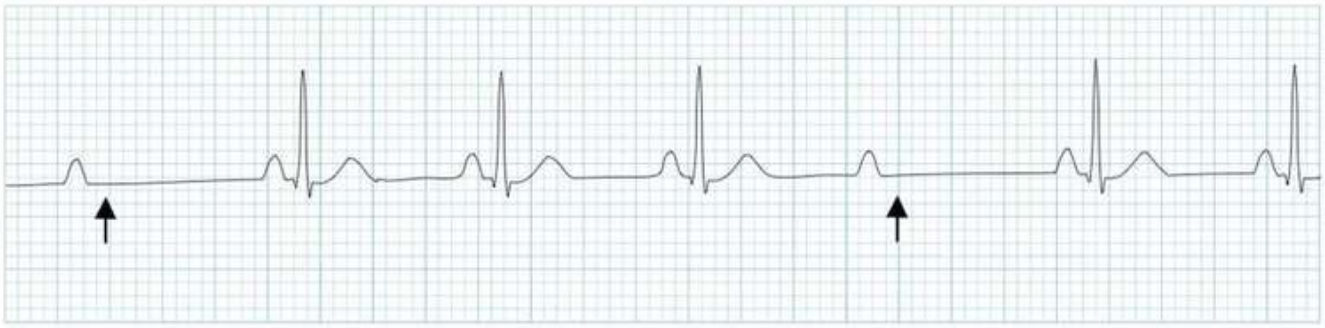

Figure 16.18 Rhythm strip showing second-degree AV block, Mobitz II: the PR interval stays the same, and the arrows mark P waves that are suddenly not conducted. (credit: "Mobitz II AV block" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

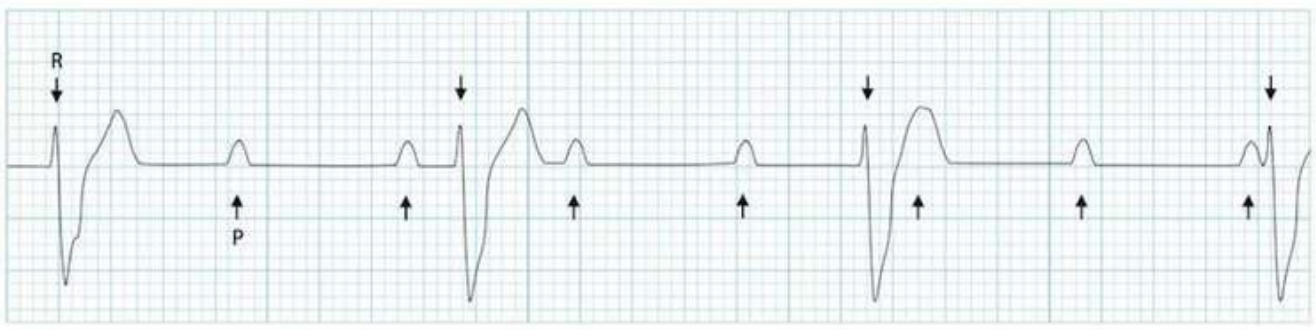

Figure 16.19 Rhythm strip showing complete (third-degree) AV block: P waves (small arrows) at about 100 per minute, unrelated to wide QRS complexes (R) at about 40 per minute. (credit: "Complete heart block" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

Causes include rate-slowing drugs such as beta-blockers, nondihydropyridine calcium channel blockers, digoxin and amiodarone; ischemia or myocardial infarction (Chapter 17); hyperkalemia (Chapter 3); and cardiac surgery (Kusumoto et al., 2019). Gradual,

age-related wear of the conduction system is another cause. First-degree block usually needs only monitoring and a drug review. Mobitz II and third-degree block are more serious because the ventricular rate can fall suddenly. When acquired Mobitz II, high-grade or third-degree block is not due to a reversible cause, the guideline recommends a permanent pacemaker whether or not the patient has symptoms (Kusumoto et al., 2019). A patient who is unstable from a slow rate needs help at once, with atropine, an adrenergic infusion or pacing as described in section 16.5; the AHA notes that immediate pacing may be considered for unstable high-degree AV block when IV access is not available (Wigginton et al., 2025).

Pacing

Transcutaneous pacing sends electrical impulses through large adhesive pads on the chest from an external pacemaker or defibrillator. It is an emergency bridge to a transvenous wire or permanent pacemaker. It is often painful, so the nurse gives analgesia or sedation as ordered (Wigginton et al., 2025). The nurse confirms that each pacing spike produces a QRS and a pulse that matches the paced rate. **Temporary transvenous pacing** uses a wire passed through a vein into the heart. After cardiac surgery, thin pacing wires attached to the outer surface of the heart may exit through the chest wall so that an external pacemaker can be connected if needed.

A **permanent pacemaker** has a small pulse generator placed under the skin of the upper chest, usually with one or more leads in the heart (Figure 16.20). It senses the heart's own activity and paces only when the rate falls too low or a beat is missed. On the strip, a paced beat starts with a **pacing spike**, a sharp vertical line just before the P wave or QRS it triggers; paced QRS complexes are wide. Two problems are important to recognize:

- **Failure to capture:** a spike appears, but no P wave or QRS follows, so the heart does not beat. The rate may drop and the patient may become dizzy or faint.
- **Sensing problems:** in **undersensing** (failure to sense), the pacemaker misses the heart's own beats and fires anyway, so spikes appear at the wrong times. In **oversensing**, it mistakes other electrical signals for heartbeats and holds back pacing, causing pauses.

The nurse assesses the patient, records a strip and a 12-lead ECG, reports promptly and arranges a device check. Lead movement is a known early risk after implantation (Guerra et al., 2024).

Implantable Cardioverter-Defibrillators

An **implantable cardioverter-defibrillator (ICD)** is a device placed under the skin that watches the heart rhythm and treats VT or VF with rapid pacing or a shock; it can also pace for bradycardia. ICDs are used for **secondary prevention** in people who have survived a cardiac arrest or sustained VT, and for **primary prevention** in people at high risk who have not yet had such an event (Guerra et al., 2024). Patients describe a shock as a sudden, uncomfortable thump in the chest. A Canadian patient guide advises a person who receives one shock to sit or lie down and contact the device clinic; to go to the emergency department right away after more than one shock, or after one shock outside clinic hours if feeling unwell; never to drive themselves; and to call 9-1-1 for fainting, dizziness or a racing heart (Nova Scotia Health, 2025). A **wearable cardioverter-defibrillator** is worn on the body for a limited time. It warns with vibration, sound and lights before a shock, which a conscious patient can cancel. It may bridge a period when risk may fall, such as soon after a heart attack, or while an ICD is removed for infection; it cannot pace (Piccini et al., 2016).

Caring for a Patient After Device Implantation

After implantation, the nurse checks the site for bleeding and hematoma, monitors the rhythm and teaches the signs of infection: warmth, redness or swelling that is getting worse, pain that is severe or growing, a temperature over 38 °C, chills, or any drainage (Nova Scotia Health, 2025). One Canadian guide tells ICD patients not to raise the arm on the device side above the head, and to avoid sudden, jerky movements that pull the arm away from the body, for 6 weeks; nurses follow their own site's instructions for pacemakers and ICDs. Patients receive a temporary device identification card, are encouraged to wear a medical alert bracelet and have regular device checks in clinic or through a home remote monitor (Nova Scotia Health, 2025). Remote monitoring can spare people in rural and remote communities long trips.

Driving rules depend on the device, its purpose and whether the person drives privately or commercially. The CCS 2023 fitness-to-drive guidelines, for example, restrict private driving for 1 week after an ICD implanted for primary prevention and for 3 months

after an ICD implanted for secondary prevention, and prohibit driving for 3 months after an appropriate ICD shock. After a pacemaker is implanted, private driving is restricted for a short period set by the CCS guideline; the team gives the exact time (Guerra et al., 2024). People should also not drive for 24 hours after sedation (Nova Scotia Health, 2025).

Many newer systems are **MR-conditional**: magnetic resonance imaging (MRI) is possible only under specific conditions. HRS consensus calls for device checks and reprogramming before and after the scan, ICD shock detection turned off, continuous ECG and oxygen saturation monitoring, and staff trained in advanced life support present (Indik et al., 2017). The nurse makes sure every device is flagged on MRI screening. A magnet over an ICD usually suspends shock therapy while it stays there, though pacing continues (Lampert et al., 2010), so magnets are used only by trained clinicians following protocol. Microwave ovens and everyday appliances are safe. Patients keep mobile phones at least 15 cm (6 inches) from the device, walk through security gates normally while showing their card, ask for a hand search instead of a wand and avoid leaning over a running engine (Nova Scotia Health, 2025).

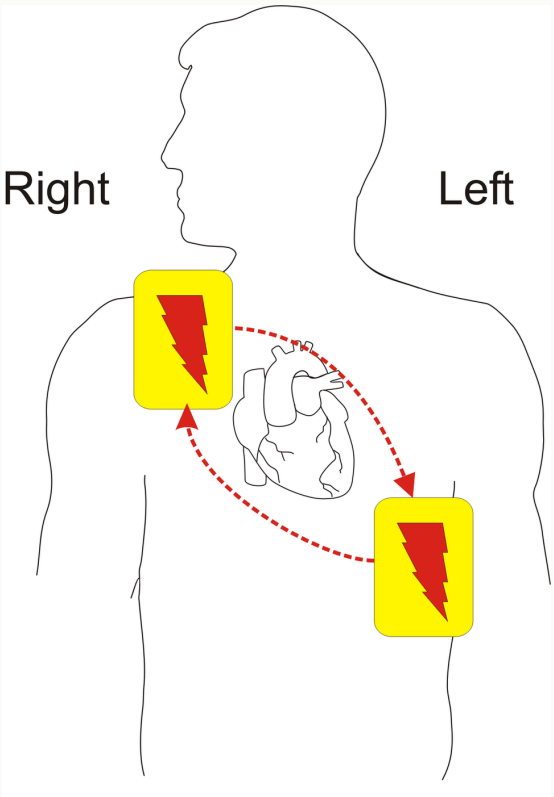

Figure 16.21 Anterolateral pad placement: one pad below the right clavicle and one on the left side of the chest, so the current passes through the heart. (credit: "Defib electrode placement" by Owain Davies/Wikimedia Commons, CC BY 3.0)

Cardioversion, Defibrillation and AEDs

Synchronized cardioversion times the shock to the QRS complex, which lowers the risk of setting off VF (Wigginton et al., 2025). It is used for unstable tachycardias with a pulse and for planned cardioversion of AF or flutter. **Defibrillation** is an unsynchronized shock delivered the moment the button is pressed; it treats VF, pulseless VT and polymorphic VT, which cannot be synchronized reliably (Wigginton et al., 2025). Table 16.4 compares them. Planned cardioversion is done under procedural sedation (Andrade et al., 2020), and the nurse monitors airway, breathing, oxygen saturation and blood pressure until recovery. Pads are placed so the current passes through the heart (Wigginton et al., 2025; Figure 16.21). Before any shock, the operator announces it loudly and confirms that no one is touching the patient or bed.

An **automated external defibrillator (AED)** analyzes the heart rhythm, decides whether a shock is needed and guides the rescuer with voice or screen prompts. AEDs are now found in arenas, recreation centres and other public places (Figure 16.22), and CPR courses teach their use (Health Canada, 2016). In Canada, defibrillators must be licensed

by Health Canada before sale (Heart and Stroke Foundation of Canada, 2025).

When a person with an ICD nears the end of life, shocks can add to the suffering of the patient and family. A person with decision-making capacity, or a substitute decision-maker, may ask for shock therapy to be turned off. HRS consensus states that these conversations begin before implantation, return as goals change and that deactivation is done by people with device expertise wherever possible (Lampert et al., 2010). Chapter 10 discusses these conversations in full.

Figure 16.22 A public-access AED in a wall cabinet. (credit: modification of Figure 19.26, "Defibrillators," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0; panel (a) only)

Table 16.4 Synchronized cardioversion and defibrillation compared (Andrade et al., 2020; Wigginton et al., 2025)

Feature	Synchronized cardioversion	Defibrillation
Timing of the shock	Timed to the QRS complex; the device waits for the next QRS	Delivered as soon as the operator presses the shock button
Main uses	Unstable tachycardia with a pulse (SVT, atrial fibrillation or flutter, monomorphic VT); planned cardioversion of atrial fibrillation or flutter	Ventricular fibrillation, pulseless VT and polymorphic VT
State of the patient	Has a pulse; often awake	Usually pulseless and unresponsive
Sedation and analgesia	Procedural sedation for planned cardioversion; sedation when time allows in an emergency	Not given before the shock; CPR comes first
Before the shock	Turn on sync mode and confirm a sync marker on each QRS; for planned AF cardioversion, confirm the anticoagulation plan	Start CPR; apply pads; shock as soon as the defibrillator is ready
After the shock	Check rhythm, pulse, blood pressure, airway and recovery from sedation	Resume CPR right away for about 2 minutes before the next rhythm check

SCOPE IN PRACTICE

Monitoring, Rhythm Interpretation and Medical Directives

Who watches monitors varies by site. Some hospitals use telemetry technicians to watch central monitors and alert nurses, but the bedside nurse remains accountable for assessing the patient. RNs and RPNs analyze rhythm strips when they have the competence and employer policy supports it (authority, competence and context; Chapter 1, section 1.3; CNO, 2025b).

- **Acting on deterioration:** every nurse who sees a dangerous rhythm acts at once: checks the patient, starts CPR if there is no pulse and calls for help. The RPN consults the RN as the patient's needs change.
- **Directives:** medical directives, orders that apply to a group of patients, let nurses record a 12-lead ECG or start a response without an individual order (College of Nurses of Ontario [CNO], 2025b).
- **Shocks:** in Ontario, applying electricity for cardioversion, defibrillation, cardiac pacemaker therapy or transcutaneous cardiac pacing is a controlled act (a prescribed form of energy) that is not authorized to RNs or RPNs, and using an AED falls under the controlled act of defibrillation (CNO, 2025a). A nurse may defibrillate, including with an AED, under the exception for first aid or temporary assistance in an emergency, or through delegation with an order or directive in place, and only with the knowledge, skill and judgment to do it safely (CNO, 2025a). Where emergencies are likely, such as in hospitals, CNO expects a standardized process with education, ongoing competence assessment and written criteria (CNO, 2025b).

- **Employer and province:** employers can limit but not expand scope, and rules differ by province or territory.

PATIENT EDUCATION

Living With a Pacemaker or ICD

- **Your wound:** Keep the dressing on and the site dry as instructed, and check it daily. Call your provider for growing swelling, redness, warmth, worsening pain, fever above 38 °C, chills or drainage.
- **Your arm:** Follow your team's limits on raising the arm on the device side and on sudden pulling movements, often for several weeks.
- **Your card:** Carry your device card, and consider a medical alert bracelet. Show the card at airport security and ask for a hand search.
- **Your checks:** Keep every device clinic appointment and keep any home monitor plugged in.
- **Your phone:** Keep mobile phones at least 15 cm (6 inches) from the device and not in a shirt pocket over it. Microwave ovens and most household appliances are safe.
- **Your tests:** Tell every provider, including dentists, about your device, especially before an MRI.
- **Driving:** Ask how long you must wait before driving. The answer depends on your device and why you have it.
- **If you have an ICD:** After one shock, sit or lie down and call the device clinic. After more than one shock, or if you feel unwell, go to the emergency department and do not drive yourself. Call 9-1-1 if you faint or feel your heart racing.

Chapter 16 Summary

Introduction

- Diseases of the heart caused 17.7% of deaths in Canada in 2024, second only to cancer.
- Nurses on every unit are often first to notice cardiac problems; this chapter builds the assessment and rhythm skills used in Chapters 17 to 20.

16.1 The Heart and Its Rhythm: A Brief Review

- Four chambers and four valves keep blood moving one way through the pulmonary and systemic circuits.
- The left ventricle receives most of its coronary blood flow in diastole, so very fast rates can starve the heart muscle.
- The SA node normally paces the heart; the AV node delays the impulse; the His–Purkinje system spreads it through the ventricles. Lower pacemakers are slower and less reliable.
- The P wave shows atrial depolarization, the QRS ventricular depolarization, and the T wave ventricular repolarization.
- Cardiac output equals heart rate times stroke volume; preload, afterload and contractility shape stroke volume, and rates that are too slow or too fast can lower output.

16.2 Focused Cardiovascular Assessment

- A chest pain history covers onset, location, radiation, character, severity, duration, triggers and associated symptoms, in the patient's own words.
- Many people, especially women, have heart attacks without chest pain; the nurse never rules out a cardiac cause because symptoms seem atypical.
- The assessment includes an apical-radial pulse deficit when the pulse is irregular, JVP, pulses, edema (ankle circumference is more reliable than pitting scales) and heart sounds.
- On darker skin, the nurse checks the lips, tongue, oral mucosa, conjunctivae and nail beds for cyanosis and pallor.
- Signs of low cardiac output and new chest pain need immediate action and escalation.

16.3 Cardiac Tests

- Correct electrode placement and skin preparation are essential for an accurate 12-lead ECG; a 2021 American chest pain guideline calls for an ECG within 10 minutes of arrival.
- High-sensitivity troponin is reported in ng/L; a rise or fall on timed repeat samples suggests acute injury.
- BNP and NT-proBNP reflect wall stress and help assess breathlessness (Chapter 18); electrolytes affect rhythm (Chapter 3).
- Nursing care for TEE, stress tests and catheterization includes consent, fasting, medication review, kidney function and post-procedure monitoring.

16.4 Cardiac Monitoring and Reading a Rhythm Strip

- Monitor only patients with an indication, and review the need every 24 to 48 hours or sooner.
- Good skin preparation, correct electrode placement and electrode changes reduce artifact and false alarms.
- Most monitor alarms are false or non-actionable; alarm fatigue can lead to missed events, so the nurse assesses the patient for every alarm.
- Analyze every strip in the same order: rate, regularity, P waves, PR interval, QRS duration, then QT and QTc.

16.5 Common Dysrhythmias and How to Respond

- The response to any new rhythm starts with the patient: check responsiveness, breathing, pulse and perfusion, and rule out artifact.
- Hypotension, sudden change in mental status, chest pain, signs of shock and acute heart failure mean a rhythm is unstable; the nurse calls for help at once.
- Sinus tachycardia is treated by treating its cause; symptomatic bradycardia may need atropine, an adrenergic infusion or pacing.
- Stable SVT is treated with vagal manoeuvres and then adenosine with cardiac monitoring; unstable SVT needs synchronized cardioversion.
- VF and pulseless VT need CPR and early defibrillation; asystole and PEA need CPR, epinephrine as soon as feasible and a search for reversible causes, with no shock.

16.6 Atrial Fibrillation and Flutter

- AF produces an irregularly irregular rhythm with no clear P waves; flutter produces regular sawtooth waves.
- AF lowers cardiac output through lost atrial kick and rapid ventricular response, and raises stroke risk through clots in the left atrial appendage.
- The CCS CHADS-65 algorithm recommends oral anticoagulation, usually a DOAC, for people 65 or older or with any CHADS2 risk factor.
- Rate control uses beta-blockers, diltiazem, verapamil or digoxin; rhythm control uses cardioversion, antiarrhythmic drugs or ablation, with anticoagulation rules around cardioversion.
- Nursing care includes apical-radial pulse checks, monitoring for instability and bleeding, teaching stroke warning signs and supporting adherence.

16.7 Heart Blocks, Pacemakers and Implantable Devices

- First-degree block is a long PR interval; Mobitz I shows a lengthening PR before a dropped beat; Mobitz II drops beats with a constant PR; third-degree block shows unrelated P waves and QRS complexes.
- Unstable bradycardia from AV block may need transcutaneous pacing as a bridge; acquired Mobitz II and third-degree block usually lead to a permanent pacemaker.
- Nurses recognize pacing spikes, failure to capture and sensing problems (undersensing and oversensing), and escalate promptly.
- After device implantation, teaching covers wound care, arm limits, ID cards, remote checks, driving rules, MRI and electromagnetic interference.

- Synchronized cardioversion is timed to the QRS for rhythms with a pulse; defibrillation is immediate and unsynchronized for pulseless VT and VF; AEDs guide any rescuer.

Key Terms (52)

afterload: The force the ventricle must work against to eject blood; raised by high blood pressure or a narrowed aortic valve.

alarm fatigue: Desensitization of clinicians exposed to many false or non-actionable alarms, leading to slower or missed responses.

artifact: A signal on an ECG or monitor that does not come from the heart's electrical activity, such as interference from movement or loose electrodes.

asystole: The absence of electrical activity in the ventricles, seen as a flat line; a non-shockable arrest rhythm.

atrial fibrillation (AF): A dysrhythmia in which disorganized atrial activity produces an irregularly irregular ventricular rhythm with no clear P waves.

atrial flutter: A dysrhythmia caused by an organized loop of atrial activity that produces regular sawtooth flutter waves.

atrioventricular (AV) node: Conduction tissue low in the right atrium that delays the impulse before it reaches the ventricles; with the bundle of His, the normal route from atria to ventricles.

automated external defibrillator (AED): A portable device that analyzes the heart rhythm, decides whether a shock is needed and guides the rescuer with prompts.

cardiac output: The volume of blood the heart pumps each minute; heart rate multiplied by stroke volume.

CHADS-65: The Canadian Cardiovascular Society algorithm that recommends oral anticoagulation for people with AF who are 65 or older or who have any CHADS2 risk factor.

contractility: The strength of the heart muscle's contraction, apart from how much it was stretched by filling.

defibrillation: An unsynchronized shock delivered immediately to treat ventricular fibrillation, pulseless VT or polymorphic VT.

depolarization: Electrical activation of heart muscle cells, which triggers contraction.

dysrhythmia: Any heart rhythm other than normal sinus rhythm, whether too fast, too slow, irregular or started from an abnormal site.

echocardiography: Ultrasound imaging of the heart's structure and movement, done through the chest wall (transthoracic) or from the esophagus (transesophageal).

failure to capture: A pacemaker problem in which a pacing spike is not followed by a P wave or QRS.

first-degree AV block: Delayed AV conduction in which every P wave is conducted but the PR interval is longer than 0.20 seconds.

high-sensitivity troponin: A blood test that measures very low levels of cardiac troponin, a protein released from injured heart muscle; reported in ng/L.

implantable cardioverter-defibrillator (ICD): An implanted device that detects VT or VF and treats it with rapid pacing or a shock.

jugular venous pressure (JVP): The vertical height of the internal jugular venous pulsation above the sternal angle; an estimate of right-sided filling pressure.

Mobitz I: Second-degree AV block in which the PR interval lengthens progressively until a P wave is not conducted (also called Wenckebach).

Mobitz II: Second-degree AV block in which the PR interval stays constant but some P waves are suddenly not conducted.

murmur: A heart sound made by turbulent blood flow, described by its timing, location, loudness and quality.

natriuretic peptide: A hormone (BNP or NT-proBNP) released by heart muscle under increased wall stress; used in assessing heart failure.

normal sinus rhythm: A regular rhythm from the SA node at 60 to 100 bpm, with an upright P wave before each QRS, a PR interval of 0.12 to 0.20 seconds and a QRS under 0.12 seconds.

P wave: The ECG wave produced by atrial depolarization.

permanent pacemaker: An implanted device with a pulse generator and leads that senses the heart's activity and paces when the rate is too slow.

PR interval: The time from the start of the P wave to the start of the QRS complex; normally 0.12 to 0.20 seconds.

preload: The filling of the ventricle, and the stretch of its muscle, just before it contracts.

premature ventricular contraction (PVC): An early beat that starts in the ventricles, seen as a wide, oddly shaped QRS with no P wave before it.

pulse deficit: The apical rate minus the radial rate, counted at the same time by two nurses; a sign that some beats do not reach the periphery.

pulseless electrical activity (PEA): An organized rhythm on the monitor without a palpable pulse; a non-shockable arrest rhythm.

QRS complex: The ECG complex produced by ventricular depolarization; normally under 0.12 seconds wide.

QT interval: The time from the start of the QRS complex to the end of the T wave; corrected for heart rate as the QTc.

rapid ventricular response (RVR): A ventricular rate above 100 per minute in atrial fibrillation or flutter.

rate control: An AF treatment strategy that slows the ventricular rate, usually with beta-blockers, nondihydropyridine calcium channel blockers or digoxin.

repolarization: The return of heart muscle cells to their resting electrical state after depolarization.

rhythm control: An AF treatment strategy that restores and maintains sinus rhythm with cardioversion, antiarrhythmic drugs or catheter ablation.

S3: An extra heart sound in early diastole, just after S2, from rapid ventricular filling.

S4: An extra heart sound in late diastole, just before S1; always abnormal.

sinoatrial (SA) node: The heart's normal pacemaker, in the high right atrium; its cells fire faster than any others.

sinus bradycardia: A sinus rhythm slower than normal; the 2018 ACC/AHA/HRS guideline defines it as a sinus rate below 50 per minute.

sinus tachycardia: A sinus rhythm faster than 100 per minute, usually a response to another problem such as fever, pain or low blood volume.

stroke volume: The volume of blood the left ventricle ejects with each beat.

supraventricular tachycardia (SVT): A regular, narrow-complex tachycardia that starts above the ventricles, often from a loop involving the AV node.

synchronized cardioversion: A shock timed to the QRS complex, used for tachycardias with a pulse.

telemetry: Continuous ECG monitoring that sends the signal from a wireless transmitter to a central station.

third-degree AV block: Complete AV block in which no atrial impulses reach the ventricles, so P waves and QRS complexes are unrelated.

transcutaneous pacing: Emergency pacing through adhesive pads on the chest, used as a bridge to transvenous or permanent pacing.

vagal manoeuvre: An action that increases vagal tone to slow AV node conduction, such as a Valsalva manoeuvre, used first for stable regular narrow-complex tachycardia.

ventricular fibrillation (VF): Chaotic electrical activity in the ventricles with no organized QRS complexes and no cardiac output.

ventricular tachycardia (VT): A fast rhythm from the ventricles with wide QRS complexes that may or may not produce a pulse.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Gloria Benoit (Questions 1–4): Gloria Benoit, 74, was admitted to a medical unit in Belleville, Ontario, after fainting at home. She is on telemetry because a cardiac cause of her syncope is suspected. Her electrodes were placed 2 days ago. An RPN is caring for her, with an RN and a central monitor technician on the team.

1. [CORE] The monitor technician reports repeated "leads off" and "irregular rhythm" alarms for Mrs. Benoit. The nurse finds her sitting up, talking and in no distress, with a radial pulse that is regular. Which finding most likely explains the alarms?

a. Her rhythm has changed to atrial fibrillation with a fast ventricular response

b. The chest electrode has been placed in the V1 position on her chest

c. The electrodes are 2 days old, with dry gel and lifting edges

d. Her heart rate is 84 bpm

Answer: c — Old electrodes with dried gel and poor contact are a leading cause of artifact and false alarms, and daily electrode changes with skin preparation reduce nuisance alarms (c) (section 16.4). A regular radial pulse in a comfortable patient makes atrial fibrillation unlikely (a), although an ECG would confirm the rhythm. V1 is a standard and useful monitoring position (b). A heart rate of 84 bpm is normal and would not trigger these alarms (d).

2. [CORE] After the electrodes are replaced, the strip shows a regular rhythm with 4 large boxes between consecutive R waves. What is Mrs. Benoit's heart rate?

a. 60 bpm

b. 75 bpm

c. 100 bpm

d. 150 bpm

Answer: b — For a regular rhythm, the rate is 300 divided by the number of large boxes between R waves: 300 ÷ 4 = 75 bpm (b) (section 16.4). Option a would need 5 large boxes, c would need 3, and d would need 2.

3. [CORE] Later, the central monitor shows a flat line in Mrs. Benoit's monitoring lead. What does the nurse do first?

a. Go to the patient and check responsiveness, breathing and pulse

b. Ask the technician to print the strip for the chart

c. Increase the size (gain) of the tracing on the monitor

d. Replace all electrodes before assessing further

Answer: a — The nurse assesses the patient before interpreting the screen. A flat line may be a loose lead or a cardiac arrest, and only the patient can tell which (a) (section 16.4). Printing the strip (b), changing the display (c) or replacing electrodes (d) first could delay resuscitation if she has no pulse.

4. [CORE] The next morning, Mrs. Benoit says she feels dizzy. Her heart rate is 38 bpm, her blood pressure is 82/50 mm Hg, and she is pale and clammy. What is the RPN's most appropriate action?

a. Recheck the vital signs in 30 minutes, since she is awake and talking

b. Ask her to stand slowly at the bedside so that orthostatic blood pressure changes can be measured

c. Document the findings and report them at the end of the shift

d. Stay with her, call for help as the rapid response criteria direct, and notify the RN

Answer: d — A slow heart rate with low blood pressure and signs of poor perfusion suggests low cardiac output. Every nurse who notices deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change (d) (sections 16.1 and 16.2; Chapter 6). Waiting (a) or delaying the report (c) puts her at risk. Standing (b) could cause her to faint and fall.

5. [CORE] A nurse is teaching a community group about heart attack signs. Which symptoms may signal a heart attack, especially in women? Select all that apply.

- **a.** Shortness of breath
- **b.** Extreme fatigue
- **c.** Pressure in the upper back
- **d.** Fever with chills
- **e.** A rash on the chest
- **f.** Dizziness or light-headedness

Answer: a, b, c, f — Heart and Stroke lists shortness of breath (a), extreme fatigue (b), upper back pressure (c), and dizziness or light-headedness (f) among heart attack signs that women may have, sometimes without chest pressure; pain or pressure in the upper abdomen is another (section 16.2). Fever with chills (d) points to infection, and a rash (e) is not a sign of a heart attack.

6. [CORE] A patient has long-standing high blood pressure. Which part of cardiac output does high blood pressure most directly increase?

- **a.** Afterload
- **b.** Preload
- **c.** Heart rate
- **d.** Contractility

Answer: a — Afterload is the force the ventricle must work against to eject blood, and high blood pressure raises it (a) (section 16.1). Preload is the filling and stretch of the ventricle before it contracts (b). High blood pressure does not directly set the heart rate (c). Contractility is the strength of the muscle's contraction (d).

7. [CORE] Two nurses count a patient's pulse at the same time for 1 minute. The apical rate is 112 bpm and the radial rate is 88 bpm. Which interpretation is correct?

- **a.** The radial pulse is the more accurate measure of heart rate, so it should be documented
- **b.** A difference this size is normal when counting at two sites
- **c.** There is a pulse deficit of 24, and some beats are not reaching the wrist
- **d.** The apical count is too high because heart sounds were counted twice

Answer: c — The pulse deficit is the apical rate minus the radial rate (112 − 88 = 24). It shows that some beats heard at the apex are not felt at the wrist, often with an irregular rhythm, and an ECG should identify the rhythm (c) (section 16.2). The apical count reflects every beat the heart makes, so the radial count underestimates the rate (a). A deficit is not a normal finding (b). With two nurses counting together, double-counting is not the explanation (d).

8. [CORE] A patient with chest pain has a high-sensitivity troponin drawn at arrival. Which statement about this test is accurate?

- **a.** A single normal result at arrival rules out heart muscle injury, so no repeat test is needed
- **b.** Results are reported in micromoles per litre
- **c.** Troponin rises only when a coronary artery is blocked
- **d.** A rise or fall between repeat samples suggests acute injury

Answer: d — Acute myocardial injury is shown by troponin above the 99th percentile with a rising or falling pattern on repeat samples, so timed repeat samples matter (d) (section 16.3). One early sample is not enough on its own (a). Results are reported in ng/L (b). Troponin can also rise with tachydysrhythmias, myocarditis, pulmonary embolism or heart failure (c).

9. [CORE] Where does the nurse place the V1 electrode for a 12-lead ECG?

- **a.** Fifth intercostal space, left midclavicular line
- **b.** Fourth intercostal space, right sternal border
- **c.** Second intercostal space, right sternal border
- **d.** Fourth intercostal space, left sternal border

Answer: b — V1 sits at the right sternal border in the fourth intercostal space (b) (section 16.3). The fifth intercostal space at the left midclavicular line is V4 (a). The second intercostal space is too high, a common error (c). The left sternal border at the fourth intercostal space is V2 (d).

10. [CORE] A telemetry unit wants to reduce nuisance monitor alarms. Which practice is supported by evidence?

- **a.** Change electrodes daily after preparing the skin
- **b.** Turn down the alarm volume at the central station
- **c.** Use the same default alarm limits for every patient
- **d.** Silence arrhythmia alarms for patients who often have artifact

Answer: a — Daily electrode changes with skin preparation reduced nuisance alarms on an adult telemetry unit (a) (section 16.4). Lowering the volume (b) and silencing alarms (d) risk missing true events. Limits should be set to each patient's baseline and the purpose of monitoring, within policy, rather than one default for all (c).

11. [CORE] On a regular rhythm strip, the nurse measures 6 small boxes from the start of the P wave to the start of the QRS complex. Which interpretation is correct?

- **a.** The PR interval is 0.12 seconds, which is normal
- **b.** The PR interval is 0.30 seconds, which is prolonged
- **c.** The PR interval is 0.24 seconds, which is prolonged
- **d.** The PR interval is 0.18 seconds, which is normal

Answer: c — Each small box equals 0.04 seconds at 25 mm per second, so 6 boxes equal 0.24 seconds. This is longer than the normal 0.12 to 0.20 seconds (c) (section 16.4). Option a would be 3 boxes, b would be 7.5 boxes, and d would be 4.5 boxes.

12. [CORE] A nurse is assessing a patient with very dark skin for central cyanosis. Where should the nurse look?

- **a.** The skin of the forearms
- **b.** The skin of the cheeks
- **c.** The palms only, in fluorescent light
- **d.** The lips, tongue and inside of the mouth

Answer: d — Cyanosis is best seen where the skin is thin and the blood supply is rich, such as the lips, tongue and oral mucosa, with the conjunctivae and nail beds also checked; on dark skin these may look grey or whitish (d) (section 16.2). Forearm (a) and cheek (b) skin hide colour changes on darker skin. Fluorescent light gives a bluish tint, and the palms alone are not enough (c).

13. [CORE] An RPN on a medical unit in Ontario notices that a patient on telemetry has a new irregular rhythm. The patient reports palpitations, and the vital signs are within the patient's usual range. Which action best reflects CNO's scope of practice standard?

a. Wait for the RN to review the central monitor at the next scheduled check

b. Assess the patient, notify the RN and prescriber, and obtain a 12-lead ECG if agency policy authorizes it

c. Ask the charge nurse to reassign the patient to an RN because any change in rhythm means the patient is no longer stable

d. Give an antidysrhythmic drug from the unit stock to control the rate

Answer: b — CNO's Scope of Practice standard asks nurses to consider authority, competence and context (College of Nurses of Ontario, 2025b). The RPN assesses the patient, consults the RN as the patient's needs change, and obtains an ECG where policy and orders allow (b) (section 16.3; Chapter 1, section 1.3). Waiting delays care (a). A change in rhythm does not by itself require reassignment (c). Giving a drug without an order is outside the RPN's authority (d).

14. [CORE] A nurse is assessing jugular venous pressure. Which technique is correct?

a. Measure the vertical height of the top of the venous pulsation above the sternal angle

b. Palpate the internal jugular vein to find the highest point of pulsation

c. Lay the patient flat and measure from the earlobe to the pulsation

d. Use the carotid pulsation as the reference point

Answer: a — The JVP is the vertical height of the top of the venous pulsation above the sternal angle, which has an upper limit of normal of about 3 cm (a) (section 16.2). The venous pulse cannot be felt (b). The bed is raised to the angle that brings the pulsation into view, and the sternal angle, not the earlobe, is the reference (c). The carotid pulse is arterial and is not the JVP (d).

15. [CORE] While auscultating, the nurse hears an extra heart sound just after S2. How is this sound described?

a. S1, from the atrioventricular valves closing

b. S4, in late diastole

c. A systolic murmur

d. S3, in early diastole

Answer: d — S3 occurs in early diastole, just after S2, from rapid filling of the ventricle (d) (section 16.2). S1 marks the start of systole (a). S4 occurs in late diastole, just before S1 (b). A murmur is a longer sound from turbulent flow, and this sound falls in diastole, not systole (c).

16. [CORE] A patient with type 2 diabetes is scheduled for coronary angiography. The patient takes metformin and has an estimated glomerular filtration rate (eGFR) of 58 mL/min/1.73 m². Based on Canadian radiology guidance, what does the nurse expect?

a. The angiogram will be cancelled to protect the kidneys

b. Metformin will be stopped for 1 week before the test and restarted only after repeat kidney tests

c. Metformin does not routinely need to be stopped for this test

d. Contrast dye cannot be used in people with diabetes

Answer: c — The Canadian Association of Radiologists does not recommend stopping metformin before contrast, except for patients with an eGFR of 30 or less or acute kidney injury (c) (section 16.3). Fear of kidney injury is not a reason to withhold needed contrast, and diabetes alone does not rule contrast out (a, d). Routine stopping of metformin is not recommended at this eGFR (b).

17. [RN] A patient's 12-lead ECG shows new ST elevation. In which group of leads would elevation be considered to be in contiguous leads?

a. aVR and V6

b. II, III and aVF

c. I and III

d. V1 and aVF

Answer: b — Leads II, III and aVF form a contiguous group that views the inferior heart (b) (section 16.3, Going Deeper). The other contiguous groups are I and aVL, and V1 to V6. aVR and V6 (a), I and III (c), and V1 and aVF (d) do not look at neighbouring areas.

18. [RN] A patient started a class III antidysrhythmic drug 2 days ago. The baseline QTc was 440 ms; today's 12-lead ECG shows a QTc of 520 ms. The patient's potassium is low. What is the nurse's priority?

a. Recheck the QTc on the bedside monitor and compare it with the 12-lead value

b. Document the finding, as some QT prolongation is expected with this drug

c. Give the next dose and repeat the ECG tomorrow

d. Hold the next dose and notify the prescriber at once

Answer: d — A QTc over 500 ms raises the risk of torsades de pointes, and the causative drug is generally stopped; low potassium adds to the risk (d) (section 16.3, Going Deeper). Monitor-derived QTc values should not be compared with 12-lead values (a). This degree of prolongation is not an acceptable expected effect (b). Giving the dose (c) increases the danger.

Case: Farah Haddad (Questions 19–24): Farah Haddad, 69, comes to the emergency department in Hamilton, Ontario, saying her heart has been "racing" since she woke 6 hours ago. She has hypertension and type 2 diabetes. She is alert. Heart rate 148 per minute and irregular, blood pressure 118/72 mm Hg, respiratory rate 20 per minute, oxygen saturation 96% on room air. The monitor shows narrow QRS complexes at irregular intervals with a wavy baseline and no clear P waves.

19. [CORE] Which finding from the monitor is most consistent with atrial fibrillation?

a. Regular sawtooth waves between the QRS complexes

b. Irregularly irregular narrow QRS complexes with no clear P waves

c. A PR interval that lengthens until one QRS is dropped

d. Wide, regular QRS complexes at 148 per minute

Answer: b — An irregularly irregular rhythm without clear P waves and with a wavy baseline is the pattern of atrial fibrillation (section 16.6). Regular sawtooth waves (a) suggest atrial flutter. A lengthening PR interval with a dropped QRS (c) is second-degree AV block, Mobitz I (section 16.7). Wide, regular complexes at this rate (d) suggest ventricular tachycardia (section 16.5).

20. [CORE] Ms. Haddad says she gets short of breath walking to the washroom. Which explanation best links this symptom to her rhythm?

a. The irregular rhythm causes her lungs to retain carbon dioxide during exertion.

b. Atrial fibrillation directly lowers her hemoglobin level.

c. Anxiety about the diagnosis is the main cause of the breathlessness.

d. A fast rate and the lost atrial kick reduce her stroke volume.

Answer: d — In AF with rapid ventricular response, the loss of atrial contraction and the short filling time reduce stroke volume and cardiac output, which can cause breathlessness on exertion (section 16.6). AF does not cause carbon dioxide retention (a) or lower hemoglobin (b). Anxiety (c) may add to symptoms, but assuming it is the main cause would miss a physiological explanation.

21. [CORE] Which concern should the nurse monitor most closely over the next hour?

a. Signs of reduced perfusion, such as hypotension or confusion

b. Bleeding from a long-term anticoagulant she has not yet started

c. Long-term weakening of the ventricle from months of fast rates

d. Her knowledge of the Heart and Stroke FAST message

Answer: a — With a heart rate of 148 per minute, the most immediate risk is hemodynamic instability: hypotension, altered mental status, chest pain, shock or acute heart failure (sections 16.5 and 16.6). Bleeding (b) is not yet a risk from a drug not yet started. Tachycardia-mediated cardiomyopathy (c) develops over weeks. Stroke teaching (d) matters but comes after stability is assured.

22. [CORE] The physician orders an IV beta-blocker to slow Ms. Haddad's heart rate. Which nursing action belongs in the plan of care?

a. Teach her to perform a Valsalva manoeuvre before each dose so the drug works faster

b. Restrict all oral fluids until her rhythm converts

c. Monitor her rhythm continuously and check heart rate and blood pressure around each dose

d. Place defibrillator pads on her chest in case the drug causes ventricular fibrillation

Answer: c — Rate-control drugs can cause hypotension and bradycardia, so continuous monitoring and blood pressure and heart rate checks before and after each dose are needed (section 16.6; Medications box). Vagal manoeuvres (a) are used for regular narrow-complex SVT, not for AF. Fluid restriction (b) has no basis here. Applying pads routinely (d) is not indicated for a stable patient receiving rate control.

23. [CORE] Thirty minutes later, Ms. Haddad's blood pressure is 80/48 mm Hg, she is confused and she reports chest pressure. Her rhythm is unchanged. What should the nurse do first?

a. Give a second dose of the beta-blocker to slow the rate further

b. Call for urgent help through the rapid response or code system and stay with her

c. Teach her slow, deep breathing to reduce anxiety

d. Reposition her and recheck her blood pressure in 15 minutes

Answer: b — Hypotension, confusion and chest pressure are signs of instability; AF that directly causes these needs urgent help and likely immediate synchronized cardioversion (sections 16.5 and 16.6). Another dose of a beta-blocker (a) could worsen hypotension. Breathing coaching (c) and waiting 15 minutes (d) delay care for an unstable patient.

24. [CORE] After synchronized cardioversion, which finding shows the treatment has had the intended effect?

a. Her heart rate is 128 per minute and irregular with no clear P waves, and her blood pressure is 90/56 mm Hg.

b. She is drowsy and difficult to rouse 2 hours after the procedure, although her rhythm is regular.

c. The monitor shows sync markers on each QRS complex.

d. She is alert, with a P wave before each QRS at 78 per minute and blood pressure 122/74 mm Hg.

Answer: d — A regular sinus rhythm with normal blood pressure and normal mental status shows restored rhythm and perfusion (section 16.7). A fast irregular rate with low blood pressure (a) shows AF has continued. Being hard to rouse 2 hours later (b) is a concern that needs reporting. Sync markers (c) are checked before the shock and show the device setting, not the outcome.

25. [CORE] The nurse is caring for patients with new tachycardias. Which findings indicate that a patient's rhythm is unstable? Select all that apply.

a. Blood pressure 82/50 mm Hg

b. New confusion

c. Palpitations at rest with blood pressure 134/82 mm Hg and normal mental status

d. Chest pain

e. New crackles in both lungs with acute shortness of breath

f. Heart rate 112 per minute with warm, dry skin and normal mental status

Answer: a, b, d, e — Heart and Stroke Foundation of Canada and AHA guidance list hypotension (a), a sudden change in mental status (b), chest pain (d) and acute heart failure (e) as signs of instability, along with signs of shock (section 16.5). Palpitations with normal blood pressure and mentation (c) and a moderate tachycardia with good perfusion (f) are not signs of instability, although both still need assessment and reporting.

26. [CORE] A patient on a medical unit is found unresponsive, not breathing normally and pulseless. The monitor shows a chaotic baseline with no recognizable QRS complexes. After calling for help, what is the nurse's priority?

a. Obtain a 12-lead ECG to confirm the rhythm before any treatment

b. Prepare for synchronized cardioversion timed to the next QRS complex

c. Start high-quality CPR and defibrillate as soon as the defibrillator is ready

d. Give epinephrine before the first shock to improve the chance of success

Answer: c — This is ventricular fibrillation, a shockable rhythm; the response is immediate high-quality CPR and defibrillation as soon as possible (section 16.5). A 12-lead ECG (a) delays care. Synchronized cardioversion (b) is for rhythms with a pulse and cannot sync to VF. In shockable rhythms, epinephrine (d) is given after the first shocks have failed.

27. [CORE] During a code, the monitor shows a flat line. The nurse has confirmed that the electrodes are attached, and the patient has no pulse. Which action should the team take?

a. Continue CPR, give epinephrine as soon as feasible and look for reversible causes

b. Deliver an unsynchronized shock at once

c. Start transcutaneous pacing

d. Pause CPR every 30 seconds to check for a pulse

Answer: a — Asystole is not shockable; care is CPR, epinephrine as soon as feasible and a search for reversible causes (the Hs and Ts) (section 16.5). A shock (b) does not help asystole. Pacing (c) is not recommended during an established cardiac arrest. Frequent pauses (d) interrupt compressions; rhythm checks occur about every 2 minutes.

28. [CORE] A stable adult has a regular, narrow-complex tachycardia at 190 per minute. A vagal manoeuvre has not worked, and the physician orders adenosine. What should the nurse tell the patient before the dose?

a. "This medicine is given slowly over an hour, so you can rest while it drips in."

b. "You will not need the heart monitor once the medicine is in."

c. "You will need to stop eating and drinking for 12 hours afterward."

d. "You may feel flushing or chest pressure right away, but it passes quickly."

Answer: d — Flushing, breathlessness and chest pressure are common and short-lived with adenosine, and warning the patient reduces fear (section 16.5). Adenosine acts within seconds rather than over an hour (a). Cardiac monitoring is required (b) because pauses, including asystole, can occur. No fasting (c) is needed afterward.

29. [CORE] Which patient's premature ventricular contractions (PVCs) are of greatest concern to the nurse?

a. A 24-year-old with occasional PVCs after drinking coffee and a normal echocardiogram

b. A 68-year-old with chest pain, new frequent PVCs and a potassium level of 3.1 mmol/L

c. A 40-year-old who notices a skipped beat once a day and has no heart disease

d. A 55-year-old whose PVCs disappeared after quitting an energy drink

Answer: b — New frequent PVCs with chest pain and low potassium suggest ischemia and electrolyte imbalance, both of which raise the risk of dangerous ventricular rhythms; this needs a 12-lead ECG and escalation (section 16.5). Occasional PVCs in a structurally normal heart (a, c) are usually benign, and PVCs that resolve when a trigger is removed (d) are reassuring.

30. [CORE] A patient's rhythm strip shows a constant PR interval of 0.18 seconds, but now and then a P wave is not followed by a QRS. How should the nurse interpret this?

a. First-degree AV block, which usually needs only monitoring

b. Second-degree AV block, Mobitz I, because the PR interval stays the same

c. Second-degree AV block, Mobitz II, which can progress to complete heart block

d. Third-degree AV block, because some P waves are not conducted

Answer: c — A constant PR interval with sudden dropped QRS complexes is Mobitz II, which is more dangerous than Mobitz I and often leads to a permanent pacemaker (section 16.7). First-degree block (a) has no dropped beats. Mobitz I (b) shows a PR interval that lengthens before the dropped beat. In third-degree block (d), no P waves are conducted and P waves and QRS complexes are unrelated.

31. [CORE] A patient's strip shows regular P waves at 80 per minute and regular wide QRS complexes at 34 per minute, with no relationship between them. The patient is dizzy and has a blood pressure of 84/50 mm Hg. What should the nurse do first?

a. Call for urgent help and prepare for transcutaneous pacing and other ordered treatment

b. Give the patient's scheduled metoprolol to control the wide QRS complexes

c. Coach the patient through a Valsalva manoeuvre

d. Recheck the vital signs in 1 hour, because the rhythm is regular

Answer: a — This is third-degree AV block with signs of poor perfusion; the patient needs urgent help, with atropine, an adrenergic infusion or pacing as ordered (sections 16.5 and 16.7). Metoprolol (b) would slow the heart further. A Valsalva manoeuvre (c) increases vagal tone and could worsen bradycardia. Waiting an hour (d) delays care for an unstable patient.

32. [CORE] The nurse is teaching a patient going home after a new permanent pacemaker. Which statement shows the patient understands the teaching?

a. "I'll keep my mobile phone in my shirt pocket so I can hear it ring."

b. "I need to stop using my microwave oven."

c. "I can leave my device card at home because the clinic has my records."

d. "I won't raise my arm on the pacemaker side above my head until my team says it's safe."

Answer: d — Limiting arm movement on the device side for the period the team advises helps the incision heal and the leads stay in place (section 16.7). Phones should be kept at least 15 cm from the device, not in a pocket over it (a). Microwave ovens are safe (b). Patients should carry the device card (c), for example to show at security screening.

33. [CORE] The nurse is helping with a planned synchronized cardioversion for atrial fibrillation. Which action is essential before the shock?

a. Switch the defibrillator to unsynchronized mode to save time
b. Confirm that a sync marker appears on each QRS complex
c. Withhold the ordered procedural sedation so the patient can report pain
d. Ask the patient to hold the bed rails during the shock

Answer: b — The shock must be timed to the QRS to lower the risk of causing ventricular fibrillation, so the nurse confirms a sync marker on each QRS (section 16.7). Unsynchronized mode (a) is for defibrillation. Planned cardioversion is done under procedural sedation (c). No one, including the patient, should touch the bed or rails during a shock (d).

34. [CORE] A visitor collapses in a hospital lobby. The nurse finds the person unresponsive and not breathing normally, and a colleague brings an AED. What should the nurse do?

a. Wait for the code team to arrive before using the AED
b. Use the AED only if the person's heart rhythm can first be read on a monitor
c. Continue CPR, turn on the AED and follow its prompts, keeping everyone clear during analysis
d. Give two minutes of rescue breaths before applying the pads

Answer: c — An AED analyzes the rhythm and guides the rescuer with prompts; CPR continues until it is ready, and no one touches the person during analysis or a shock (sections 16.5 and 16.7). Waiting (a) delays defibrillation. An AED does its own rhythm analysis (b). Delaying pads for rescue breaths (d) delays a possible shock.

35. [CORE] An RPN on a medical unit sees that a patient's rhythm has changed to a fast, wide-complex rhythm. The patient is pale and responsive, with a blood pressure of 80/50 mm Hg. The RN is in another room. What should the RPN do?

a. Stay with the patient, call the rapid response team and inform the RN
b. Wait for the RN to return and interpret the rhythm before taking any action
c. Record the strip and recheck the patient in 15 minutes
d. Tell the patient to rest because only the RN can respond to rhythm changes

Answer: a — Every nurse who sees deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change (Scope in Practice box; Chapter 1, section 1.3). Waiting for the RN (b), delaying reassessment (c) or believing only the RN can respond (d) all delay care for an unstable patient.

36. [CORE] On the first day after bowel surgery, a patient has sinus tachycardia at 122 per minute, a temperature of 38.6 °C and pain rated 8 out of 10. What is the nurse's best action?

a. Ask the physician for a rate-control drug to bring the heart rate below 100 per minute
b. Encourage the patient to perform a Valsalva manoeuvre
c. Prepare the patient for synchronized cardioversion
d. Assess for causes such as pain, fever, bleeding and low fluid volume, and report the findings

Answer: d — Sinus tachycardia is usually a response to another problem, so the nurse looks for and treats the cause (section 16.5). Slowing the rate with a drug (a) could reduce cardiac output if the tachycardia is compensating. Vagal manoeuvres (b) are for SVT. Cardioversion (c) does not treat sinus tachycardia.

37. [RN] A 58-year-old with newly diagnosed atrial fibrillation has hypertension and no other conditions. According to the CCS CHADS-65 algorithm, what is the recommended antithrombotic approach?

a. No antithrombotic drug, because the patient is younger than 65
b. Acetylsalicylic acid (ASA) alone
c. Oral anticoagulation, preferably a direct oral anticoagulant
d. Oral anticoagulation only once the patient reaches 75

Answer: c — Under the CCS algorithm, a person younger than 65 with at least one CHADS2 risk factor (here hypertension) should receive oral anticoagulation, and a DOAC is preferred over warfarin for most patients (section 16.6). No therapy (a) applies only when there are no CHADS2 risk factors and no arterial disease. ASA alone (b) is for people under 65 with no CHADS2 risk factors but with coronary or arterial disease. The algorithm's age threshold is 65, not 75 (d).

38. [RN] A patient with a permanent pacemaker reports dizziness. The strip shows pacing spikes at regular intervals, but several spikes are not followed by a QRS, and the heart rate is 38 per minute. How should the nurse interpret this?

a. Failure to capture
b. Failure to sense
c. Normal demand pacing
d. Third-degree AV block with normal pacemaker function

Answer: a — A spike without a following P wave or QRS means the impulse did not stimulate the heart: failure to capture (section 16.7). Failure to sense (b), or undersensing, shows spikes at the wrong times that compete with the patient's own beats; oversensing causes pauses with no spikes at all. Normal pacing (c) has a QRS after each ventricular spike. A normally functioning pacemaker (d) would capture and prevent such a slow rate.

39. [RN] A patient who has taken amiodarone for 8 months reports a new dry cough and increasing shortness of breath. What should the nurse do?

a. Reassure the patient that a cough is an expected, harmless effect
b. Report the symptoms promptly, because they may signal pulmonary toxicity
c. Advise the patient to take a double dose to control the rhythm better
d. Tell the patient to stop amiodarone right away without contacting the prescriber

Answer: b — Pulmonary toxicity is the most important potentially fatal adverse effect of amiodarone, and new respiratory symptoms call for prompt reassessment (Medications box). The cough is not harmless (a). Doubling the dose (c) is unsafe. Stopping the drug without the prescriber (d) is unsafe, and its long half-life means effects persist for months anyway.

40. [RN] A stable patient has had atrial fibrillation for at least 3 weeks and is booked for a planned electrical cardioversion. According to CCS guidance, what is the usual anticoagulation plan?

a. No anticoagulation is needed, provided the cardioversion restores sinus rhythm.

b. Anticoagulation is needed only if the patient's CHADS2 score is 2 or higher.

c. A single dose of anticoagulant on the morning of the procedure is enough to prevent clots.

d. At least 3 weeks of therapeutic anticoagulation before, or a transesophageal echocardiogram to rule out clot, and at least 4 weeks after

Answer: d — For AF lasting more than 48 hours, the CCS recommends at least 3 weeks of therapeutic anticoagulation before planned cardioversion (or a transesophageal echocardiogram), and at least 4 weeks afterward, then long-term therapy by the CHADS-65 algorithm (section 16.6). Clots can form or travel after a successful cardioversion (a). The CHADS2 rule (b) applies only to AF of 12 to 48 hours. A single dose (c) is not adequate.

17 Coronary Artery Disease and Acute Coronary Syndromes

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how atherosclerosis develops and relate it to stable angina and the acute coronary syndromes.
2. Identify cardiovascular risk factors using Canadian data, and interpret lipid test results in mmol/L against CCS thresholds.
3. Teach patients with stable angina about their medications, including sublingual nitroglycerin and when to call 9-1-1.
4. Recognize acute coronary syndromes, including presentations common in women and older adults, and take the immediate actions in order.
5. Describe reperfusion for STEMI and the early medications for ACS, and monitor for bleeding and other complications.
6. Provide nursing care before and after PCI and after CABG, including access-site checks and sternal precautions.
7. Support cardiac rehabilitation and secondary prevention, naming the structural barriers to referral and completion.
8. Distinguish RN and RPN roles in ACS care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4, 5	Clinician; Scholar	Foundations of Practice
3, 6, 7	Clinician; Educator; Advocate; Collaborator	Foundations of Practice; Collaborative Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Coronary artery disease (CAD) is the narrowing of the coronary arteries by atherosclerotic plaque, which limits blood flow to the heart muscle. Canadian Chronic Disease Surveillance System data for 2023 to 2024 show that 8.2% of Canadian adults had diagnosed **ischemic heart disease** (about 10% among males and 7% among females aged 20 years and older) (Public Health Agency of Canada [PHAC], 2026). In preliminary data for 2024, diseases of the heart ranked second among causes of death in Canada, behind cancer, and accounted for 17.7% of all deaths (Statistics Canada, 2026).

Every nurse, on every unit, may be the first to notice an **acute coronary syndrome (ACS)**: a patient admitted for pneumonia can develop chest pressure in the night. Heart muscle starts to die soon after a coronary artery closes, so fast recognition and escalation save lives.

This chapter covers atherosclerosis and cardiovascular risk (section 17.1), stable angina and chronic coronary disease (17.2), recognizing acute coronary syndromes (17.3), early treatment and complications of ACS (17.4), care around percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG) (17.5), and cardiac rehabilitation and living with coronary disease (17.6). It builds on Chapter 16 (cardiac assessment and the 12-lead electrocardiogram [ECG]) and links to Chapters 14 (smoking), 18 (heart failure), 19 (hypertension) and 22 (diabetes).

17.1 Atherosclerosis and Cardiovascular Risk

How Plaque Forms

Atherosclerosis is a chronic inflammatory disease of the artery wall in which lipids, immune cells and fibrous tissue collect beneath the inner lining. It develops silently over many years.

The process begins with **endothelial dysfunction**. A healthy endothelium keeps the vessel relaxed, smooth and resistant to clotting. High blood lipids, hypertension, smoking and diabetes increase oxidative stress and reduce nitric oxide, so the lining becomes leaky, sticky and prone to spasm. Damage tends to start where blood flow is disturbed, such as at branch points (Jebari-Benslaiman et al., 2022).

Next, **low-density lipoprotein (LDL)** particles cross the damaged lining and become trapped in the intima, the innermost layer of the wall. There they are chemically altered, mainly by oxidation. Oxidized LDL acts as an alarm signal: endothelial cells display adhesion molecules and release chemical attractants that pull monocytes into the wall. The monocytes mature into macrophages and engulf altered LDL until they are swollen with fat. These **foam cells** form the **fatty streak**, the earliest visible lesion. Smooth muscle cells can also take up lipid and become foam cells (Jebari-Benslaiman et al., 2022).

As the lesion grows, smooth muscle cells move in from the middle layer of the wall, multiply and lay down collagen. This builds a **fibrous cap** that keeps the lesion's contents away from the bloodstream. Under the cap, macrophages that die and are not cleared away form a soft **necrotic core**, rich in lipid and in tissue factor, a strong trigger of clotting.

A **stable plaque** has a thick cap and little inflammation. It may narrow the lumen enough to limit flow during exertion, causing angina. A **vulnerable plaque** has a large necrotic core, a thin cap and active inflammation, and enzymes released by inflammatory cells weaken the cap further (Jebari-Benslaiman et al., 2022). When the cap tears, called **plaque rupture**, blood meets the core. Platelets stick and activate, the clotting cascade makes thrombin and fibrin, and a thrombus forms that can partly or fully block the artery. Loss of the lining over a plaque without a tear, called erosion, can also start a thrombus. Plaque rupture or erosion with thrombosis is the mechanism of most heart attacks, classed as type 1 myocardial infarction (Thygesen et al., 2018).

Risk Factors

In the INTERHEART case-control study, which compared 15,152 people with a first myocardial infarction with 14,820 controls in 52 countries, nine potentially modifiable factors together accounted for 90% of the population attributable risk in men and 94% in women (Yusuf et al., 2004). Smoking, an unfavourable balance of blood apolipoproteins, hypertension, diabetes, abdominal obesity and psychosocial stress were strongly linked to heart attack, while fruit and vegetable intake and regular physical activity were protective.

Modifiable risk factors include:

- **Smoking and vaping:** cessation support is covered in Chapter 14.
- **Hypertension:** see Chapter 19.
- **Dyslipidemia:** high LDL cholesterol or other atherogenic lipoproteins (described below).
- **Diabetes:** see Chapter 22; most adults with diabetes have a condition for which the Canadian Cardiovascular Society (CCS) recommends a statin (Pearson et al., 2021).
- **Abdominal obesity, physical inactivity and an unhealthy diet:** for example, low intake of vegetables, fruit and fibre.
- **Psychosocial stress.**
- **Chronic kidney disease:** another statin-indicated condition (Chapter 27).

Nonmodifiable factors include older age, male sex and inherited lipid disorders such as familial hypercholesterolemia and a high lipoprotein(a) level. A 2017 PHAC surveillance report found that a first heart attack was about twice as likely in men as in women (PHAC, 2017).

Some risk factors are specific to women. Preeclampsia and gestational hypertension raise the chance of hypertension later in life, and gestational diabetes raises the chance of type 2 diabetes. After menopause, LDL cholesterol, triglycerides, blood pressure and weight

tend to rise (Heart and Stroke Foundation of Canada, n.d.-c). The CCS recommends a full lipid panel late in the postpartum period for women who had a pregnancy complication such as a hypertensive disorder of pregnancy, along with counselling about their higher lifetime risk (Pearson et al., 2021).

Risk is also shaped by structural conditions such as income, housing, food access and distance from care, not by race as biology (Chapter 2). The CCS suggests considering earlier lipid screening for South Asian and Indigenous people at higher risk, and it notes that high lipoprotein(a) carries a particularly high population burden among South Asian and Latin American people (Pearson et al., 2021). When First Nations data are used, the First Nations principles of OCAP® (ownership, control, access and possession) apply.

Assessing Risk and Lipid Tests

The CCS recommends lipid screening for adults over age 40, and at any age when certain risk conditions are present (Pearson et al., 2021). Screening uses a **lipid panel**: total cholesterol, LDL cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), triglycerides and **non-HDL cholesterol (non-HDL-C)**, which is total cholesterol minus HDL-C. A nonfasting sample is recommended, except for people with known triglycerides above 4.5 mmol/L. When triglycerides are above 1.5 mmol/L, the CCS prefers non-HDL-C or **apolipoprotein B (ApoB)** to LDL-C. **Lipoprotein(a) [Lp(a)]** should be measured a single time in life, at the first lipid screen (Pearson et al., 2021). Reference ranges vary by laboratory.

Some people need a statin whatever their calculated risk. The CCS lists these **statin-indicated conditions** (Pearson et al., 2021):

- clinical atherosclerotic cardiovascular disease (ASCVD), such as previous myocardial infarction or angina;
- abdominal aortic aneurysm larger than 3.0 cm, or previous aneurysm surgery;
- most people with diabetes (aged 40 or older; aged 30 or older with diabetes for 15 years or more; or with microvascular complications);
- chronic kidney disease, not on dialysis, with an estimated glomerular filtration rate below 60 mL/min/1.73 m^2 or albuminuria (urine albumin-to-creatinine ratio of 3 mg/mmol or more) for at least 3 months;
- LDL-C of 5.0 mmol/L or more, or familial hypercholesterolemia.

For everyone else aged 40 to 75, the CCS recommends estimating 10-year cardiovascular risk every 5 years with the Framingham Risk Score or the Cardiovascular Life Expectancy Model. A 10-year risk of 20% or more is high, 10% to 19.9% is intermediate, and below 10% is low (Pearson et al., 2021). Table 17.1 summarizes the lipid tests.

Table 17.1 Lipid tests and when CCS suggests intensifying treatment (Pearson et al., 2021; original wording)

Test	What it measures	Threshold for intensifying therapy (ASCVD on the highest tolerated statin dose)	Notes
LDL-C	Cholesterol carried in low-density lipoprotein particles, the main target of treatment	In a person with ASCVD on the highest tolerated statin dose: LDL-C 1.8 mmol/L or more	Less reliable when triglycerides are above 1.5 mmol/L
Non-HDL-C	All cholesterol in atherogenic particles (total cholesterol minus HDL-C)	Non-HDL-C 2.4 mmol/L or more	Preferred over LDL-C when triglycerides are above 1.5 mmol/L; nonfasting sample is fine
ApoB	The number of atherogenic particles (each carries one ApoB molecule)	ApoB 0.7 g/L or more	Alternative to non-HDL-C; reported in g/L
Lp(a)	An inherited lipoprotein particle that adds risk	Not a treatment target; 50 mg/dL (100 nmol/L) or more calls for earlier, more intensive risk-factor management in primary prevention	Measure once in a lifetime at the first lipid screen

Lowering Risk

Health behaviours are the base of prevention. The CCS recommends a Mediterranean dietary pattern first and also names the Portfolio, DASH (Dietary Approaches to Stop Hypertension), low-glycemic-index and plant-based patterns, along with nuts,

legumes, olive oil, vegetables and fruit, fibre and whole grains. It recommends 150 minutes or more each week of moderate- to vigorous-intensity aerobic activity, plus muscle- and bone-strengthening activity on at least 2 days a week (Pearson et al., 2021).

Statins are the first lipid-lowering drugs for people with ASCVD or another statin-indicated condition, at the highest dose the person tolerates (Pearson et al., 2021). Atorvastatin and rosuvastatin are common examples. When a person with ASCVD stays at or above the thresholds in Table 17.1, the CCS recommends intensifying treatment with **ezetimibe**, a **proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitor** such as evolocumab or alirocumab, or both. If ezetimibe is added first and LDL-C stays at 1.8 mmol/L or more, a PCSK9 inhibitor is recommended next. **Icosapent ethyl** is recommended for people with ASCVD, or with diabetes and at least one other cardiovascular risk factor, whose fasting triglycerides stay between 1.5 and 5.6 mmol/L on the highest tolerated statin dose (Pearson et al., 2021).

The main adverse effects of statins involve muscle. Muscle aches (myalgia) can occur, true myopathy is less common, and rhabdomyolysis, which can cause acute kidney injury, is rare. Risk is higher with age over 65, hypothyroidism, kidney impairment and some interacting drugs. The Canadian atorvastatin monograph tells patients to report, without delay, muscle pain, tenderness or weakness that has no clear cause, particularly if they also have a fever or feel generally unwell, and it advises liver tests before treatment starts (Apotex Inc., 2024). The nurse asks about muscle symptoms, reports them, and encourages the patient not to stop a statin without talking to the prescriber, because a lower or different statin dose often works (Pearson et al., 2021).

CANADIAN CONTEXT

Coronary Disease and Equity

- **Women:** The Heart and Stroke Foundation's 2018 report named heart disease as the top cause of early death among women in Canada. It noted that women were less likely than men to receive bypass surgery, stents, statins and anticlotting therapy, and only half as likely to take part in or complete cardiac rehabilitation (Heart and Stroke Foundation of Canada, 2018). Women with ST-elevation myocardial infarction (STEMI) are slower to recognize their symptoms and to seek help, and they wait longer for an ECG and for reperfusion (Mulvagh et al., 2024).
- **First Nations, Inuit and Métis Peoples:** The same report described a death rate from coronary heart disease that was 53% higher among Indigenous women than among non-Indigenous women, and too few cardiac care resources in the remote and rural hospitals serving women who live on reserve (Heart and Stroke Foundation of Canada, 2018). Many sources do not report data by distinct Nation or People; the causes are structural, rooted in colonization and access to care (Chapter 2).
- **Rural and remote communities:** Canada's geography makes timely reperfusion hard, which is why the CCS calls for regional STEMI networks with set transport and treatment pathways (Wong et al., 2019).

17.2 Stable Angina and Chronic Coronary Disease

What Stable Angina Is

Angina pectoris is discomfort caused by **myocardial ischemia**, a shortfall of oxygen to heart muscle. In **stable angina**, a fixed plaque narrows a coronary artery. At rest, enough blood gets through. When exertion or emotional stress raises the heart rate, blood pressure and force of contraction, the muscle's oxygen demand outstrips the limited supply, and ischemia follows.

The classic picture is discomfort behind the breastbone that is brought on by exertion or emotional stress and eased by rest or nitroglycerin (Vrints et al., 2024). Patients often describe pressure, squeezing, tightness or heaviness rather than pain, and it may spread to the neck, jaw, shoulders, arms or back. What makes the angina "stable" is its predictable pattern: a similar trigger, a similar feeling and a similar response to rest or nitroglycerin each time.

Some people never feel chest discomfort. An **anginal equivalent** is a symptom other than chest pain that reflects ischemia, such as breathlessness or unusual fatigue on exertion. Breathlessness on exertion can be the main symptom for some people, and women may describe breathlessness and fatigue (Vrints et al., 2024). The European Society of Cardiology (ESC) recommends avoiding the word "atypical" for these symptoms, because it can lead clinicians to dismiss them (Byrne et al., 2023).

Stable angina is one form of **chronic coronary disease**, the long-term phase of CAD that also includes people living with CAD after an ACS or a revascularization procedure. Diagnosis rests on the history, a resting 12-lead ECG, blood tests including a lipid profile,

and functional or anatomical tests such as stress testing, coronary computed tomography angiography or invasive angiography (Vrints et al., 2024; Figure 17.1). Stress testing and cardiac catheterization are described in Chapter 16, section 16.3.

At each contact, the nurse asks about the pattern: how often episodes occur, what brings them on, how long they last and how many nitroglycerin doses the patient uses. A change in pattern, such as angina at rest or with much less effort than usual, may mean unstable angina and needs urgent assessment (section 17.3).

Treatment

Treatment has two goals: to relieve symptoms and to prevent heart attack and death. The drug guidance in this subsection comes from the United Kingdom's National Institute for Health and Care Excellence (NICE) and the 2024 ESC guideline, which are not Canadian guidelines; local protocols may differ. All patients need risk-factor management as described in section 17.1, including a statin, since clinical ASCVD is a statin-indicated condition (Pearson et al., 2021). Low-dose acetylsalicylic acid (ASA) is commonly used as an antiplatelet drug, weighed against the person's bleeding risk (NICE, 2011). NICE also suggests considering an angiotensin-converting enzyme (ACE) inhibitor for people who have both stable angina and diabetes.

For symptoms, NICE names a **beta-blocker** as one first-line anti-anginal choice and a **calcium channel blocker** as the other (NICE, 2011). Both lower the heart's oxygen demand. When these cannot be used or do not control symptoms, a long-acting nitrate or another agent may be added, and a combination is often needed (NICE, 2011; Vrints et al., 2024). Every patient also has a short-acting nitrate for relief, described below.

Revascularization, by PCI or CABG, is considered when symptoms persist despite medical treatment or when testing shows high-risk coronary anatomy (Vrints et al., 2024). Section 17.5 covers nursing care around these procedures.

The nurse checks heart rate and blood pressure before giving rate-lowering drugs as ordered, asks about dizziness and fatigue, and helps the patient keep a simple record of angina episodes to bring to appointments.

Teaching About Nitroglycerin

Nitroglycerin is a fast-acting nitrate taken under the tongue as a spray or tablet (Figure 17.2). It is used to relieve an episode of angina, and it can also be taken just before an activity that usually brings on angina (NICE, 2011). Heart and Stroke Foundation of Canada advice is clear on one point: when heart attack signs appear, the person calls 9-1-1 first, and a person who has nitroglycerin then takes their usual dose (Heart and Stroke Foundation of Canada, n.d.-d).

Canadian patient guidance from British Columbia health authorities gives a simple rule. The person sits down and takes one dose; the pain should ease within 5 minutes, and if it has not, the person calls 9-1-1. If the pain comes back, another dose may be taken after 5 minutes, with no more than 3 doses in 15 minutes (Fraser Health et al., 2023). The Canadian spray monograph allows the dose to be repeated twice at 5- to 10-minute intervals and tells people to seek emergency help if the pain persists (sanofi-aventis Canada, 2021). The nurse teaches the plan the prescriber has chosen and makes sure the patient knows when to call 9-1-1.

Headache is the most common side effect and can be severe. Dizziness and flushing are also common, so the person sits before each dose (Fraser Health et al., 2023; sanofi-aventis Canada, 2021). Nitroglycerin must never be combined with a phosphodiesterase-5 (PDE5) inhibitor, a drug class used for erectile dysfunction, because the combination can cause a dangerous fall in blood pressure (sanofi-aventis Canada, 2021). The Canadian tadalafil monograph states that at least 48 hours should pass after the last tadalafil dose before a nitrate is given in a life-threatening situation, under close medical supervision (Teva Canada, 2020). The vardenafil

Figure 17.2 Three forms of nitroglycerin: an intravenous solution (used in hospital), a sublingual spray and a transdermal patch. (credit: "Nitro" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

monograph sets an interval of at least 24 hours, again only for a life-threatening situation (Angita Pharma, 2022), and the sildenafil monograph states that it is not known when a nitrate can be given safely (Upjohn Canada, 2020).

PATIENT EDUCATION

Using Nitroglycerin and Calling 9-1-1

- **Carry it always.** Keep your nitroglycerin with you. Store the spray at room temperature, 15 °C to 30 °C (sanofi-aventis Canada, 2021). Keep extra tablets or spray in a dry place, not in a bathroom or car (Fraser Health et al., 2023).
- **Stop and sit down** at the first sign of angina.
- **Take one dose** under your tongue as your prescriber has taught you. Do not inhale the spray.
- **Call 9-1-1 if the pain has not eased 5 minutes after you use your nitroglycerin**, or if it feels different or worse than your usual angina. If the pain comes back, you may take another dose after 5 minutes, but no more than 3 doses in 15 minutes (Fraser Health et al., 2023).
- **If you think you are having a heart attack,** call 9-1-1 right away, then take your usual nitroglycerin dose. Chew and swallow ASA if you are not allergic or intolerant (Heart and Stroke Foundation of Canada, n.d.-d).
- **Expect a headache, flushing or light-headedness.** Get up slowly afterward.
- **Never combine nitroglycerin with erectile dysfunction drugs** such as sildenafil or tadalafil. Tell emergency staff if you have taken one.
- **Keep a record** of when angina happens and how many doses you needed, and report any change in your usual pattern.

17.3 Recognizing Acute Coronary Syndromes

The ACS Spectrum

An **acute coronary syndrome** is a sudden fall in blood flow to the heart muscle, most often caused by plaque rupture or erosion with thrombus. Unstable angina, non-ST-elevation myocardial infarction and ST-elevation myocardial infarction are grouped together as ACS (Thygesen et al., 2018). They share a cause and differ in how much heart muscle is injured and in what the ECG shows (Table 17.2).

A **myocardial infarction (MI)** is death of heart muscle cells caused by ischemia. Under the Fourth Universal Definition of Myocardial Infarction, acute MI is diagnosed when cardiac troponin (cTn) rises and/or falls with at least one value above the 99th percentile upper reference limit, together with clinical evidence of ischemia, such as symptoms, new ischemic ECG changes or

imaging showing newly lost heart muscle (Thygesen et al., 2018). A single troponin value cannot show a rise or fall, which is why samples are repeated. High-sensitivity troponin testing and rapid pathways are explained in Chapter 16, section 16.3.

The three ACS types are:

- **Unstable angina:** myocardial ischemia at rest or on minimal exertion without acute injury or death of heart muscle cells (Byrne et al., 2023). Troponin does not show an MI pattern. A previously stable pattern that changes, with angina at rest or with much less effort, fits this picture.
- **Non-ST-elevation myocardial infarction (NSTEMI):** an MI, confirmed by a troponin rise and/or fall, without persistent ST elevation. The ECG may show ST depression or T-wave inversion, or it may look normal.
- **ST-elevation myocardial infarction (STEMI):** an MI with new ST elevation in at least two contiguous leads. New, convex ST elevation, especially with reciprocal ST depression, usually reflects acute occlusion of a coronary artery (Thygesen et al., 2018).

The definition also separates MI by cause. **Type 1 MI** results from atherothrombosis: plaque rupture or erosion with a clot. **Type 2 MI** results from an imbalance between the heart's oxygen supply and its demand, without acute plaque disruption (Thygesen et al., 2018). Causes include severe anemia, hypoxemia, hypotension or shock, a fast or very slow heart rhythm, severe hypertension and coronary spasm. Type 2 MI can develop in hospitalized patients, for example during severe bleeding or shock. Treatment targets the cause, such as restoring blood volume or oxygenation, rather than opening an artery.

Table 17.2 Stable angina and the acute coronary syndromes compared (Byrne et al., 2023; Thygesen et al., 2018; Vrints et al., 2024; original wording)

Feature	Stable angina	Unstable angina	NSTEMI	STEMI
Pattern of pain	Predictable; brought on by exertion or emotional stress and eased by rest or nitroglycerin	New, at rest or on minimal exertion, or a change from the usual pattern	Ischemic symptoms, often at rest; may occur without chest pain	Ischemic symptoms, often at rest; may occur without chest pain
ECG	No new acute changes at rest	May show ST depression or T-wave inversion, or be normal	May show ST depression or T-wave inversion, or be normal	New ST elevation in at least 2 contiguous leads, or an equivalent pattern
Troponin	No rise and fall pattern	No rise and fall pattern above the 99th percentile	Rises and/or falls with at least one value above the 99th percentile	Rises and/or falls; the ECG identifies STEMI before results return
Usual urgency	Planned outpatient follow-up	Urgent assessment in hospital	Urgent assessment and treatment in hospital	Emergency; reperfusion as fast as possible
Main treatment	Risk reduction, anti-anginal drugs, revascularization if symptoms persist	Antithrombotic therapy and risk-based angiography (section 17.4)	Antithrombotic therapy and risk-based angiography (section 17.4)	Primary PCI, or fibrinolysis when PCI would be delayed

Presentation

Ischemic discomfort in ACS is often felt as pressure, squeezing, fullness, burning or heaviness in the chest. It may spread to the neck, jaw, shoulders, arms or back and may come with sweating, nausea, shortness of breath or light-headedness (Heart and Stroke Foundation of Canada, n.d.-d). Unlike stable angina, it often comes at rest or with little effort and is not reliably eased by rest.

Chest discomfort is the most common symptom in both women and men, but many people with MI have none. In a large United States registry, 42.0% of women and 30.7% of men with MI presented without chest pain, and the gap between the sexes narrowed with age (Canto et al., 2012). Women more often report breathlessness, fatigue or weakness with or without chest discomfort (Mehta et al., 2016), and they may feel pressure or pain in the lower chest, upper abdomen or upper back, dizziness, fainting or extreme fatigue (Heart and Stroke Foundation of Canada, n.d.-d). The ESC lists breathlessness, epigastric pain, and pain in either arm or in the neck or jaw as chest pain equivalents (Byrne et al., 2023). The chest pain history and presentations in older adults are covered in Chapter 16, section 16.2, and Chapter 8.

Physical findings may include anxiety, sweating, cool skin, pallor, a fast or slow heart rate, and high or low blood pressure. Colour changes are harder to see on darker skin. On very dark skin, pallor may look ash-grey and on brown skin yellow-brown, so the nurse

checks the conjunctivae and the lining of the mouth and compares with the patient's usual colour (Pusey-Reid et al., 2023). Cyanosis on darker skin may look grey or whitish around the mouth (Chapter 12, section 12.2). Findings of shock, such as confusion or low urine output, need immediate escalation (Chapter 6).

Immediate Actions

The nurse treats new chest discomfort, or a symptom that could stand in for it, as ACS until proven otherwise, and works through the Clinical Judgment Measurement Model (Chapter 1, section 1.4) quickly. To **recognize cues**, the nurse notes the patient's description of the discomfort, its onset and any associated symptoms, along with vital signs, oxygen saturation (SpO2), heart rhythm, colour and level of consciousness. To **analyze cues and prioritize hypotheses**, the nurse puts ischemia first but also looks for other causes, such as bleeding, low SpO2 or a fast rhythm, that can cause a type 2 MI. To **generate solutions and take action**, the nurse:

- stays with the patient, stops all activity and helps the patient into a comfortable position, then calls for help as agency policy directs, such as the prescriber or the rapid response team (Chapter 6);
- obtains a 12-lead ECG within 10 minutes of first medical contact and shows it to a physician or nurse practitioner (NP) at once (Byrne et al., 2023; Chapter 16, section 16.3);
- starts continuous cardiac monitoring, keeps the defibrillator close by (Chapter 16) and establishes intravenous access;
- sends blood for troponin and other tests, then repeats troponin at the times the pathway sets (Chapter 16);
- gives ASA, to be chewed and swallowed, under an order or medical directive, if the patient has no allergy or intolerance; for the public, Heart and Stroke advises one 325 mg tablet or two 81 mg tablets (Heart and Stroke Foundation of Canada, n.d.-d);
- gives oxygen only if SpO2 is low: a guideline panel recommended not starting oxygen in suspected MI when SpO2 on room air is above 92%, and suggested not starting it at 90% to 92% (Siemieniuk et al., 2018), and the nurse follows the ordered target range (Chapter 12);
- gives nitroglycerin as ordered unless the patient has hypotension, a suspected right ventricular infarction or recent PDE5 inhibitor use (see the Clinical Safety box);
- gives analgesia as ordered if discomfort continues (Chapter 5);
- explains each step calmly and supports and informs the family.

To **evaluate outcomes**, the nurse reassesses discomfort, vital signs, rhythm and SpO2 after each intervention and repeats the ECG, as ordered, if symptoms change or return.

Every nurse who notices these signs acts and escalates at once. A registered practical nurse (RPN), or a practical nurse (PN) elsewhere (licensed practical nurse [LPN] in many provinces), starts these first steps and consults the registered nurse (RN) as the patient's needs change. Actions such as giving ASA or nitroglycerin need an order or medical directive, and what each nurse may do depends on authority, competence and context, employer policy and the province or territory (Chapter 1, section 1.3).

CLINICAL SAFETY

Nitroglycerin Cautions

Before each dose of nitroglycerin, the nurse checks blood pressure and heart rate and holds the dose and reports when:

- **Blood pressure is low.** The Canadian monograph lists acute circulatory failure, including severe hypotension, as a contraindication (sanofi-aventis Canada, 2021). The order or directive sets the blood pressure limit.
- **Right ventricular infarction is suspected.** The monograph warns of serious reflex effects, including fatal dysrhythmias, mainly in acute inferior MI with right ventricular involvement (sanofi-aventis Canada, 2021). With an inferior STEMI, right-sided leads are recorded early, as ordered (Thygesen et al., 2018).
- **A PDE5 inhibitor has been taken.** Ask every patient, of every sex, in private and without judgment. Sildenafil, tadalafil and vardenafil are absolutely contraindicated with nitroglycerin (sanofi-aventis Canada, 2021).
- **Certain structural heart conditions are known.** The monograph's contraindications include heart failure caused by hypertrophic obstructive cardiomyopathy, constrictive pericarditis, or aortic or mitral stenosis (sanofi-aventis Canada, 2021).

The patient sits or lies down for each dose, and the nurse watches for headache, dizziness and falling blood pressure.

STEMI and Reperfusion

A STEMI is a race against time. When the ECG shows ST elevation that meets the criteria in the Going Deeper box, the nurse makes sure a physician or NP sees it immediately and activates the agency's STEMI process. **Reperfusion**, restoring blood flow through the blocked artery, is the cornerstone of STEMI care (Wong et al., 2019).

Primary PCI is emergency coronary angiography with balloon and stent opening of the blocked artery, without fibrinolytic drugs given first. It is preferred when it can be done quickly. **Fibrinolysis** is an intravenous drug that dissolves the fibrin in a clot. Canadian guidance from Emergency Care BC advises considering fibrinolysis when primary PCI cannot be done within 120 minutes of first medical contact, with a target of 30 minutes or less from first medical contact to the drug. After successful fibrinolysis, the patient should have angiography within 24 hours, and a patient whose ST elevation does not settle by more than 50%, or who has ongoing pain or instability, needs urgent rescue PCI (Emergency Care BC, 2020). Emergency Care BC prefers a fibrin-specific drug such as tenecteplase. The ESC uses the same 120-minute threshold for choosing fibrinolysis (Byrne et al., 2023). The 2019 CCS guideline could not be read for this edition, so these time targets are given as Emergency Care BC and the ESC state them. Nursing care during and after fibrinolysis is covered in section 17.4.

Canada's distances shape these choices. The CCS and the Canadian Association of Interventional Cardiology call for regional STEMI networks with set pathways for identification, transport and reperfusion, whether the patient is first seen in the field, at a hospital without PCI or at a PCI centre (Wong et al., 2019). In eastern Ontario, the regional paramedic program advises that paramedics aim to record a 12-lead ECG within 10 minutes and that a STEMI-positive ECG is required before they take a patient directly to a PCI centre, under provincial standards and local agreements (Regional Paramedic Program for Eastern Ontario, 2023). In rural and remote hospitals, the nurse may care for a patient receiving fibrinolysis while transfer to a PCI centre is arranged.

GOING DEEPER

STEMI on the 12-Lead ECG

Required for RN students; optional for PN students.

Chapter 16 introduced contiguous leads and ST changes. The Fourth Universal Definition sets these STEMI criteria (Thygesen et al., 2018):

- **ST elevation:** new elevation at the J point in at least 2 contiguous leads, of 1 mm or more in all leads other than V2 and V3. In V2 and V3, the cut-off is 2 mm or more in men aged 40 and older, 2.5 mm or more in men under 40, and 1.5 mm or more in women of any age.
- **Lead groups:** as in Chapter 16, the contiguous groups are I and aVL; V1 to V6; and II, III and aVF, the inferior leads (Figures 17.3 and 17.4). ST elevation in the anterior precordial leads is linked to significant occlusion of the left anterior descending artery.
- **Reciprocal changes:** ST depression in leads facing the opposite wall. Convex ST elevation with reciprocal depression usually means acute occlusion, and reciprocal changes help tell STEMI apart from pericarditis or early repolarization.
- **Right ventricular infarction:** with an inferior STEMI, right-sided leads V3R and V4R are recorded early. ST elevation of 0.5 mm or more (1 mm or more in men under 30) supports the diagnosis, but normal right-sided leads do not rule it out. Lead aVR or V1 may also show ST elevation.
- **Posterior (inferobasal) ischemia:** ST depression in V1 to V3, especially with an upright terminal T wave, may reflect blockage of the circumflex artery. Posterior leads V7 to V9 (left posterior axillary line, midscapular line and paraspinal border) are then recorded; elevation of 0.5 mm or more is significant (1 mm or more in men under 40).
- **Left bundle branch block (LBBB):** ST elevation of 1 mm or more in the same direction as the QRS in any lead may signal acute ischemia.
- **Lead aVR:** ST elevation of more than 1 mm can be seen with anterior or inferior STEMI and is linked to higher 30-day mortality.

The nurse who sees possible STEMI changes escalates immediately; the physician or NP confirms the diagnosis.

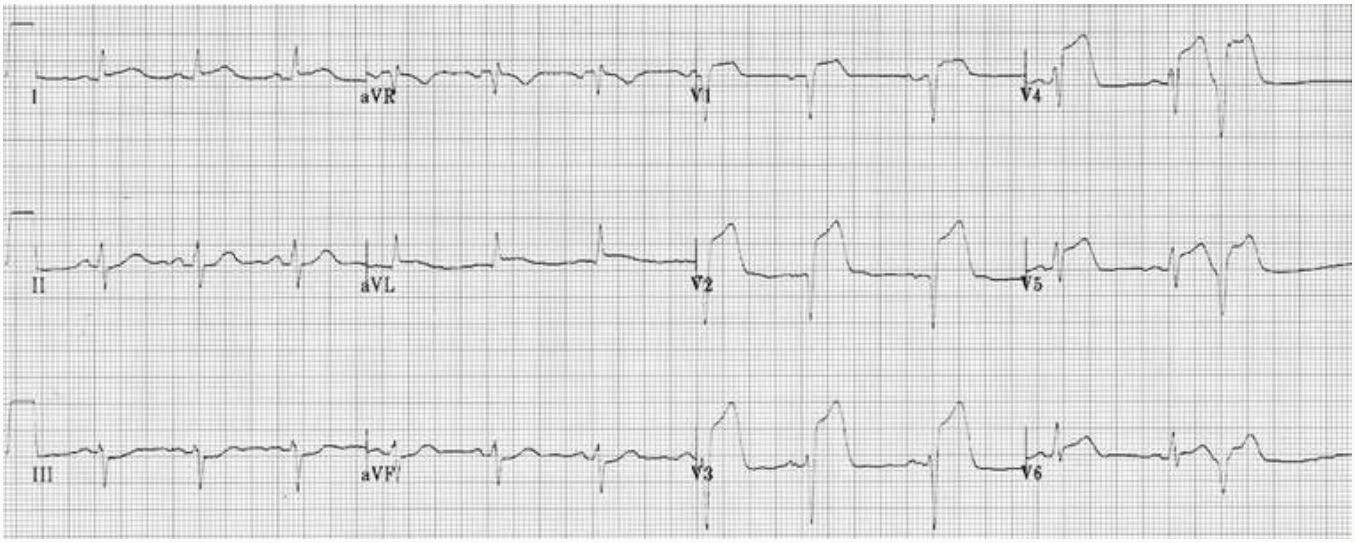

Figure 17.3 A 12-lead ECG showing an acute extensive anterior STEMI: ST elevation across the chest leads and in I and aVL, with reciprocal ST depression in the inferior leads. (credit: "Extensive Anterior STEMI (acute)" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

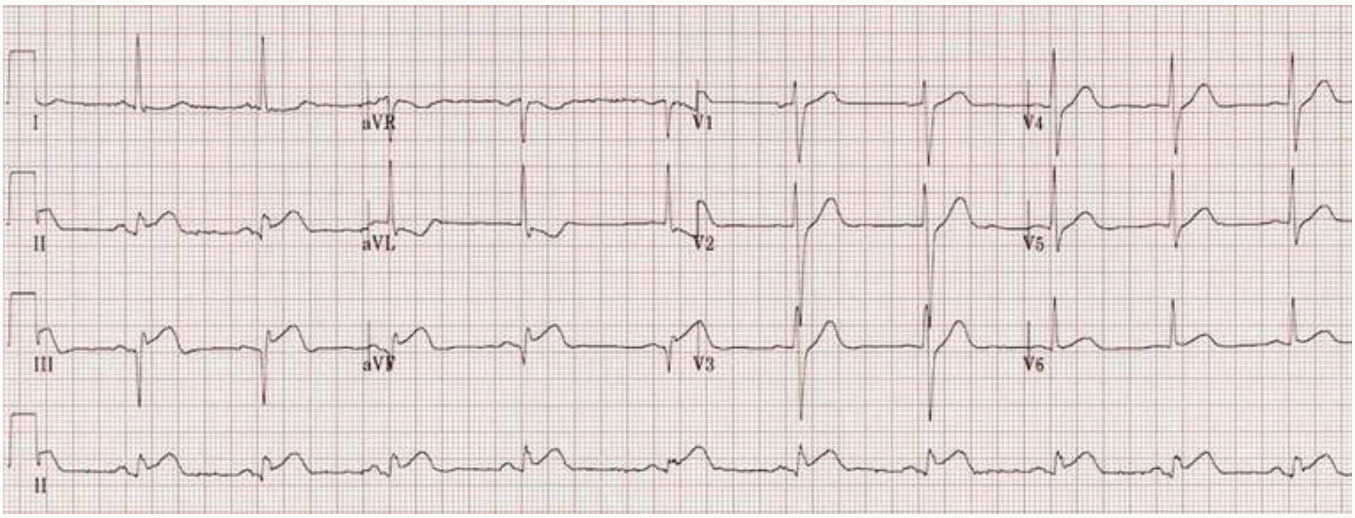

Figure 17.4 A 12-lead ECG showing an inferior STEMI: ST elevation in leads II, III and aVF, with reciprocal ST depression in aVL. (credit: "Inferior STEMI" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

17.4 Early Treatment and Complications of ACS

Medications in the First Days

Once the first actions described in section 17.3 are under way, treatment has four aims: keep the culprit artery open, stop new clots from forming, protect the heart muscle and lower the chance of another event. The nurse gives these drugs as ordered, watches for their adverse effects and starts teaching early, because many of them continue for months or for life (Medications box).

Dual antiplatelet therapy (DAPT) is the combination of ASA with a **P2Y12 inhibitor**, a drug that blocks the P2Y12 receptor on platelets so they are less able to stick together and form a clot. Three P2Y12 inhibitors are marketed in Canada: clopidogrel, ticagrelor and prasugrel. The CCS and Canadian Association of Interventional Cardiology (CAIC) updated their antiplatelet guidance in 2023, and it puts bleeding risk at the centre of the decision. For a patient at high bleeding risk after PCI, it supports DAPT for only 1 to 3 months, followed by a single antiplatelet drug, when no clotting or bleeding event occurs in the first month. It also allows a switch from ticagrelor or prasugrel to clopidogrel in selected patients with ACS treated with PCI who have had at least

a month of the stronger drug without a new clotting event (Bainey et al., 2024). Where Canadian guidance does not address a point, Canadian teams follow international guidelines, and this chapter uses the 2025 American College of Cardiology/American Heart Association (ACC/AHA) ACS guideline for those points. That guideline recommends adding an oral P2Y12 inhibitor to ASA for patients with ACS. For patients treated with PCI, it prefers ticagrelor or prasugrel over clopidogrel. It names at least 12 months of DAPT as the default for patients who are not at high risk of bleeding (Rao et al., 2025). The cardiology team sets the plan and its length. The nurse makes sure the patient knows the plan and leaves with it in writing.

During the acute phase, many patients also receive a parenteral anticoagulant such as heparin, enoxaparin or fondaparinux. The team chooses the drug based on the treatment plan, kidney function and bleeding risk. Chapter 19 covers anticoagulants in full.

Other drugs protect the heart over the long term. The 2025 guideline recommends a high-intensity statin for every patient with ACS (Rao et al., 2025); section 17.1 explains statins and lipid targets. Many patients also start a beta-blocker and an ACE inhibitor or an angiotensin II receptor blocker (ARB). The choice depends on heart function, blood pressure, heart rate, kidney function and other conditions. For patients at risk of bleeding from the stomach or bowel, the guideline recommends a proton pump inhibitor (Rao et al., 2025).

Every one of these antithrombotic drugs raises the risk of bleeding, and the risk adds up when they are combined and when an artery has just been punctured. Prasugrel is contraindicated after a stroke or transient ischemic attack (TIA). Its Canadian monograph also advises against it for people aged 75 or older or weighing less than 60 kg (JAMP Pharma Corporation, 2020). Ticagrelor causes shortness of breath in some patients. This is usually mild to moderate and often settles while the patient keeps taking the drug (AstraZeneca Canada, 2026). Patients are taught to report it and not to stop the drug on their own.

MEDICATIONS

Antiplatelets, Anticoagulants and Other ACS Drugs

All drugs named here are marketed in Canada. Doses are not listed.

- **ASA plus a P2Y12 inhibitor (clopidogrel, ticagrelor, prasugrel):** watch for bleeding from gums, nose, urine, stool and puncture sites. Ticagrelor can cause shortness of breath; it is usually mild and often settles, but the patient reports it. Ticagrelor is used with caution in patients at higher risk of slow heart rhythms. Its monograph warns that stopping it early raises the risk of cardiac events (AstraZeneca Canada, 2026).
- **Prasugrel:** contraindicated after a stroke or TIA and with active bleeding. It is not recommended for people aged 75 or older or weighing less than 60 kg (JAMP Pharma Corporation, 2020).
- **Heparin, enoxaparin, fondaparinux:** watch for bleeding and check kidney function and blood counts as ordered (Chapter 19).
- **High-intensity statin (for example, atorvastatin):** ask about new muscle pain or weakness and report it (section 17.1).
- **Beta-blocker (for example, metoprolol):** check apical pulse and blood pressure before giving it; report a slow heart rate, dizziness or new breathlessness.
- **ACE inhibitor (for example, ramipril) or ARB:** watch blood pressure, potassium and creatinine; a dry cough is a common reason patients stop an ACE inhibitor, so they are asked to report it rather than stop.
- **Teaching:** no antiplatelet drug is stopped without the cardiology team's advice.

Monitoring and Nursing Care

In the first days, the patient has continuous cardiac monitoring because dangerous rhythms are most likely early (Chapter 16, sections 16.4 and 16.5). Any new or returning chest pain is treated as possible new ischemia. The nurse stops the activity, assesses the pain, records a 12-lead ECG under the order or directive in place and reports at once (section 17.3). A patient who has had a stent may be having stent thrombosis (section 17.5), described in section 17.5.

The nurse trends vital signs, oxygen saturation, urine output and mental status. Oxygen is given only when saturation falls below the threshold in section 17.3 (Chapter 12). The nurse listens for crackles and looks for new breathlessness, rising heart rate, falling blood pressure, cool or clammy skin and confusion. These are cues of heart failure or cardiogenic shock (Chapter 6, section on shock; Chapter 18). Early warning scores and rapid response are described in Chapter 6.

Activity increases step by step as ordered once the patient is stable. The nurse watches the patient's response and stops the activity if chest pain, marked breathlessness, dizziness or a sharp change in heart rate occurs. Fear is common after a heart attack. The nurse

explains what each monitor and test is for, protects sleep by grouping night-time care, and includes the family in teaching when the patient agrees. An interpreter is used whenever needed (Chapter 2).

Bleeding precautions apply to every patient on these drugs. The nurse checks puncture sites, intravenous sites, urine and stool, and trends hemoglobin and platelets as ordered (Chapter 20). The nurse also prevents falls (Chapter 8) and offers a soft toothbrush and an electric razor. Patients are taught to report black or bloody stools, blood in the urine, vomit that looks like coffee grounds, a severe headache or bleeding that will not stop.

CLINICAL JUDGMENT

Fatigue and Nausea in a Woman Aged 68

Names and details are fictional; this is a composite story.

Margaret Chen, 68, is on a surgical unit 2 days after a hip replacement. She has type 2 diabetes and hypertension. At 1400 she tells the RPN she feels "washed out" and queasy and does not want to walk. She denies chest pain.

- **Recognize cues:** new fatigue and nausea; she looks pale and is sweating; heart rate 108 per minute (was 84), blood pressure 104/62 mm Hg (was 138/76), respiratory rate 22 per minute, oxygen saturation 93% on room air. She has diabetes and is an older woman, so her ACS symptoms may not be typical (Chapter 16, section 16.2).
- **Analyze cues:** possible causes include ACS, bleeding, pulmonary embolism (Chapter 15), infection, hypoglycemia and drug effects. Surgery, anemia and pain all strain the heart.
- **Prioritize hypotheses:** ACS is the most time-critical, along with bleeding and pulmonary embolism.
- **Generate solutions:** stay with her; record a 12-lead ECG within 10 minutes under the directive in place (section 17.3); check capillary glucose; call the RN and the rapid response team (Chapter 6); check the wound and drain.
- **Take action:** the ECG shows new ST depression. The team assesses her. ASA is weighed against her bleeding risk after surgery, and nitroglycerin against her low blood pressure. Oxygen is not started at a saturation of 93% (section 17.3; Chapter 12). Troponin is drawn.
- **Evaluate outcomes:** the nurse repeats vital signs, asks about her symptoms, and follows the repeat ECG and the troponin trend. Her family is told what is happening. She is transferred for cardiology care, and the nurse gives a full handover.

Complications

Dysrhythmias are the most immediate threat. Ventricular fibrillation can cause sudden death, and ischemia can damage the conduction system and cause atrioventricular (AV) block (Chapter 16, sections 16.5 and 16.7). Atrial fibrillation (AF) may also appear and brings its own stroke risk (Chapter 16, section 16.6).

Heart failure and **cardiogenic shock** develop when a large area of muscle stops pumping well. The cues listed above under Monitoring and Nursing Care call for immediate escalation (Chapter 6; Chapter 18).

Mechanical complications are tears in heart structures weakened by the infarct. They include **papillary muscle rupture**, which causes sudden, severe leakage through the mitral valve; **ventricular septal rupture**, a hole in the wall between the ventricles; and **free wall rupture**, a tear in the outer wall that can cause sudden death. They are rare. A 2021 AHA scientific statement notes that they mainly threaten patients with large infarcts or delayed reperfusion, and that each carries a substantial risk of death. Care depends on a multidisciplinary team that recognizes the problem quickly, confirms it with imaging, supports the circulation and decides on definitive treatment, often surgery, or on palliative care (Damluji et al., 2021). The nurse's role is to notice when a patient who was improving suddenly becomes breathless, hypotensive or collapses, and to escalate at once.

Inflammation of the pericardium (pericarditis) can follow MI and is covered in Chapter 18. New chest pain after MI is always assessed and reported, never assumed to be pericarditis.

Depression is common after ACS. An AHA scientific statement concluded that the weight of evidence supports treating depression after ACS as a risk factor for a poor prognosis. The outcomes linked to it included death from any cause, cardiac death, and composite outcomes that combine death with nonfatal events (Lichtman et al., 2014). The nurse asks about mood, sleep and hopelessness, uses the screening tool the unit uses and reports positive results (section 17.6).

LIFESPAN CONSIDERATIONS

Older Adults With ACS

- **Presentation:** older adults more often have ACS without classic chest pain. Fatigue, breathlessness, nausea, confusion or a fall may be the only signs (Chapter 16, section 16.2).
- **Bleeding:** age raises bleeding risk with antithrombotic drugs. Prasugrel is not recommended at age 75 or older (JAMP Pharma Corporation, 2020). Kidney function guides drug choices and contrast decisions (Chapter 16, section 16.3).
- **Frailty and polypharmacy:** frailty affects recovery and how much invasive treatment a person can tolerate. Adding several cardiac drugs to an existing list raises the risk of falls, low blood pressure and drug interactions (Chapter 8).
- **Delirium:** new confusion may be the first cue of ACS or of a complication. Delirium needs its own assessment (Chapter 8).
- **Shared decisions:** treatment choices, including whether to have angiography or PCI, should fit the person's goals, values and quality of life. The nurse makes sure the patient and family have the information to take part, and that any advance care plan is known (Chapter 10).

17.5 Care Around PCI and CABG

Before Catheterization or PCI

Percutaneous coronary intervention (PCI) opens a narrowed or blocked coronary artery through a catheter, usually with a balloon and a **stent**: a small mesh tube left in the artery to hold it open (Figure 17.5). The catheter enters through an artery in the wrist (**radial access**) or the groin (**femoral access**). Heart and Stroke Foundation of Canada (n.d.-a) explains to patients that the catheter is removed with a clamp and pressure.

Before the procedure, the nurse confirms that informed consent has been obtained by the physician performing it (Chapter 1, section 1.5). The nurse asks about allergies and any past reaction to contrast dye, and reviews kidney function. Canadian radiology guidance states that kidney injury after contrast is a concern mainly for people with an estimated glomerular filtration rate (eGFR) of 30 mL/min/1.73 m^2 or less, or with existing acute kidney injury. Under that guidance, metformin is held only for those patients (Macdonald et al., 2022; Chapter 16, section 16.3). Anticoagulants and diabetes drugs are held or adjusted only as ordered (Chapter 22). Fasting follows local policy. The nurse records baseline vital signs and checks pulses, colour, warmth and sensation in both arms and both legs, so later checks can be compared. The nurse also explains what to expect. Local anesthetic and mild to moderate sedation, with a warm room, reduce anxiety, discomfort and spasm of the radial artery (Mason et al., 2018). After a groin approach, the patient will need several hours of bed rest (Heart and Stroke Foundation of Canada, n.d.-a). Knowing this ahead of time eases fear and helps the patient keep still.

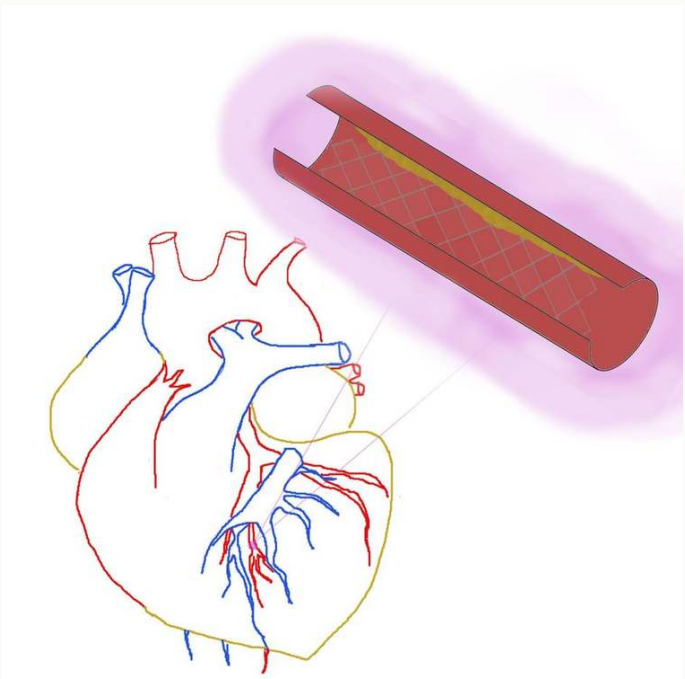

Figure 17.5 An expanded coronary stent holding a narrowed artery open (enlarged view). (credit: “Cobalt Chromium Coronary Stent in Heart” by ETTon/Wikimedia Commons, CC BY-SA 4.0)

After PCI

After PCI, the nurse checks the access site and the limb beyond it often, as the unit protocol directs (Table 17.3). Limb checks compare the two sides for pulses, warmth, capillary refill, movement and sensation. Colour changes are easy to miss on darker skin.

Pallor may show as an ashen or greyish tone, so the nurse also looks at nail beds and palms and relies on warmth, capillary refill and the patient's report of numbness or tingling.

After radial access, a compression band holds pressure on the wrist. Air is released in steps on a schedule set by protocol. An AHA scientific statement names **radial artery occlusion** as a common complication. It calls keeping some blood flowing through the artery during compression (patent hemostasis) critical to prevention, and lists checks of distal pulses, skin temperature and colour as nursing best practices (Mason et al., 2018). A **hematoma** (a collection of blood under the skin) at the wrist or a swelling, tight and painful forearm is reported at once.

After femoral access, the patient lies flat or nearly flat with the leg straight for the time set by protocol. Heart and Stroke Foundation of Canada (n.d.-a) tells patients to expect 4 to 6 hours of bed rest. **Retroperitoneal bleeding**, bleeding into the space behind the abdominal organs, may show no blood at the groin at all. The cues are back, flank or lower abdominal pain, a rising heart rate, falling blood pressure, restlessness and a falling hemoglobin. These need urgent escalation.

Contrast-associated acute kidney injury is a decline in kidney function after contrast dye. The nurse follows the ordered fluid plan, records urine output and checks creatinine as ordered, especially in patients with low eGFR (Chapter 27).

New chest pain after PCI may mean **stent thrombosis**: a clot forming inside the stent and suddenly blocking the artery. It presents like a new MI. The nurse records a 12-lead ECG at once and calls for urgent help (section 17.3).

Why radial first? The RIVAL trial randomly assigned 7,021 patients with ACS at 158 hospitals in 32 countries. The combined rate of death, MI, stroke or major bleeding not related to CABG at 30 days was similar: 3.7% with radial and 4.0% with femoral access. Large hematomas and pseudoaneurysms needing closure were less common with radial access (Jolly et al., 2011). The MATRIX trial randomized 8,404 patients with ACS. Net adverse clinical events at 30 days were 9.8% with radial and 11.7% with femoral access. The difference came mainly from less major bleeding (1.6% vs 2.3%) and lower death from any cause (1.6% vs 2.2%) (Valgimigli et al., 2015). The 2025 guideline prefers the radial approach for PCI in ACS to reduce bleeding (Rao et al., 2025).

Before discharge, the nurse teaches why DAPT matters. Stopping a P2Y12 inhibitor early leaves the new stent unprotected. The ticagrelor monograph states that patients who stop it are at higher risk of cardiac events (AstraZeneca Canada, 2026). The patient learns not to stop or skip a dose without speaking to the cardiology team, to tell every dentist and surgeon about the stent, and to refill before running out. The nurse also asks whether the patient can afford the drugs and connects them with help if needed (Chapter 2).

Table 17.3 Caring for the access site after catheterization: radial and femoral compared (Heart and Stroke Foundation of Canada, n.d.-a; Mason et al., 2018; Jolly et al., 2011; original wording)

Feature	Radial access	Femoral access
Closure and compression	Compression band on the wrist; air released in steps per protocol; aim is to stop bleeding while keeping some flow in the artery	Manual pressure, a closure device or a compression device per protocol
Positioning and mobility	Patient can usually sit up and walk sooner; the wrist is kept still and the arm is not used for lifting while the band is on	Bed rest with the leg straight for the time set by protocol (patients are told to expect 4 to 6 hours); head of bed raised only as allowed
What to check	Site; hand colour, warmth, capillary refill, movement and sensation; radial and ulnar pulses compared with the other side	Site; foot colour, warmth, capillary refill, movement and sensation; pedal pulses compared with the other side and with baseline
Bleeding cues	Oozing at the band; swelling, firmness or pain in the wrist or forearm	Bleeding or swelling at the groin; back, flank or lower abdominal pain, rising heart rate and falling blood pressure (possible retroperitoneal bleeding)
Other complications	Radial artery occlusion; radial artery spasm; forearm hematoma	Hematoma; pseudoaneurysm (a pulsing lump); limb ischemia
Teaching	Avoid heavy use of that hand and wrist for the time advised; report numbness, coldness or swelling	Avoid heavy lifting and straining for the time advised; report groin swelling, a pulsing lump or bleeding; apply pressure and call 9-1-1 for bleeding that will not stop

SCOPE IN PRACTICE

Directives, Access Sites and Nitroglycerin

Care around ACS and PCI uses the three ideas in the College of Nurses of Ontario's (CNO's) Scope of Practice standard: authority, competence and context (Chapter 1, section 1.3). Employer policy and the province or territory also matter.

- **Directives:** a medical directive is an order written by an authorized provider that applies to a group of patients when stated conditions are met (CNO, 2025b). Many hospitals use directives that let RNs and RPNs record a 12-lead ECG and give ASA and sublingual nitroglycerin for suspected ACS. The CNO Medication standard requires the nurse to accept only clear, complete and appropriate orders, and to act only within their own competence (CNO, 2025a). CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (CNO, 2026).
- **Access sites:** sheath removal, manual compression and compression band release are done by nurses whom the employer authorizes and who have the education and competence for them.
- **Infusions:** titrated cardiac infusions are usually managed by RNs in critical care or step-down settings, according to employer policy; this is RN-level depth.
- **Deterioration:** every nurse who notices bleeding, new chest pain or a cool, pulseless limb acts at once and escalates. The RPN consults the RN as the patient's needs change.

After CABG on the Ward

Coronary artery bypass grafting (CABG) is surgery that carries blood around blocked coronary arteries using grafts. The grafts are arteries, such as one from inside the chest wall or from the forearm, or veins taken from the leg. Most patients have the surgery through a sternotomy, an incision through the breastbone. They spend the first day or so in intensive care and then move to a cardiac surgery ward. The ward nurse receives a report on drains (Chapter 15), temporary pacing wires (Chapter 16, section 16.7), pain control (Chapter 5) and the activity plan. On arrival, the ward nurse completes a full assessment and compares it with the report: vital signs and rhythm, oxygen saturation, breath sounds, pain, incisions, drain and urine output, glucose and mental status. Transfers are a common point for lost information, so the nurse clarifies anything unclear, including which drugs were stopped, started or held.

Sternal precautions are limits on arm and upper-body use that protect the healing breastbone. Under traditional precautions, patients limit how they use their arms for as long as 12 weeks after sternotomy (Park et al., 2021). A newer approach, "Keep Your Move in the Tube," replaces fixed weight and time limits. Patients use their arms for everyday activities, moving mindfully and guided by pain, and keep their movements close to the body ("in the tube") (Gach et al., 2021; Park et al., 2021). In a Canadian quasi-experimental study of 100 patients per group, return to function was slower over time with traditional precautions, but the gap narrowed by 12 weeks. After adjustment, the two approaches did not differ (Park et al., 2021). In a before-and-after study of 1,104 patients at one large hospital, those taught the newer approach had about three times the odds of going home rather than to a rehabilitation or nursing facility. Sternal wound complications and 30-day readmissions did not differ significantly (Gach et al., 2021). The nurse teaches the approach the program uses and reinforces it every time the patient moves.

The nurse checks the sternal incision and the arm or leg donor site for redness, drainage, separation and swelling. The leg is raised when the patient sits, and the patient learns to report fever or a wound that opens or drains. Other postoperative priorities are covered elsewhere: pain (Chapter 5), chest drains (Chapter 15) and new AF after surgery (Chapter 16, section 16.6). Delirium (Chapter 8), glucose control, including in patients without known diabetes (Chapter 22), and early walking with deep breathing and coughing (Chapter 12) also need attention. Canadian guidance favours DAPT over a single antiplatelet drug after CABG, whether or not the surgery followed ACS (Bainey et al., 2024). Mood often dips after surgery. The nurse screens for depression as for any patient after ACS (section 17.4).

PRACTICE STORY

The Ache in His Back

Names and details are fictional; this is a composite story.

Nurse: Aisha Rahman, RPN. Years in practice: 4. Setting: cardiac step-down unit, regional hospital, Ontario.

Mr. Doucet was 72 and had come back from the catheterization lab at noon after PCI through his right groin. His radial arteries were small, so the femoral route had been used. At 1400 his groin dressing was dry, his foot was warm and his pedal pulses matched the baseline I had marked that morning. He was chatting about his grandson's hockey game.

At 1500 he said, "My back's killing me. Must be lying flat on this mattress." He wanted something for the pain and to sit up. It would have been easy to agree. Lying flat for hours is uncomfortable, and his groin still looked clean. But his heart rate had gone from 72 to 96 and his blood pressure from 134/80 to 108/68. He was restless, and his face looked greyer than an hour before.

I remembered that bleeding after a femoral puncture can track backward, where you can't see it. I kept him flat, checked the site and his foot again, and asked my RN colleague, Tom, to come. Tom agreed this could be retroperitoneal bleeding and called the interventional cardiologist while I repeated his vital signs. His blood pressure was now 96/60 mm Hg. I documented each set with the time.

The team ordered a stat hemoglobin and a computed tomography (CT) scan, and gave fluids. His hemoglobin had dropped from 138 to 104 g/L. The CT confirmed a retroperitoneal hematoma. He did not need surgery, but he did need a transfusion and a night in the coronary care unit.

Later, Mr. Doucet's daughter thanked me for "not just giving him a pill." I think about how ordinary his words sounded. The numbers told the story his back was starting to tell.

Reflect: What cues, together, made back pain after a femoral PCI a warning sign? Which parts of this patient's care were within the RPN's scope, and at what point was consulting the RN required?

17.6 Cardiac Rehabilitation and Living With Coronary Disease

Cardiac Rehabilitation

Cardiac rehabilitation is a structured program that combines exercise, education and counselling to help people recover after a heart attack, heart surgery or other heart conditions (Heart and Stroke Foundation of Canada, n.d.-b). It is a core part of **secondary prevention**: care that lowers the risk of another event in someone who already has coronary disease. Programs differ but usually include a medical assessment, supervised physical activity, education on nutrition and other risk factors, and psychosocial support for depression, anxiety and return to work (Table 17.4). The team may include physicians, nurses, exercise physiologists, dietitians, physiotherapists, occupational therapists, psychologists and social workers (Heart and Stroke Foundation of Canada, n.d.-b).

The benefits are well studied. A 2021 Cochrane review pooled 85 trials with 23,430 people with coronary heart disease. Over 6 to 12 months, exercise-based rehabilitation reduced MI (risk ratio 0.72) and hospital admission for any cause (risk ratio 0.58). It probably caused a slight reduction in death from any cause and improved health-related quality of life. Over longer follow-up, it may also lower cardiovascular death (Dibben et al., 2021).

Referral is where many patients are lost. A Canadian review names lack of referral and lack of a physician's recommendation among the main barriers. It also notes a national policy position calling for systematic referral of eligible inpatients (Grace et al., 2014). When referral is automatic, part of the standard discharge order set, it no longer depends on someone remembering. The 2025 guideline recommends referral to cardiac rehabilitation and includes home-based programs as an option (Rao et al., 2025). Home-based and virtual programs can reach people who cannot travel to a hospital program. For people with no program nearby, Heart and Stroke Foundation of Canada (n.d.-b) offers a self-guided recovery plan to use with their provider's approval.

Table 17.4 Components of cardiac rehabilitation (Heart and Stroke Foundation of Canada, n.d.-b; Grace et al., 2014; original wording)

Component	What it includes	The nurse's role
Assessment	Review of physical abilities, limits, symptoms and risk factors at entry	Share the discharge summary, drug list and procedure details; make sure the referral is sent before discharge
Exercise training	Supervised aerobic and strength activity, progressed over weeks	Teach warning signs to stop exercise; explain why activity is safe and helps recovery
Risk factor management	Blood pressure, lipids, glucose, weight, smoking and vaping, alcohol	Reinforce targets (section 17.1); refer for smoking cessation support (Chapter 14)
Education	Heart disease, drugs, nutrition, symptoms and when to call 9-1-1	Start teaching in hospital; use plain language and an interpreter when needed; include family
Psychosocial support	Screening and help for depression, anxiety and stress; return to work and daily roles	Screen for low mood; listen to fears; link to counselling and peer support

Who Gets Left Out

In Canada, rehabilitation works when people attend, but many do not. A Canadian review reported that only 34% of eligible patients take part. It added that ways of widening access for groups that are under-represented, for example women and members of ethnic minority groups, were not yet in wide use (Grace et al., 2014). Heart and Stroke Foundation of Canada (n.d.-b) reports that women are only half as likely as men to attend and follow a program, in part because physicians refer them less often and because work or family demands lead some to stop. In a study of cardiac inpatients from 11 Ontario hospitals, patients of lower socioeconomic status were less likely to be referred, to enrol and to participate. Rural patients, defined as living more than a 30-minute drive from hospital, attended fewer sessions. Both groups reported more barriers, especially distance, cost and transportation (Shanmugasegaram et al., 2013).

Many of these barriers are structural rather than personal: where programs are located, when sessions run, transportation, lost wages, language and past experiences of racism in health care (Chapter 2). First Nations, Inuit and Métis patients in rural, remote or northern communities may be far from any program. The nurse can help close these gaps:

- Make sure every eligible patient leaves with a referral, not only those who ask.
- Explain in plain language what rehabilitation is and why it helps, and that women and older adults benefit too.
- Ask about transportation, cost, work, caregiving and language, and involve the social worker or discharge planner.
- Offer home-based or virtual options where they exist, and connect patients with community, Indigenous health or culturally specific services when the patient wants this.

Living Well After ACS

Living well starts with the drugs. The nurse reviews each drug's purpose, explains that DAPT and statins work quietly even when the patient feels well, and helps set up reminders and refills (section 17.5). Risk factor control continues for life: lipids and physical activity (section 17.1), smoking and vaping cessation (Chapter 14), blood pressure (Chapter 19) and diabetes (Chapter 22).

Mood needs regular attention because depression after ACS is linked to worse outcomes (Lichtman et al., 2014). The nurse asks about mood at each contact and makes sure the follow-up plan includes screening.

Many patients want to ask about sex but wait to be asked. An AHA scientific statement considers it reasonable to resume sex 1 week or more after an uncomplicated MI, provided mild to moderate exertion causes no heart symptoms. Sex may resume several days after PCI if the access site has no complications, and 6 to 8 weeks after standard CABG once the sternotomy has healed. The statement adds that anxiety and depression about sexual activity should be assessed, and that counselling the patient and partner helps (Levine et al., 2012). Cardiac rehabilitation and regular exercise can also lower the risk of complications during sexual activity (Levine et al., 2012). Drugs for erectile dysfunction must not be combined with nitrates (section 17.2).

Return to work depends on the person's recovery, the type of work and the treatment received, and cardiac rehabilitation programs can help plan it (Heart and Stroke Foundation of Canada, n.d.-b). The nurse encourages the patient to talk with the employer about a gradual return or lighter duties where possible, and to include family in planning. Driving is also individual. After ACS, PCI or CABG, the CCS 2023 fitness-to-drive guideline restricts driving for a period set by the guideline; the team gives the exact time. Its recommendations are stricter for commercial drivers, and in some provinces, clinicians are required to report a driver they judge to be unsafe (Guerra et al., 2024). The nurse tells patients not to drive until their cardiologist confirms it is safe.

Every patient leaves knowing what to do if symptoms return, including how to use nitroglycerin and when to call 9-1-1 (section 17.2, Patient Education box).

Chapter 17 Summary

Introduction

- In 2023 to 2024, 8.2% of Canadian adults had diagnosed ischemic heart disease; diseases of the heart ranked second among causes of death in 2024.
- Any nurse may be the first to recognize an acute coronary syndrome, so every nurse needs to know its signs and first actions.

17.1 Atherosclerosis and Cardiovascular Risk

- Atherosclerosis begins with endothelial dysfunction and LDL retention, leading to foam cells, a fibrous cap and a necrotic core; thin-capped, inflamed plaques can rupture and cause thrombosis.
- Smoking, hypertension, dyslipidemia, diabetes, abdominal obesity, inactivity, diet and stress are modifiable; pregnancy complications and menopause add risk for women.
- CCS recommends nonfasting lipid screening from age 40, Lp(a) once in a lifetime, and statins for statin-indicated conditions.
- In ASCVD on the highest tolerated statin, CCS suggests intensifying therapy when LDL-C is 1.8 mmol/L or more, non-HDL-C 2.4 mmol/L or more, or ApoB 0.7 g/L or more.
- Patients report unexplained muscle pain, tenderness or weakness on a statin promptly.

17.2 Stable Angina and Chronic Coronary Disease

- Stable angina is predictable ischemic discomfort from a fixed narrowing, brought on by exertion or stress and eased by rest or nitroglycerin; breathlessness and fatigue can be anginal equivalents.
- Treatment combines risk reduction, antiplatelet therapy and a statin with beta-blockers or calcium channel blockers (NICE and ESC guidance); revascularization is considered for persistent symptoms or high-risk anatomy.
- Patients sit, take one nitroglycerin dose, and call 9-1-1 if the pain has not eased within 5 minutes; nitroglycerin is never combined with PDE5 inhibitors.

17.3 Recognizing Acute Coronary Syndromes

- ACS includes unstable angina, NSTEMI and STEMI; MI requires a troponin rise and/or fall with at least one value above the 99th percentile plus evidence of ischemia.
- Type 1 MI comes from plaque disruption and thrombus; type 2 MI from a supply–demand mismatch.
- Many people, especially women, have MI without chest pain.
- First actions: stay, call for help, 12-lead ECG within 10 minutes, monitoring, IV access, troponin, chewed ASA, oxygen only for low SpO2, nitroglycerin unless contraindicated.
- STEMI needs immediate reperfusion by primary PCI, or fibrinolysis when PCI cannot happen within 120 minutes of first medical contact.

17.4 Early Treatment and Complications of ACS

- DAPT combines ASA with a P2Y12 inhibitor (clopidogrel, ticagrelor or prasugrel). The 2025 ACC/AHA guideline names at least 12 months as the default, and Canadian guidance shortens it for people at high bleeding risk.
- Parenteral anticoagulants, high-intensity statins, beta-blockers, ACE inhibitors or ARBs and, when bleeding risk is high, a proton pump inhibitor complete early treatment.
- Bleeding is the main hazard. Prasugrel is contraindicated after stroke or TIA, and ticagrelor can cause mild shortness of breath.
- The nurse monitors rhythm, chest pain, perfusion and bleeding, and escalates any cue of heart failure or shock.
- Complications include dysrhythmias, heart failure, cardiogenic shock, rare but deadly mechanical ruptures and depression.

17.5 Care Around PCI and CABG

- Before PCI, the nurse confirms consent, allergies, kidney function, drug holds as ordered and baseline limb checks.
- After PCI, the nurse checks the access site and limb often and watches for hematoma, radial artery occlusion and hidden retroperitoneal bleeding.
- New chest pain after PCI may be stent thrombosis and needs an immediate ECG and urgent help.
- Radial access lowers bleeding and vascular complications (RIVAL, MATRIX), and DAPT must never be stopped early.
- After CABG, care covers sternal protection, incisions, pain, drains, AF, delirium, glucose, mobility and mood.

17.6 Cardiac Rehabilitation and Living With Coronary Disease

- Cardiac rehabilitation combines assessment, exercise, risk factor management, education and psychosocial support, and reduces MI and hospital admission.
- Only about one in three eligible Canadians take part. Women, people of lower socioeconomic status and rural residents face extra barriers.
- Automatic referral before discharge, plus home-based or virtual options, helps close these gaps.
- Living well includes drug adherence, risk factor control, depression screening and frank talk about sex, work and driving.

Key Terms (37)

acute coronary syndrome (ACS): a sudden fall in blood flow to the heart muscle, usually from plaque rupture or erosion with thrombus; includes unstable angina, NSTEMI and STEMI.

anginal equivalent: a symptom other than chest pain, such as breathlessness or unusual fatigue on exertion, that reflects myocardial ischemia.

apolipoprotein B (ApoB): the protein on each atherogenic lipoprotein particle; its level, in g/L, reflects the number of particles that can enter the artery wall.

atherosclerosis: a chronic inflammatory disease of the artery wall in which lipids, immune cells and fibrous tissue build up beneath the lining to form plaque.

cardiac rehabilitation: A structured program of assessment, exercise, education and psychosocial support after a heart event or heart surgery.

contrast-associated acute kidney injury: A decline in kidney function after contrast dye, a concern mainly when eGFR is 30 mL/min/1.73 m² or less or acute kidney injury is already present.

coronary artery bypass grafting (CABG): Surgery that carries blood around blocked coronary arteries using arterial or venous grafts.

dual antiplatelet therapy (DAPT): Treatment with ASA plus a P2Y12 inhibitor to prevent clots after ACS or stent placement.

femoral access: Entry to the arterial system through the femoral artery in the groin for catheterization or PCI.

fibrinolysis: reperfusion with an intravenous drug that dissolves the fibrin in a coronary clot, used when primary PCI would be delayed.

hematoma: A collection of blood under the skin or in tissue, seen as a firm, tender swelling.

LDL cholesterol (LDL-C): cholesterol carried in low-density lipoprotein particles, reported in mmol/L; the main target of lipid-lowering treatment.

lipoprotein(a) [Lp(a)]: an inherited lipoprotein particle that adds cardiovascular risk; measured once in a lifetime.

mechanical complications of MI: Rare tears in heart structures weakened by infarction, including papillary muscle rupture, ventricular septal rupture and free wall rupture.

myocardial infarction (MI): death of heart muscle cells from ischemia, shown by a rise and/or fall in cardiac troponin with at least one value above the 99th percentile plus clinical evidence of ischemia.

non-HDL cholesterol (non-HDL-C): total cholesterol minus HDL cholesterol; the cholesterol in all atherogenic particles.

NSTEMI (non-ST-elevation myocardial infarction): an MI confirmed by troponin without persistent ST elevation on the ECG.

P2Y12 inhibitor: A drug that blocks the P2Y12 receptor on platelets so they are less able to clump; clopidogrel, ticagrelor and prasugrel are examples.

papillary muscle rupture: A tear in a muscle that anchors the mitral valve, causing sudden severe mitral leakage after MI.

percutaneous coronary intervention (PCI): A catheter procedure that opens a narrowed or blocked coronary artery, usually with a balloon and a stent.

plaque rupture: a tear in the fibrous cap of a plaque that exposes its core to blood and triggers thrombus formation.

primary PCI: emergency coronary angiography with balloon and stent opening of a blocked artery, without fibrinolysis first.

radial access: Entry to the arterial system through the radial artery at the wrist for catheterization or PCI.

radial artery occlusion: Blockage of the radial artery after radial access, a common complication that patent hemostasis helps prevent.

reciprocal changes: ST depression in leads facing the wall opposite an area of ST elevation, supporting acute coronary occlusion.

reperfusion: restoring blood flow through a blocked coronary artery by primary PCI or fibrinolysis.

retroperitoneal bleeding: Bleeding into the space behind the abdominal organs, a hidden complication of femoral access shown by back or flank pain, rising heart rate and falling blood pressure.

right ventricular infarction: MI involving the right ventricle, often with inferior STEMI; nitroglycerin is used with great caution or avoided.

secondary prevention: Care that lowers the risk of another event in a person who already has coronary disease.

stable angina: predictable chest discomfort brought on by exertion or emotional stress and eased by rest or nitroglycerin, caused by a fixed coronary narrowing.

statin: a lipid-lowering drug that is the first-line treatment for people with ASCVD or another statin-indicated condition.

STEMI (ST-elevation myocardial infarction): an MI with new ST elevation in at least two contiguous leads, usually from acute occlusion of a coronary artery.

stent: A small mesh tube left in a coronary artery to hold it open after PCI.

stent thrombosis: A clot that forms inside a stent and suddenly blocks the artery; it presents like a new MI.

sternal precautions: Limits on arm and upper-body movement that protect the breastbone while it heals after sternotomy.

type 2 myocardial infarction: MI caused by an imbalance between the heart's oxygen supply and demand, such as severe anemia or hypotension, without acute plaque disruption.

unstable angina: myocardial ischemia at rest or on minimal exertion without heart muscle cell death.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Daniel Okafor (Questions 1–4): Mr. Daniel Okafor, 64, is on a medical unit for cellulitis of the left leg. He has hypertension and type 2 diabetes. At 0215 h he calls the nurse, pale and sweating, and says his chest feels "heavy, like someone is sitting on it." Pulse 104 beats/min, blood pressure 142/86 mm Hg, SpO2 95% on room air.

1. [CORE] What is the nurse's first action?

a. Go to the medication room to get nitroglycerin under the medical directive

b. Stay with Mr. Okafor, have him stop all activity, and call for help

c. Document the episode and reassess in 30 minutes

d. Apply oxygen by nasal cannula at 4 L/min

Answer: b — New chest heaviness with pallor and sweating is treated as ACS; the nurse stays with the patient, stops activity and calls for help so that other actions can happen at once (b) (section 17.3). Leaving to get nitroglycerin (a) leaves an unstable patient alone; it is given only after a blood pressure check and with help on the way. Waiting 30 minutes (c) delays ECG, ASA and possible reperfusion. Oxygen (d) is not indicated with SpO2 95% on room air; a guideline panel recommends not starting oxygen in suspected MI when SpO2 is above 92% (section 17.3; Chapter 12).

2. [CORE] The rapid response team is on its way. Within what time should Mr. Okafor's 12-lead ECG be recorded and shown to a physician or nurse practitioner?

a. Within 60 minutes of the first troponin result

b. Within 30 minutes, after the first troponin is drawn

c. Within 20 minutes of his report of chest discomfort

d. Within 10 minutes of first medical contact

Answer: d — A 12-lead ECG within 10 minutes of first medical contact identifies STEMI, which needs immediate reperfusion (d) (section 17.3; Chapter 16). The ECG does not wait for troponin (a, b); STEMI is identified from the ECG before results return. Twenty minutes (c) is longer than the recommended target.

3. [CORE] The ECG shows no ST elevation. The physician orders sublingual nitroglycerin. Mr. Okafor quietly mentions he took tadalafil the previous evening. What should the nurse do?

a. Hold the nitroglycerin and report the tadalafil use to the physician at once

b. Give the nitroglycerin with the patient lying flat

c. Give half the usual nitroglycerin dose and recheck blood pressure in 5 minutes

d. Give the nitroglycerin, because his blood pressure is 142/86 mm Hg

Answer: a — Nitroglycerin is contraindicated with PDE5 inhibitors such as tadalafil because the combination can cause a dangerous fall in blood pressure; the Canadian tadalafil monograph allows a nitrate only in a life-threatening situation, at least 48 hours after the last dose and under close medical supervision (a) (section 17.2 and Clinical Safety box). Positioning (b) does not remove the risk. A nurse does not change an ordered dose (c), and a reduced dose is still contraindicated. A normal blood pressure now (d) does not protect against the interaction.

4. [CORE] A repeat ECG 15 minutes later shows new ST elevation in leads II, III and aVF. The registered practical nurse (RPN) caring for Mr. Okafor sees the printout first. What is the RPN's best action?

a. Wait for the next troponin result to confirm the change before reporting

b. Mount the ECG in the chart so the cardiology team can review it on morning rounds

c. Report the ECG to the RN and the responding team immediately

d. Give a second dose of ASA, then reassess

Answer: c — New ST elevation in contiguous leads suggests STEMI; every nurse who notices it escalates at once, and the RPN consults the RN as the patient's needs change, so reperfusion can begin (c) (section 17.3; Chapter 1, section 1.3). Waiting for troponin (a) or the morning team (b) wastes heart muscle; STEMI is identified from the ECG. A second ASA dose (d) is not ordered and does not replace escalation.

5. [CORE] Which risk factors for coronary artery disease can be modified? Select all that apply.

a. Smoking

b. Older age

c. Hypertension

d. Abdominal obesity

e. Familial hypercholesterolemia

f. Physical inactivity

Answer: a, c, d, f — Smoking (a), hypertension (c), abdominal obesity (d) and physical inactivity (f) are among the potentially modifiable factors that together accounted for about 90% of attributable heart attack risk in INTERHEART (section 17.1). Older age (b) cannot be changed. Familial hypercholesterolemia (e) is an inherited disorder; its LDL level can be treated, but the condition itself is not modifiable.

6. [CORE] A patient who had a myocardial infarction asks what "LDL-C 2.6" on his report means. He takes the highest statin dose he tolerates. Which response by the nurse is accurate?

a. "It is your total cholesterol, measured in milligrams per decilitre, and a value of 2.6 is well within the healthy range."

b. "It is your protective HDL cholesterol, measured in grams per litre, so a higher number like yours is better for your heart."

c. "It is cholesterol carried in LDL particles, in mmol/L; with heart disease, extra treatment is suggested at 1.8 or more."

d. "It measures lipoprotein(a), which is checked once in a lifetime."

Answer: c — LDL-C is reported in mmol/L in Canada; in a person with ASCVD on the highest tolerated statin dose, CCS suggests intensifying therapy when LDL-C is 1.8 mmol/L or more (c) (section 17.1, Table 17.1). It is not total cholesterol, and Canadian labs do not use mg/dL for LDL-C (a). HDL-C is the protective lipoprotein, and g/L is used for ApoB, not LDL-C (b). Lp(a) is a separate test (d).

7. [CORE] A patient taking atorvastatin tells the nurse she has new, unexplained aching and weakness in both thighs and feels feverish. What should the nurse do?

a. Report the symptoms to the prescriber promptly

b. Advise her to stop the statin permanently

c. Reassure her that statins do not affect muscles

d. Suggest she increase her exercise to stretch the muscles

Answer: a — The Canadian monograph tells patients to report unexplained muscle pain, tenderness or weakness promptly, especially with fever or malaise, because it can signal myopathy or, rarely, rhabdomyolysis (a) (section 17.1). Stopping permanently (b) is a prescriber decision, and a lower or different statin dose often works. Statins can affect muscle (c). More exercise (d) delays assessment and excessive exercise is itself a risk factor for myopathy.

8. [CORE] Which description best distinguishes unstable angina from stable angina?

a. Unstable angina is always relieved by one dose of nitroglycerin.

b. Unstable angina causes troponin to rise and fall with at least one value above the 99th percentile.

c. Unstable angina occurs only during heavy exertion.

d. Unstable angina occurs at rest or with minimal exertion.

Answer: d — Unstable angina is ischemia at rest or on minimal exertion without heart muscle death, often a change from a previously stable pattern (d) (section 17.3). Predictable relief by rest or nitroglycerin describes stable angina (a). A troponin rise and fall above the 99th percentile defines MI, not unstable angina (b). Angina with predictable exertion describes stable angina (c).

9. [CORE] Which statement shows that a patient understands teaching about sublingual nitroglycerin?

a. "I will lie flat in bed before I take it, and then walk around to see if it worked."

b. "I'll sit down, take one dose, and call 9-1-1 if the pain isn't better in 5 minutes."

c. "I can keep taking doses every few minutes for as long as I need until the pain goes away completely."

d. "If I get a headache, it means the medicine has stopped working."

Answer: b — The person sits, takes one dose, and calls 9-1-1 if the pain has not eased within 5 minutes; if the pain comes back, a dose may be repeated after 5 minutes, to no more than 3 doses in 15 minutes (b) (section 17.2). Walking afterward (a) increases demand and risks a fall from low blood pressure. Doses are limited, and waiting for relief delays emergency care (c). Headache is the most common side effect and does not mean the drug has failed (d).

10. [CORE] A woman with suspected ACS has an SpO2 of 96% on room air and no shortness of breath. The family asks why the nurse has not started oxygen. Which reply is accurate?

a. "Oxygen is given to every patient with chest pain because extra oxygen protects the heart muscle from damage."

b. "Oxygen is only used after the troponin results come back."

c. "Oxygen helps only when the oxygen level is low, and hers is normal."

d. "Oxygen would make the ECG hard to read."

Answer: c — Oxygen is given in ACS only for low SpO2; a guideline panel recommends against starting it in suspected MI when SpO2 is above 92% on room air (c) (section 17.3; Chapter 12). Routine oxygen (a) is no longer recommended. Troponin results (b) do not decide oxygen use. Oxygen does not affect the ECG (d).

11. [CORE] A 58-year-old woman on a surgical unit reports sudden extreme fatigue, shortness of breath and pressure in her upper back, but no chest pain. What is the nurse's best interpretation?

a. These can be heart attack signs in women and need an ECG and escalation now.

b. Without chest pain or pressure, a cardiac cause is unlikely, so the nurse can monitor her overnight.

c. The symptoms are expected after surgery and need rest.

d. These symptoms point to anxiety and need reassurance.

Answer: a — Women may have MI without chest pressure, presenting instead with breathlessness, upper back pressure or extreme fatigue, so the nurse obtains an ECG and escalates (a) (section 17.3). Many people with MI, especially women, have no chest pain (b). Attributing the symptoms to surgery (c) or anxiety (d) delays diagnosis; under-recognition in women is a documented equity gap (section 17.1, Canadian Context box).

12. [CORE] A patient with chest discomfort that began 40 minutes ago has a first high-sensitivity troponin within the reference range and a nondiagnostic ECG. What does the nurse anticipate?

a. Discharge home, because a normal first troponin has ruled out myocardial infarction

b. Fibrinolytic therapy

c. No further troponin testing unless pain returns

d. A repeat troponin at the time the chest pain pathway sets

Answer: d — MI is diagnosed by a rise and/or fall in troponin, so one value cannot show the pattern; the nurse anticipates a repeat sample as the pathway directs (d) (section 17.3; Chapter 16). One normal value early after onset does not rule out MI (a, c). Fibrinolysis (b) is a STEMI treatment, and this ECG does not show STEMI.

13. [CORE] A patient on a medical unit has suspected ACS. The agency's medical directive allows the nurse to give ASA. Which action is correct?

a. Give an enteric-coated ASA tablet with water, to be swallowed whole to protect the stomach

b. Check for ASA allergy or intolerance, then have the patient chew it

c. Hold ASA until troponin confirms MI

d. Give ASA only if the ECG shows ST elevation

Answer: b — ASA is chewed and swallowed for suspected ACS if the person has no allergy or intolerance (b) (section 17.3). Swallowing a coated tablet whole (a) defeats the purpose of chewing. ASA is given for suspected ACS, so it does not wait for troponin (c) or for STEMI changes (d).

14. [CORE] On a medical unit in Ontario, an RPN finds a patient with new chest pressure. Which action reflects the RPN's scope and accountability?

a. Wait for the RN to assess before taking any action

b. Interpret the 12-lead ECG independently and decide whether the patient needs reperfusion

c. Ask the family to watch the patient while the RPN finishes medications

d. Stay with the patient, call for help and consult the RN right away

Answer: d — Every nurse who notices deterioration acts at once; the RPN starts the first steps and consults the RN as the patient's needs change (d) (section 17.3; Chapter 1, section 1.3). Waiting (a) delays care. Diagnosing STEMI and choosing reperfusion (b) belong to the physician or NP. A family member cannot take over the nurse's monitoring (c).

15. [CORE] Which statement about lipid testing reflects the 2021 CCS dyslipidemia guideline?

a. A nonfasting sample is acceptable for most people, and lipoprotein(a) is measured once in a lifetime.

b. Patients must fast for 12 hours, and lipoprotein(a) is checked every year.

c. Lipid screening should begin at age 65 for everyone, and earlier only when heart symptoms appear.

d. LDL-C is preferred over non-HDL-C when triglycerides are high.

Answer: a — CCS recommends nonfasting testing except when triglycerides are known to be above 4.5 mmol/L, and Lp(a) once in a lifetime (a) (section 17.1). Fasting is not routinely needed and Lp(a) is not repeated yearly (b). Screening starts after age 40, or earlier with risk conditions (c). When triglycerides exceed 1.5 mmol/L, the CCS prefers non-HDL-C or ApoB to LDL-C (d).

16. [CORE] A patient with a bleeding duodenal ulcer has a hemoglobin of 68 g/L and a rising troponin, with no new ST elevation. The physician documents "type 2 MI." What does this mean?

a. A coronary plaque has ruptured and a new clot is now blocking one of the coronary arteries.

b. Oxygen supply could not meet demand, here because of severe anemia.

c. The patient has stable angina.

d. The troponin rise is a laboratory error.

Answer: b — Type 2 MI results from a supply–demand mismatch without acute plaque disruption; severe anemia reduces oxygen delivery (b) (section 17.3). Plaque rupture with thrombus is type 1 MI (a). Stable angina (c) does not raise troponin in an MI pattern. The rising troponin reflects real injury (d), and treatment targets the cause, such as stopping the bleeding and replacing blood.

17. [RN] A patient's ECG shows ST elevation in II, III and aVF. Blood pressure is 88/56 mm Hg and the lungs are clear. Which nursing action is the priority?

a. Give sublingual nitroglycerin now to relieve the pain and reduce myocardial oxygen demand

b. Repeat the standard 12-lead ECG in 1 hour

c. Record V3R and V4R as ordered, hold nitroglycerin and report the hypotension

d. Sit the patient upright with legs dependent to ease breathing and pain

Answer: c — Inferior STEMI with hypotension raises concern for right ventricular infarction; right-sided leads are recorded early, and nitroglycerin is held because severe hypotension is a contraindication and the monograph warns of serious effects in inferior MI with right ventricular involvement (c) (section 17.3, Going Deeper and Clinical Safety boxes). Giving nitroglycerin (a) could worsen hypotension. Waiting an hour (b) delays diagnosis. Sitting upright with legs down (d) reduces venous return and could lower blood pressure further; it does not treat the cause.

18. [RN] A 12-lead ECG shows ST elevation in V1 to V4 with ST depression in II, III and aVF. How should the nurse interpret the ST depression?

a. As a separate inferior STEMI

b. As a sign that the anterior ST elevation is caused by pericarditis rather than ischemia

c. As early repolarization, a normal variant

d. As reciprocal change, which supports an acute anterior STEMI

Answer: d — ST depression in leads facing the opposite wall is a reciprocal change; with convex ST elevation it usually means acute occlusion and helps tell STEMI apart from pericarditis or early repolarization (d) (section 17.3, Going Deeper box). Inferior STEMI (a) would show ST elevation, not depression, in II, III and aVF. Reciprocal changes argue against pericarditis (b) and early repolarization (c).

Case: Lucien Bergeron (Questions 19–24): Lucien Bergeron, 61, had PCI with a stent through his right femoral artery this morning for a non-ST-elevation MI at a hospital in Kingston, Ontario. He takes ASA and ticagrelor and received heparin during the procedure. He has type 2 diabetes, and his eGFR this morning was 52 mL/min/1.73 m². He returned to the cardiac step-down unit 2 hours ago on bed rest with his right leg straight, per protocol. Baseline pedal pulses were strong and equal.

19. [CORE] At the 2-hour check, which finding should the nurse follow up first?

a. A dry dressing with a small, unchanged mark from the procedure

b. Heart rate 76 per minute and blood pressure 130/78 mm Hg

c. A new, firm, tender swelling beside the dressing

d. The patient's request for something to drink

Answer: c — A new, firm, tender swelling at a femoral puncture site suggests bleeding under the skin and needs follow-up first (section 17.5, Table 17.3). An unchanged mark on a dry dressing (a) is expected. The vital signs (b) are within normal limits and unchanged. Thirst (d) matters, but he can drink if allowed, and it does not threaten the limb or circulation.

20. [CORE] Which explanation best fits the new groin swelling?

a. A hematoma from blood leaking out of the arterial puncture

b. An allergic reaction to the contrast dye

c. A blood clot forming in a deep leg vein

d. Stent thrombosis in the coronary artery that was treated this morning

Answer: a — A firm, tender swelling at the puncture site after femoral access is most consistent with a hematoma, a collection of blood from the arterial puncture; antiplatelets and heparin add to the risk (sections 17.4 and 17.5). A contrast reaction (b) causes hives, itching or breathing problems, not a local lump. A deep vein clot (c) causes calf or leg swelling and pain, not a firm lump at the groin. Stent thrombosis (d) causes chest pain and ECG changes, not groin swelling.

21. [CORE] Thirty minutes later, Mr. Bergeron's right foot is cooler than the left and his right pedal pulses are weaker than at baseline. The groin swelling is unchanged. Which problem is the priority?

a. Discomfort from lying flat

b. Reduced blood flow to the right leg

c. Anxiety about the procedure

d. Risk of urinary retention from bed rest

Answer: b — A cooler foot with weaker pulses than baseline suggests reduced arterial flow to the limb. This threatens the limb and needs urgent escalation (section 17.5). Discomfort (a), anxiety (c) and urinary retention (d) all need attention, but none is as time-critical as possible limb ischemia.

22. [CORE] Which plan is most appropriate for the RPN caring for Mr. Bergeron?

a. Raise the head of the bed so he is more comfortable, then reassess the site and foot in 1 hour

b. Remove the dressing, apply a warm compress to the swelling and document its size in the chart

c. Encourage him to walk to the bathroom to improve circulation in the leg

d. Keep the leg straight, apply pressure per protocol, consult the RN and call the physician

Answer: d — The plan keeps him safe and gets the right people involved quickly. He stays still with the leg straight, pressure is applied as the protocol directs, the RPN consults the RN because his needs are changing, and the physician is notified urgently (section 17.5; Scope in Practice box). Raising the head of the bed and waiting an hour (a) delays care and may worsen bleeding. Warm compresses (b) are not appropriate for a new arterial bleed. Walking (c) breaks bed rest and may increase bleeding.

23. [CORE] That evening, Mr. Bergeron reports new chest pressure rated 7 out of 10. What should the nurse do first?

a. Record a 12-lead ECG under the directive and call for urgent help

b. Give his evening dose of ticagrelor early

c. Ask him to rest quietly and reassess the pain in 30 minutes to see if it settles

d. Reassure him that chest discomfort is expected after PCI

Answer: a — New chest pain after PCI may mean stent thrombosis, which acts like a new MI. A 12-lead ECG and urgent help come first (sections 17.3 and 17.5). Changing drug timing (b) is not the nurse's decision and does not treat a blocked stent. Waiting 30 minutes (c) delays reperfusion. Chest pain is not an expected finding after PCI (d).

24. [CORE] The next morning, which finding best shows that Mr. Bergeron's access-site care has been effective?

a. He says he slept well

b. The groin swelling has not grown past its marked edges, and his right foot is warm with pedal pulses equal to baseline

c. His urine output was 400 mL overnight

d. His heart rate is 58 per minute after his beta-blocker

Answer: b — A stable hematoma inside its marked edges, a warm foot and pulses back to baseline show that bleeding is controlled and blood flow to the limb is restored (section 17.5, Table 17.3). Sleep (a) is good but does not show site or limb safety. Urine output (c) relates to kidney function after contrast. A slow heart rate after a beta-blocker (d) relates to the drug, not the access site.

25. [CORE] A patient had PCI through the femoral artery 4 hours ago. Which findings may indicate retroperitoneal bleeding? Select all that apply.

a. New lower back or flank pain
b. Heart rate rising from 70 to 104 per minute
c. Blood pressure falling from 132/78 to 96/58 mm Hg
d. New restlessness
e. Hemoglobin falling from 136 to 108 g/L
f. Warm foot with strong pedal pulses
g. Mild itch at the dressing edge

Answer: a, b, c, d, e — Bleeding behind the abdominal organs may show no blood at the groin. Back, flank or lower abdominal pain (a), a rising heart rate (b), falling blood pressure (c), restlessness (d) and a falling hemoglobin (e) are its cues and need urgent escalation (section 17.5). A warm foot with strong pulses (f) shows good limb perfusion and does not rule out retroperitoneal bleeding. A mild itch at the dressing (g) is usually from the adhesive.

26. [CORE] Two weeks after PCI with a stent, a patient calls the cardiac clinic. He says he plans to stop his ticagrelor because he bruises easily, and he will keep taking ASA. What is the nurse's best response?

a. "Bruising is a sign of a serious reaction, so stop both drugs now."
b. "That's a reasonable plan as long as you keep taking ASA every day without missing doses."
c. "Please don't stop it. Let's have the cardiology team review the bruising first."
d. "Take it every second day to reduce the bruising."

Answer: c — Stopping a P2Y12 inhibitor early leaves a new stent at risk of stent thrombosis, so the nurse asks him not to stop it. The ticagrelor monograph states that patients who stop it are at higher risk of cardiac events, so the team should review the bruising before any change (section 17.5). Stopping both drugs (a) is dangerous and is not justified by mild bruising. ASA alone (b) is not the prescribed plan. Taking it every second day (d) is an unsafe dose change the nurse cannot make.

27. [CORE] A patient has a compression band on the right wrist after radial catheterization. Forty-five minutes later, the patient reports tingling fingers, and the hand is cooler and paler than the left. What should the nurse do?

a. Assess the hand fully and act on the band per protocol, then notify the physician if perfusion does not improve
b. Tighten the band to make sure the site does not bleed
c. Raise the arm above the head and recheck in 2 hours
d. Remove the band completely and apply a gauze dressing

Answer: a — Tingling, coolness and pallor suggest reduced hand perfusion. The nurse assesses the hand fully and follows the protocol for the band, which aims to stop bleeding while keeping some flow in the artery, and escalates if perfusion does not improve (section 17.5; Mason et al., 2018). Tightening the band (b) would reduce flow further. Waiting 2 hours (c) delays care. Removing the band completely (d) outside protocol risks bleeding.

28. [CORE] A patient on the second day after CABG is being taught the "Keep Your Move in the Tube" approach. Which statement shows correct understanding?

a. "I can't lift my arms above my waist for 12 weeks."
b. "I can use my arms for everyday tasks if I keep my movements close to my body."
c. "I should push up from a chair with my arms spread wide."
d. "I don't need to protect my breastbone once the drains are out."

Answer: b — The approach lets patients use their arms for everyday activities, guided by pain, with movements kept close to the body (section 17.5). Strict limits on arm use for 12 weeks (a) describe traditional precautions. Spreading the arms wide to push up (c) is the movement the approach avoids. The breastbone still needs protection after drain removal (d).

29. [CORE] On the second day after CABG, a patient's monitor shows a new irregularly irregular rhythm at 136 per minute. Blood pressure is 102/64 mm Hg (was 124/72). What is the nurse's first action?

a. Encourage the patient to walk in the hallway to see whether the rhythm settles on its own
b. Document the rhythm in the chart and recheck it at the next scheduled assessment in 4 hours
c. Remove the temporary pacing wires
d. Assess the patient, get an ECG as directed and notify the team promptly

Answer: d — New AF is common after heart surgery and can lower blood pressure. The nurse assesses the patient, documents the rhythm and notifies the team promptly (section 17.5; Chapter 16, section 16.6). Walking (a) could worsen hypotension. Waiting for the next scheduled assessment (b) delays care. Pacing wires (c) are removed only by order and procedure, and removing them does not treat AF.

30. [CORE] Which nursing action is most likely to increase a patient's participation in cardiac rehabilitation after MI?

a. Telling the patient to ask their family doctor about rehabilitation at a future visit
b. Waiting until the patient raises the topic of exercise programs before discussing it
c. Advising the patient to start exercising alone at a gym as soon as they get home from hospital
d. Making sure a referral is sent before discharge and explaining what the program offers

Answer: d — Lack of referral and physician recommendation are main barriers, and a national position calls for systematic inpatient referral (Grace et al., 2014). A referral sent before discharge, with an explanation, is the strongest step (section 17.6). Leaving it to the patient (a, b) means many patients will never be referred. Unsupervised exercise (c) does not replace rehabilitation and may not be safe without assessment.

31. [CORE] Three days after an MI, a patient says, "I don't see the point of any of this anymore," and reports sleeping poorly. What is the most appropriate nursing response?

a. Explore the feelings, screen with the unit's tool and report the results

b. Tell the patient that everyone feels this way after a heart attack and it will pass

c. Ask the family to cheer the patient up

d. Document "patient tired" and continue care

Answer: a — Depression after ACS is linked to poorer outcomes, so these cues need screening and reporting, including asking about safety (Lichtman et al., 2014; section 17.4). Dismissing the feelings (b), handing the problem to family (c) or labelling it as tiredness (d) leaves possible depression unrecognized.

32. [CORE] A patient who drives a delivery truck for a living asks when he can drive again after his MI and PCI. What is the nurse's best response?

a. "You can drive as soon as you feel well."

b. "Drivers are never allowed to return to commercial driving after a heart attack."

c. "The waiting period depends on your situation, and commercial drivers have stricter rules. Please check with your cardiologist first."

d. "You can drive your own car but not the truck, so there is no need to ask."

Answer: c — The CCS 2023 guideline restricts driving for a set period after these events, with stricter recommendations for commercial drivers; the cardiology team gives the exact time (Guerra et al., 2024; section 17.6). Feeling well (a) is not the standard. A lifetime ban (b) is incorrect. Option d gives a rule the nurse cannot confirm and discourages him from getting advice.

33. [CORE] A patient is going home on ASA and clopidogrel. Which teaching about bleeding is correct?

a. "Use a stiff toothbrush to keep your gums healthy."

b. "Use a soft toothbrush and report black stools or blood in your urine."

c. "Take ibuprofen for any aches and pains so that you can avoid needing stronger drugs."

d. "Small nosebleeds mean the dose is too high, so skip a day."

Answer: b — A soft toothbrush reduces minor bleeding, and black stools or blood in the urine can signal serious bleeding (section 17.4). A stiff toothbrush (a) increases gum bleeding. Nonsteroidal anti-inflammatory drugs such as ibuprofen (c) add to bleeding risk and should not be taken without advice. Skipping doses (d) raises the risk of stent thrombosis.

34. [CORE] A patient admitted 4 days ago with a large MI, who arrived many hours after symptoms began and did not have early reperfusion, had been improving. He suddenly becomes very short of breath with crackles throughout both lungs, and his blood pressure falls to 84/50 mm Hg. What should the nurse suspect and do?

a. Anxiety; coach slow breathing and recheck in 30 minutes

b. Pericarditis; position him upright and give his usual analgesic

c. A possible mechanical complication of MI; call for urgent help and stay with him

d. Constipation from bed rest; give a laxative as ordered

Answer: c — Sudden breathlessness and hypotension in a patient with a large, late-treated MI may signal a mechanical complication such as papillary muscle rupture. These complications are rare but carry a substantial risk of death and need rapid team assessment with imaging and, often, surgery (Damluji et al., 2021; section 17.4). Anxiety (a) and constipation (d) do not explain crackles and shock. Pericarditis (b) does not usually cause sudden pulmonary edema and hypotension, and assuming it would delay care.

35. [CORE] An RPN on a cardiac step-down unit is asked to remove a femoral sheath for the first time. The RPN has not completed the hospital's sheath-removal education. What should the RPN do?

a. Remove the sheath, because RPNs may perform any task an RN performs

b. Ask a family member to hold pressure while the RPN removes the sheath

c. Remove the sheath under the physician's verbal order, because the order gives the RPN the authority and competence needed

d. Decline the task, explain the reason, and ask the RN or charge nurse to arrange care by an authorized, competent nurse

Answer: d — Under CNO's Scope of Practice standard, a nurse needs authority, competence and a supportive context. Employers can limit practice through policy, and a nurse who lacks the competence declines and makes sure care is still provided (Chapter 1, section 1.3; Scope in Practice box). RN and RPN roles are not identical (a). Family members (b) cannot take on clinical procedures. An order (c) does not give the RPN competence.

36. [CORE] A patient asks when it is safe to resume sexual activity after an uncomplicated MI. Based on the AHA scientific statement, which response is accurate?

a. "Usually from about 1 week after an uncomplicated MI, if mild to moderate activity causes you no heart symptoms."

b. "You will need to wait at least 6 months."

c. "It is safe right away, whatever your symptoms."

d. "You can resume only after you finish cardiac rehabilitation."

Answer: a — The AHA statement considers sex reasonable from 1 week or more after an uncomplicated MI when mild to moderate exertion causes no heart symptoms (Levine et al., 2012; section 17.6). A 6-month wait (b) is not supported. Ignoring symptoms (c) is unsafe. Finishing rehabilitation (d) is not required, although rehabilitation can help.

37. [RN] A patient with NSTEMI is going for PCI. She is 78, weighs 56 kg and had a TIA 2 years ago. The draft order set lists prasugrel as the P2Y12 inhibitor. What should the RN do?

a. Give prasugrel, because it is preferred over clopidogrel for patients with ACS who are having PCI

b. Hold all antiplatelet drugs until after PCI

c. Give prasugrel at the usual time and monitor for bleeding

d. Question the order, because of her TIA, age and weight

Answer: d — Prasugrel is contraindicated after a stroke or TIA and is not recommended for people aged 75 or older or weighing less than 60 kg (JAMP Pharma Corporation, 2020; Rao et al., 2025; section 17.4). The general preference for potent P2Y12 inhibitors (a) does not override a contraindication. Holding all antiplatelets (b) is not the plan for ACS. Giving it with bleeding monitoring (c) ignores the contraindication.

38. [RN] On day 2 after a large anterior MI, which group of findings most strongly suggests cardiogenic shock?

a. Blood pressure 142/88 mm Hg, warm skin, urine output 60 mL/h

b. Blood pressure 84/56 mm Hg, cool clammy skin, new confusion, urine output 15 mL/h

c. Heart rate 58 per minute after a beta-blocker, alert, warm skin

d. Temperature 37.9 °C, mild chest discomfort when breathing deeply, stable blood pressure

Answer: b — Low blood pressure with signs of poor perfusion (cool clammy skin, confusion, low urine output) suggests cardiogenic shock, which needs immediate escalation (section 17.4; Chapter 6). Option a shows adequate perfusion. Option c is an expected beta-blocker effect with good perfusion. Option d may suggest pericarditis (Chapter 18) but not shock.

39. [RN] Based on Canadian radiology guidance, which patient scheduled for coronary angiography is at greatest risk of contrast-associated acute kidney injury?

a. A 54-year-old with eGFR 26 mL/min/1.73 m²

b. A 70-year-old with eGFR 64 mL/min/1.73 m²

c. A 48-year-old with type 2 diabetes and eGFR 88 mL/min/1.73 m²

d. A 61-year-old with a past rash after contrast and eGFR 75 mL/min/1.73 m²

Answer: a — Canadian guidance identifies an eGFR of 30 mL/min/1.73 m² or less, or existing acute kidney injury, as the main risk for contrast-associated kidney injury (Macdonald et al., 2022; section 17.5). Age alone with eGFR 64 (b) and diabetes with normal kidney function (c) are lower risk. A past contrast rash (d) raises concern about an allergic-type reaction, not kidney injury.

40. [RN] A student asks why the unit uses a radial-first approach for PCI in ACS. Which statement accurately reflects the trial evidence?

a. In RIVAL, radial access cut the combined rate of death, MI, stroke or major bleeding at 30 days by about half

b. Both trials found that femoral access caused fewer hematomas and other vascular complications

c. In MATRIX, radial access reduced net adverse clinical events, mainly through less major bleeding and lower death from any cause

d. Both trials found no differences of any kind between radial and femoral access

Answer: c — In MATRIX, radial access reduced net adverse clinical events (9.8% vs 11.7%), mainly through less major bleeding and lower all-cause death (Valgimigli et al., 2015; section 17.5). In RIVAL the combined outcome was similar (3.7% vs 4.0%), so it was not halved (a). RIVAL found fewer large hematomas and pseudoaneurysms with radial access, not with femoral access (b). Option d ignores these differences.

18 Heart Failure, Valvular and Inflammatory Heart Disease

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how heart failure develops, and classify it by ejection fraction and NYHA class.
2. Recognize worsening and acute heart failure on a range of skin tones, interpret key tests in SI units, and escalate.
3. Provide nursing care for acute decompensated heart failure using the CJMM.
4. Monitor and teach patients taking the main heart failure drug classes.
5. Teach self-management (daily weights, an action plan, sodium and fluid guidance) and plan safe transitions home, with attention to older adults and rural and Indigenous communities.
6. Care for patients with valvular heart disease and after valve replacement, including anticoagulation safety.
7. Recognize and respond to infective endocarditis, pericarditis, cardiac tamponade, myocarditis and the cardiomyopathies.
8. Distinguish RN and RPN roles in heart failure and valve care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 6, 7	Clinician; Scholar	Foundations of Practice
4, 5	Clinician; Educator; Advocate	Foundations of Practice; Collaborative Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Heart failure (HF) is a clinical syndrome in which a structural or functional problem of the heart causes symptoms and signs, supported by raised natriuretic peptide levels or objective evidence of congestion in the lungs or body (Bozkurt et al., 2021). Put simply, the heart can no longer fill or pump well enough to meet the body's needs without abnormally high pressures inside it. **Valvular heart disease** is narrowing or leaking of one or more heart valves. **Inflammatory heart disease** includes infection or inflammation of the heart's inner lining and valves (endocarditis), its outer sac (pericarditis) and its muscle (myocarditis).

These conditions fill medical units. Heart failure is one of the top reasons people in Canada are admitted to hospital, and about 1 in 5 patients with heart failure is readmitted within a month of discharge (Heart and Stroke Foundation of Canada, 2022). Many patients are older adults living with several other illnesses, so nurses on general medical, surgical, rehabilitation and long-term care units, not only cardiac units, care for them every day.

This chapter explains how heart failure develops (section 18.1), how to recognize and manage worsening heart failure (18.2), the medications and devices that treat it (18.3), and self-management and transitions home (18.4). It then covers valvular heart disease and care after valve replacement (18.5), infective endocarditis (18.6), and pericarditis, myocarditis and the cardiomyopathies (18.7). The chapter builds on cardiac assessment and tests in Chapter 16 and on coronary artery disease in Chapter 17. It links to recognizing deterioration and shock (Chapter 6), non-invasive ventilation (Chapter 15), and hypertension and anticoagulation (Chapter 19).

18.1 Heart Failure: How It Develops

What Goes Wrong

Cardiac output depends on heart rate and stroke volume, and stroke volume depends on preload, afterload and contractility (section 16.1). Heart failure develops when injury or strain to the heart muscle upsets this balance.

Two main problems can occur, and many patients have both. In **systolic dysfunction**, the left ventricle cannot contract forcefully, so it ejects a smaller share of its blood with each beat; the chamber often enlarges. In **diastolic dysfunction**, the ventricle squeezes adequately but is stiff and does not relax and fill normally. Higher pressure is needed to fill it, and that pressure backs up into the lungs. A stiff ventricle relies heavily on the atria to top up its filling, which is one reason atrial fibrillation (AF) can tip a stable patient into failure (section 16.6).

Which side of the heart fails determines where congestion appears. In **left-sided heart failure**, pressure rises in the left atrium and the pulmonary veins. Fluid moves out of the pulmonary capillaries into lung tissue and, when severe, into the alveoli, causing breathlessness and crackles. In **right-sided heart failure**, the right ventricle cannot move blood forward into the lungs, so pressure rises in the systemic veins. The result is a raised jugular venous pressure (JVP) (Figure 18.1), swelling of the legs and abdomen, and congestion of the liver and gut.

Left-sided failure is the usual reason the right side fails. Chronically high pressure in the pulmonary circulation forces the right ventricle to pump against a heavy load until it, too, weakens. Right-sided failure can also arise on its own from chronic lung disease or pulmonary embolism (Chapters 14 and 15).

Many conditions damage or overload the heart:

- **Coronary artery disease:** loss of muscle after a myocardial infarction (MI) is named by Canadian surveillance as the most common cause of heart failure (Public Health Agency of Canada [PHAC], 2018; Chapter 17).
- **Hypertension:** years of high afterload thicken and stiffen the ventricle (Chapter 19).
- **Valve disease:** narrowed or leaking valves overload the chambers (section 18.5).
- **Cardiomyopathies and myocarditis:** diseases of the muscle itself, some of them inherited (section 18.7).
- **Dysrhythmias:** a persistently fast or irregular rhythm reduces filling and output (section 16.6).
- **Toxins:** heavy alcohol use (section 18.7) and some cancer treatments. Damage from anthracycline chemotherapy is related to the total lifetime dose and is largely irreversible, whereas heart dysfunction linked to trastuzumab in early breast cancer is mostly reversible (Virani et al., 2016; Chapter 9).

Figure 18.1 A markedly raised jugular venous pressure: the distended external jugular vein (arrow) runs up the side of the neck. The face was masked by the photographer, and the Commons page records the person's consent. (credit: “Elevated JVP1” by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

Compensation and Remodelling

When output falls, the body responds much as it would to blood loss: it tries to raise blood pressure and hold on to fluid. Two systems lead this response (Hartupee & Mann, 2017):

- The **sympathetic nervous system** speeds the heart, strengthens contraction and narrows blood vessels.
- The kidneys sense reduced flow and activate the **renin–angiotensin–aldosterone system (RAAS)**. Angiotensin II constricts arterioles, and aldosterone makes the kidneys keep sodium, with water following it.

A third system pushes the other way. Stretched heart muscle releases **natriuretic peptides**, hormones that promote sodium and water excretion and relax blood vessels (Ezekowitz et al., 2017). In established heart failure, however, their effect is outweighed.

In the short term, these responses keep blood pressure and organ flow steady. Kept up for months, they cause harm (Hartupee & Mann, 2017). Retained sodium and water raise preload until the lungs and tissues become congested. Narrowed arterioles raise afterload, so a weak ventricle must push against more resistance. A faster heart rate raises the heart's own oxygen demand. Angiotensin II, aldosterone and the stress hormones also act directly on the heart: muscle cells enlarge or die, and scar tissue builds up between them. This process, called **remodelling**, changes the ventricle's size, shape and function. In systolic failure, the chamber typically becomes larger, rounder and weaker, which lowers output further and keeps the cycle turning.

This cycle explains the treatment in section 18.3. The drugs that help people with a reduced ejection fraction live longer interrupt these systems: beta-blockers blunt sympathetic activity, RAAS blockers and mineralocorticoid receptor antagonists block angiotensin II and aldosterone, and neprilysin inhibition boosts the body's own natriuretic peptides (Hartupee & Mann, 2017; McDonald et al., 2021).

Classifying Heart Failure

Ejection fraction (EF) is the percentage of the blood in the left ventricle that is pumped out with each beat, usually measured by echocardiography (section 16.3). Canadian guidelines group patients by EF because the groups respond differently to drugs (Table 18.1).

Heart failure with reduced ejection fraction (HFrEF) means an EF of 40% or less (Bozkurt et al., 2021). When the EF of a person with HFrEF later rises above 40%, the condition is called **heart failure with improved ejection fraction (HFimpEF)**. The international definition requires a rise of at least 10 percentage points from baseline and a second measurement above 40% (Bozkurt et al., 2021). The person still has heart failure.

International documents divide an EF above 40% into **heart failure with mildly reduced ejection fraction (HFmrEF)**, 41% to 49%, and **heart failure with preserved ejection fraction (HFpEF)**, 50% or more (Bozkurt et al., 2021). The 2025 update from the Canadian Cardiovascular Society (CCS) and the Canadian Heart Failure Society (CHFS) joins these into one group, **heart failure with nonreduced ejection fraction (HFnrEF)**: heart failure symptoms and signs with an EF above 40%. The panel noted that patients across this range have similar clinical outcomes (Virani et al., 2025). This book uses the Canadian terms.

The **New York Heart Association (NYHA) functional class** describes how much symptoms limit daily activity (Guidelines and Protocols Advisory Committee [GPAC], 2023):

- **Class I:** no symptoms with ordinary activity.
- **Class II:** slight limitation; ordinary activity brings on symptoms such as breathlessness or fatigue.
- **Class III:** marked limitation; less than ordinary activity brings on symptoms, but the person is comfortable at rest.
- **Class IV:** symptoms at rest; any activity brings on symptoms.

A person's NYHA class can change from week to week as congestion comes and goes, whereas the EF category describes the underlying heart.

Table 18.1 Heart failure categories by ejection fraction and what they mean for treatment (Bozkurt et al., 2021; McDonald et al., 2021; Virani et al., 2025)

Category	Ejection fraction	What it means	Treatment focus
HF with reduced EF (HFrEF)	40% or less	The ventricle contracts weakly and is often enlarged	Four drug classes started early and adjusted by the prescriber: ARNI (or ACE inhibitor or ARB), beta-blocker, MRA and SGLT2 inhibitor; loop diuretic for congestion; devices for selected patients

Category	Ejection fraction	What it means	Treatment focus
HF with improved EF (HFimpEF)	Was 40% or less; now above 40% after a rise of at least 10 points	Pumping has partly recovered with treatment; heart failure is still present	Ongoing treatment and follow-up planned by the heart failure team; the 2025 Canadian update does not address this group specifically
HF with nonreduced EF (HFnrEF)	Above 40% (includes HFmrEF, 41% to 49%, and HFpEF, 50% or more)	The ventricle contracts but is often stiff and fills poorly; other conditions often drive symptoms	SGLT2 inhibitor and MRA; ARNI or glucagon-like peptide-1 (GLP-1) receptor agonist for selected patients; loop diuretic for congestion; control of blood pressure, AF and other conditions; beta-blockers are not indicated for HF itself in this group

Heart Failure in Canada

The Canadian Chronic Disease Surveillance System (CCDSS) tracks diagnosed heart failure among adults aged 40 and older. In 2012–2013, 669,600 adults in this age group were living with diagnosed heart failure (PHAC, 2018). From 2000–2001 to 2012–2013, the age-standardized rate of new diagnoses fell by 35%, from 8.1 to 5.3 per 1,000, while prevalence stayed close to 3.5%. In a given year, adults with heart failure were about six times as likely to die of any cause as adults without it. Prevalence was higher among men than women, rose with age in both, and the gap between the sexes narrowed with age (PHAC, 2018). More recently, Heart and Stroke Foundation of Canada (2022) reported that 750,000 people in Canada live with heart failure and that more than 100,000 are diagnosed each year.

Heart failure is also costly in hospital days: about 1 in 5 patients is readmitted within a month of discharge (Heart and Stroke Foundation of Canada, 2022). Many eligible patients in Canada do not take all the recommended medications, and fewer still reach target doses (Canadian Cardiovascular Society [CCS], 2022). Closing that gap is shared work, and nurses play a large part in it (section 18.4).

CANADIAN CONTEXT

Heart Failure Across Canada

Heart failure is not spread evenly across Canada. Among Métis citizens in Ontario, a population-based study of 2006 to 2011 data, commissioned by the Métis Nation of Ontario (MNO), found an adjusted heart failure prevalence of 5.1%, compared with 3.9% in the general Ontario population. Métis people with heart failure were hospitalized more often and had twice as many heart failure–related emergency department visits in the year after diagnosis (Atzema et al., 2015). The study was carried out under a data-sharing agreement with the MNO, and three of the authors worked for the MNO. When First Nations data are used, the First Nations principles of ownership, control, access and possession (OCAP®) apply (Chapter 2).

Differences like these come from structural causes, not from the people affected: colonial policies, unequal access to primary care, distance from specialist services, and higher rates of diabetes and hypertension driven by those same conditions (Chapter 2). Specialized heart function clinics are concentrated in larger centres. Provinces have tried to bridge the distance. In British Columbia, for example, primary care clinicians can phone a specialist for advice through the Rapid Access to Consultative Expertise (RACE) line and refer to heart function clinics (GPAC, 2023). Nurses in rural, remote and northern settings often carry much of the monitoring and teaching between visits (section 18.4).

18.2 Recognizing and Managing Worsening Heart Failure

Signs of Congestion and Low Output

Worsening heart failure shows up in two ways: too much fluid in the wrong places (congestion) and too little blood flow to the organs (low output) (Table 18.2). A large European registry used a simple bedside version of this idea. Congestion was present with any of these: crackles, edema of both legs, a JVP above 6 cm, an enlarged liver or a positive hepatojugular reflux. Low perfusion was marked by cold extremities, low urine output or confusion (Chioncel et al., 2019).

Breathlessness is usually the first symptom. It starts with exertion and, as congestion builds, comes on with less activity. **Orthopnea** is breathlessness when lying flat that eases on sitting up, because lying down returns more blood to an overloaded heart. The nurse asks how many pillows the patient sleeps on and whether this has changed. **Paroxysmal nocturnal dyspnea (PND)** is waking from sleep suddenly short of breath and needing to sit up or go to a window for air. A dry cough at night can be an early sign.

On examination, the nurse listens for crackles, which start at the lung bases and climb as congestion worsens (Chapter 12). The nurse also listens for a third heart sound (S3) and measures the JVP (section 16.2). Edema (Figure 3.1) collects where gravity pulls it: the ankles and shins when the patient is up, and the sacrum and back of the thighs when the patient is in bed. Weight gain from retained fluid often comes before visible edema, which is why daily weights matter. Right-sided congestion can cause a full, tender abdomen, ascites, nausea and poor appetite.

Low output is quieter and easier to miss: fatigue, weakness, cool hands and feet, slow capillary refill, new confusion, and less urine. Blood pressure may fall or stay normal while the heart rate climbs.

Colour changes look different on different skin tones. On darker skin, cyanosis may show as grey or whitish lips and tongue, with a bluish tinge in the conjunctivae, palms, soles and nail beds; pallor can make very dark skin look ashen grey (Pusey-Reid et al., 2023). The nurse inspects mucous membranes and conjunctivae in good natural or halogen light, compares with an unaffected area, and never relies on sight alone. Skin temperature, capillary refill and oxygen saturation complete the picture (Chapter 12; section 16.2). Edema is assessed by pressing and feeling for pitting, as described in section 16.2, rather than by colour.

Table 18.2 Signs of left-sided congestion, right-sided congestion and low output (Chioncel et al., 2019; Ezekowitz et al., 2017)

Problem	What the nurse sees or hears	Why it happens
Left-sided congestion	Breathlessness with exertion, then at rest; orthopnea; paroxysmal nocturnal dyspnea; cough; crackles; falling oxygen saturation; S3	High pressure in the left atrium and pulmonary veins pushes fluid into lung tissue and alveoli; lying flat returns more blood to the heart
Right-sided congestion	Raised JVP; edema of the legs, or of the sacrum in bed; weight gain; full, tender liver; ascites; bloating, nausea and poor appetite	High pressure in the systemic veins pushes fluid into tissues and congests the liver and gut
Low output	Fatigue and weakness; cool, pale or mottled skin; slow capillary refill; confusion; low urine output; rising heart rate; low or falling blood pressure	Too little blood reaches the brain, kidneys and skin; the body narrows vessels to protect the heart and brain

Tests

Natriuretic peptides, B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP), help confirm or rule out heart failure when the cause of breathlessness is unclear (Ezekowitz et al., 2017; section 16.3). Results are reported in ng/L, which is numerically the same as pg/mL. In an acute setting, a BNP below 100 ng/L or an NT-proBNP below 300 ng/L makes heart failure unlikely, and a BNP above 400 ng/L makes it very likely. The NT-proBNP level that makes heart failure likely rises with age. In an outpatient setting, even a mildly raised result (BNP above 50 ng/L or NT-proBNP above 125 ng/L) calls for further investigation (GPAC, 2023).

Several factors change the result (Ezekowitz et al., 2017):

- **Higher levels:** older age, kidney dysfunction, anemia, lung disease, sepsis, and other heart conditions such as valve disease or ischemia.
- **Lower levels:** obesity, so a modest value in a person with obesity does not exclude heart failure as confidently.
- **Sacubitril/valsartan:** BNP is broken down by neprilysin, so it rises when neprilysin is blocked; NT-proBNP is not affected in the same way and is the peptide to follow in patients taking this drug (Ezekowitz et al., 2017; Novartis Pharmaceuticals Canada, 2026).

A raised peptide never replaces imaging (GPAC, 2023). **Echocardiography** confirms the diagnosis, measures EF and shows valve problems and wall motion, but treatment should not wait for it when heart failure is likely (GPAC, 2023). A 12-lead electrocardiogram (ECG) looks for AF, ischemia, old infarction and conduction problems (section 16.3). A chest X-ray is part of the initial work-up (GPAC, 2023); it can show congestion (Figure 18.2) and other causes of breathlessness, such as pneumonia.

Initial blood tests include a complete blood count, sodium, potassium, creatinine and estimated glomerular filtration rate (eGFR), thyroid-stimulating hormone, hemoglobin A1C and ferritin (GPAC, 2023). In acute heart failure, high-sensitivity troponin is measured on admission to look for an acute coronary syndrome (Ezekowitz et al., 2017; Chapter 17). Results use SI units: potassium

and sodium in mmol/L, creatinine in µmol/L, eGFR in mL/min/1.73 m² and hemoglobin in g/L; reference ranges vary by laboratory (Chapter 3).

Acute Decompensated Heart Failure and Pulmonary Edema

Acute heart failure is a new or worsening change in heart failure symptoms and signs, whether sudden or gradual, that calls for urgent treatment (Ezekowitz et al., 2017). Most hospital patients have **acute decompensated heart failure (ADHF)**, a worsening of known heart failure. Other presentations are acute pulmonary edema, isolated right ventricular failure and cardiogenic shock (McDonagh et al., 2021).

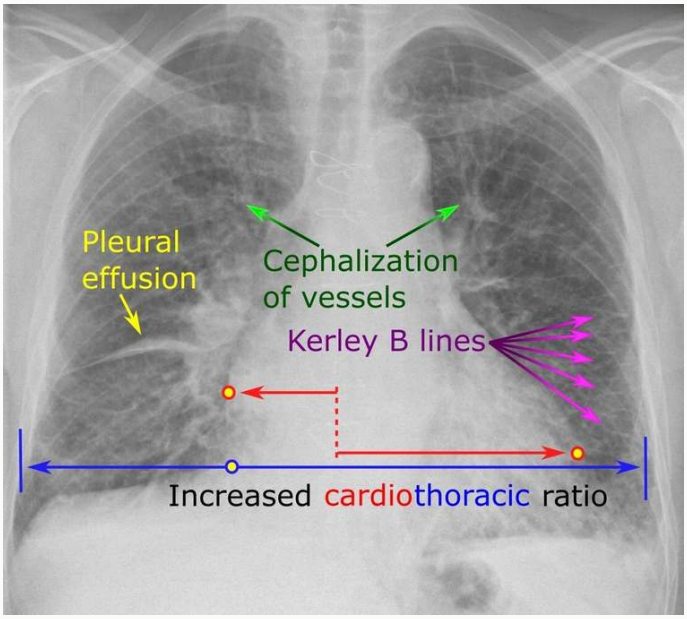

Figure 18.2 Chest X-ray in heart failure, labelled: an enlarged heart, upper-lobe vessels that are more prominent than usual, Kerley B lines from fluid in the lung tissue, and a small pleural effusion.

A trigger can often be found. In a large US registry, about 6 in 10 admissions had at least one; pneumonia or another respiratory illness, ischemia and dysrhythmias were the most frequent. Uncontrolled hypertension, worsening kidney function and not following the medication or diet plan also played a part (Fonarow et al., 2008). Nonsteroidal anti-inflammatory drugs (NSAIDs) blunt diuretics and can harm the kidneys (GPAC, 2023). Finding and treating the trigger is part of the plan.

Acute pulmonary edema is an emergency in which fluid floods the alveoli. The patient is severely breathless, sits bolt upright, is often anxious and sweaty, and has crackles throughout the chest and a falling oxygen saturation. The nurse:

- stays with the patient and calls for help (rapid response; Chapter 6);
- sits the patient upright;
- gives oxygen if saturation is below the target range, titrated to that target (Chapter 12);
- secures intravenous (IV) access and gives an IV loop diuretic as ordered;
- prepares for non-invasive ventilation if the team orders it (Chapter 15).

Opioids are not given routinely (McDonagh et al., 2021).

After the emergency, care follows the clinical judgment model (CJMM; Chapter 1, section 1.4):

- **Daily weight:** same scale, same time (usually morning, after voiding and before breakfast), similar clothing. The trend is the most practical bedside measure of fluid change.
- **Intake and output:** urine volume after each IV diuretic dose shows whether the drug is working.
- **Laboratory values:** diuretics waste potassium and magnesium, and low levels raise the risk of dysrhythmias (Chapter 3). The nurse also trends sodium and creatinine and reports changes.
- **Blood pressure and falls:** brisk diuresis can cause dizziness on standing. The nurse checks for orthostatic changes, keeps a commode or urinal close and helps the patient to the toilet promptly (Chapter 8).
- **Skin:** stretched, edematous skin tears and breaks down easily, so the nurse repositions the patient and protects the heels and sacrum (Chapter 35).
- **Fluid restriction:** applied only if ordered.

Before discharge, oral heart failure drugs are started or resumed and congestion is carefully cleared, with follow-up within 1 to 2 weeks (McDonagh et al., 2021). Patients who leave hospital still congested have higher mortality at 1 year (Chioncel et al., 2019; section 18.4).

Every nurse who sees deterioration acts and escalates at once; the registered practical nurse (RPN) consults the registered nurse (RN) as the patient's needs change (Chapter 1, section 1.3). Cues of **cardiogenic shock** include a falling blood pressure, rising heart rate, cool and clammy or mottled skin, new confusion, falling urine output and a rising lactate (Chapter 6). Signs of poor perfusion matter even before blood pressure falls (Chioncel et al., 2019). Rising respiratory rate, falling saturation despite oxygen and exhaustion signal respiratory failure (Chapter 15).

CLINICAL JUDGMENT

Breathless at 0300

Names and details are fictional; this is a composite story.

Mrs. Lucille Arsenault, 84, has HFrEF (EF 30%) and was admitted two days ago with a urinary tract infection. IV normal saline has run at 100 mL/h since admission because she was eating little.

- **Recognize cues:** At 0300 she is sitting on the edge of the bed, unable to lie down. Respiratory rate 28 breaths/min, heart rate 114 beats/min and irregular, blood pressure 156/92 mm Hg, SpO2 88% on room air (95% at 2300), temperature 37.1 °C. Crackles reach the mid-lung fields on both sides. Her weight is 2.1 kg above admission. Evening potassium was 3.4 mmol/L.
- **Analyze cues:** Orthopnea, crackles, hypoxemia and weight gain point to fluid overload. Continuous IV fluid is a likely trigger; the irregular rhythm suggests AF.
- **Prioritize hypotheses:** Acute pulmonary edema from decompensated heart failure comes first; pneumonia and pulmonary embolism remain possible.
- **Generate solutions:** Restore oxygenation, get help, stop the fluid load, start decongestion, identify the rhythm.
- **Take action:** The nurse stays, sits her upright, starts oxygen to target (Chapter 12) and calls the rapid response team. The SBAR (Situation, Background, Assessment, Recommendation) report (Chapter 6) names the infusion and asks for an immediate review. The team orders IV furosemide, a 12-lead ECG, potassium and magnesium.
- **Evaluate outcomes:** One hour later, SpO2 is 93% on 2 L/min, respiratory rate 22 breaths/min, and she has passed 650 mL of urine. The nurse plans a repeat potassium and an assisted walk to the commode.

GOING DEEPER

Warm or Cold, Wet or Dry

Required for RN students; optional for PN students.

A quick bedside profile sorts patients with acute heart failure by two questions. Is there congestion ("wet" or "dry")? Is perfusion adequate ("warm" or "cold")? Congestion was judged from crackles, edema of both legs, a raised JVP, an enlarged liver or hepatojugular reflux. Poor perfusion was judged from cold extremities, low urine output or confusion. In a European registry of 7,865 patients, 69.9% were warm and wet, 19.8% cold and wet, 9.9% warm and dry, and 0.4% cold and dry. In-hospital mortality rose from 2.0% (warm and dry) and 3.8% (warm and wet) to 9.1% (cold and dry) and 12.1% (cold and wet) (Chioncel et al., 2019).

- **Warm and wet:** the most common profile. The main need is decongestion, usually with IV loop diuretics; vasodilators are among the options the guideline describes.
- **Cold and wet:** congestion plus poor perfusion. These patients may be heading toward cardiogenic shock and need critical care assessment (Chapter 6).
- **Inotropes:** these drugs strengthen contraction. They are not used routinely when cardiogenic shock is absent (McDonagh et al., 2021).
- **Warm and dry:** compensated; the focus is optimizing oral therapy.

The profile also matters at discharge. In the same registry, 30.9% of survivors still had congestion when they left hospital, and they had higher 1-year mortality (Chioncel et al., 2019).

18.3 Medications and Devices

Drugs That Change the Course of HFrEF

The 2021 CCS/CHFS update defined a new standard of care for HFrEF. Four drug classes are recommended for most patients (McDonald et al., 2021):

- an **angiotensin receptor–neprilysin inhibitor (ARNI)**, sacubitril/valsartan, or an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB) if an ARNI is not used;
- an evidence-based **beta-blocker**;
- a **mineralocorticoid receptor antagonist (MRA)**;
- a **sodium–glucose cotransporter 2 (SGLT2) inhibitor**.

The four classes are started early and adjusted in parallel rather than one after another (GPAC, 2023). The prescriber raises each dose step by step toward a target the patient tolerates. Many patients in Canada never reach full therapy (CCS, 2022), so the nurse's monitoring, reporting and teaching help each step happen safely.

What each class does:

- **ARNI:** sacubitril blocks neprilysin, the enzyme that breaks down natriuretic peptides, so their beneficial effects last longer; valsartan blocks angiotensin II (Novartis Pharmaceuticals Canada, 2026). ACE inhibitors and ARBs block angiotensin II's formation or action.
- **Beta-blockers:** slow the heart and shield it from the long-term effects of sympathetic stimulation.
- **MRAs:** block aldosterone, limiting sodium retention and scarring of heart muscle.
- **SGLT2 inhibitors:** make the kidneys excrete glucose and sodium. In adults with heart failure, they lower the risk of cardiovascular death and heart failure hospitalization (AstraZeneca Canada, 2025).

Relieving Congestion

Loop diuretics such as furosemide remove excess sodium and water. The CCS recommends them to control congestion and edema (Virani et al., 2025). They are not among the four classes that change the course of HFrEF. They relieve breathlessness and swelling, and the prescriber adjusts the dose to the patient's weight and symptoms.

HF With Nonreduced Ejection Fraction

The 2025 CCS/CHFS update gives these recommendations for symptomatic heart failure with an EF above 40% (Virani et al., 2025):

- an SGLT2 inhibitor, to reduce heart failure hospitalization (strong recommendation);
- an MRA, including the newer nonsteroidal MRA finerenone, to reduce hospitalization (strong recommendation);
- sacubitril/valsartan as a suggestion for patients at low risk of symptomatic low blood pressure (weak recommendation). The Canadian product monograph lists HFrEF as its indication (Novartis Pharmaceuticals Canada, 2026);
- an evidence-based glucagon-like peptide-1 (GLP-1) receptor agonist as a suggestion for patients with an EF of 45% or more and a body mass index of 30 kg/m² or more, to reduce hospitalization and improve quality of life (weak recommendation).

The update also carries forward earlier recommendations: candesartan may be considered (it is the preferred renin–angiotensin system blocker when an ARNI cannot be used), blood pressure is controlled (Chapter 19) and loop diuretics are used for congestion (Virani et al., 2025). Treating AF (section 16.6), obesity, diabetes (Chapter 22) and kidney disease (Chapter 27) is central, because these conditions often drive symptoms.

What the Nurse Monitors

Before giving heart failure drugs, the nurse checks blood pressure, heart rate, dizziness on standing and the most recent potassium, creatinine and eGFR. These are compared with the ordered parameters. When a value falls outside them, the nurse holds the dose only as ordered or per policy and reports it promptly, so the prescriber can adjust therapy rather than lose it.

- **ARNI, ACE inhibitor or ARB:** watch for low blood pressure, rising potassium and creatinine. **Angioedema** is swelling of the lips, tongue, face or throat. If it occurs, sacubitril/valsartan is stopped at once and never restarted, and the airway is an emergency. Sacubitril/valsartan must not be given until at least 36 hours after the last ACE inhibitor dose. It has not been studied in patients starting with a systolic pressure below 100 mm Hg, and low volume or sodium is corrected before the first dose (Novartis Pharmaceuticals Canada, 2026). A rise in creatinine of up to 30% is not unexpected after starting an ACE inhibitor or ARB; the nurse still reports it so the prescriber can judge whether it settles (GPAC, 2023).

- **MRA:** the main risk is **hyperkalemia** (Chapter 3). The 2025 CCS/CHFS update advises that spironolactone or eplerenone is not started when eGFR is below 30 mL/min/1.73 m² (finerenone, below 25), and that no MRA is started when potassium is above 5.0 mmol/L. Potassium and creatinine are checked within a week after an MRA is started or its dose is changed. Monitoring is closer during illnesses that dehydrate, such as vomiting or diarrhea (Virani et al., 2025).
- **Beta-blocker:** watch for slow heart rate, low blood pressure and fatigue, especially after a dose increase.
- **SGLT2 inhibitor:** teach that genital yeast infections are more likely and that genital itching or discharge or urinary symptoms should be reported (AstraZeneca Canada, 2025). These drugs also raise the risk of urinary tract infection, and a rare but dangerous infection of the perineum (Fournier's gangrene) requires urgent surgery, so pain, swelling or redness in the genital area with fever is reported at once. They are not recommended when the patient is volume depleted, which matters when loop diuretics are also working hard. A small early drop in eGFR is expected (GPAC, 2023). Ketoacidosis can occur even when blood glucose is not high. A temporary pause is considered on sick days with poor intake or fluid loss, and the drug is stopped at least 3 days ahead of major surgery when feasible (AstraZeneca Canada, 2025).
- **Loop diuretic:** trend weight, intake and output, potassium, magnesium, sodium and creatinine.
- **NSAIDs:** patients avoid them. They reduce the diuretic effect, can worsen kidney function and add to hyperkalemia with an MRA (GPAC, 2023).

The CCS names other drugs for patients with specific characteristics (McDonald et al., 2021). Ivabradine slows the heart rate in sinus rhythm. Hydralazine combined with isosorbide dinitrate dilates arteries and veins. Digoxin has a narrow safety margin: nausea, visual changes, a slow pulse and dysrhythmias signal toxicity, and low potassium or magnesium or kidney impairment raises the risk. Patients taking digoxin learn to check their pulse and to contact their provider if it is below 60 beats/min (Pharmascience, 2022).

MEDICATIONS

Heart Failure Drug Classes

- **ARNI:** sacubitril/valsartan. Check blood pressure, potassium and creatinine; at least 36 hours after the last ACE inhibitor dose; stop and get help for angioedema.
- **ACE inhibitors and ARBs:** for example ramipril and candesartan. Check blood pressure, potassium and creatinine; watch for angioedema and dizziness.
- **Beta-blockers:** bisoprolol and carvedilol. Check heart rate and blood pressure; fatigue may increase for a short time after a dose increase.
- **MRAs:** spironolactone and eplerenone (finerenone in HFnrEF). Check potassium and creatinine within a week after a start or dose change; avoid NSAIDs.
- **SGLT2 inhibitors:** dapagliflozin and empagliflozin. Teach about genital infections, sick-day pauses and signs of ketoacidosis; expect a small early drop in eGFR.
- **Loop diuretics:** furosemide. Daily weight, intake and output, potassium, magnesium, orthostatic blood pressure and fall precautions.
- **Other agents for selected patients:** ivabradine, hydralazine with isosorbide dinitrate, and digoxin. Before digoxin, check the apical pulse and potassium and watch for toxicity.

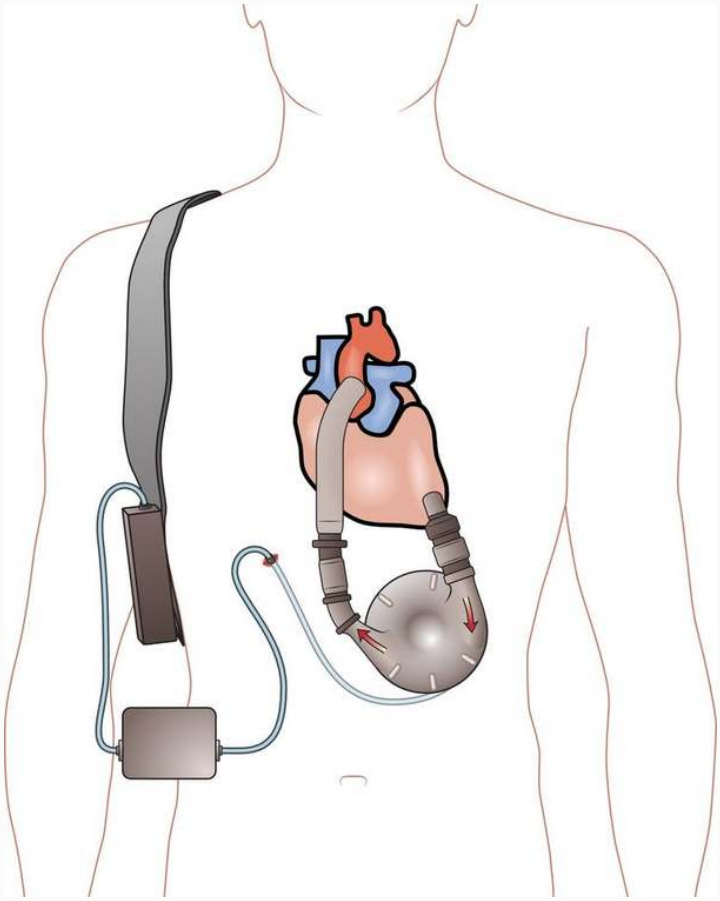

Figure 18.4 A left ventricular assist device: the pump draws blood from the left ventricle and returns it to the aorta; a driveline through the skin connects it to an external controller and batteries. (credit: "Ventricular assist device" by Madhero88/Wikimedia Commons, CC BY-SA 3.0)

Devices and Advanced Heart Failure

For selected patients with HFrEF, an implantable cardioverter-defibrillator (ICD) protects against sudden death from ventricular dysrhythmias. **Cardiac resynchronization therapy (CRT)** (Figure 18.3) paces both ventricles so they contract together, which can improve symptoms and EF (section 16.7).

When heart failure advances despite full therapy, a **left ventricular assist device (LVAD)** may be considered (Figure 18.4). This implanted pump moves blood from the left ventricle into the aorta, either as a bridge to heart transplant or as long-term support. Transplant is offered to a small number of carefully selected patients at specialized centres. Throughout, a palliative approach to care can run alongside active treatment, with advance care planning and symptom relief from early in the illness (Chapter 10).

18.4 Self-Management and Transitions

Most HF care happens at home. A person admitted with worsening HF usually goes home within days, and the following weeks carry a high risk of readmission. In HF, **self-care** means three linked activities: keeping the condition stable, watching for change, and responding when change appears. The nurse's teaching builds these skills from the first day of admission.

Daily Weights and an Action Plan

Fluid builds up before swelling or breathlessness is obvious, so a rising weight over a day or two is often the earliest cue of the congestion described in section 18.2. The nurse teaches the patient to weigh every morning after emptying the bladder and before breakfast, on the same scale, in about the same clothing, and to write the result down and compare it with the day before (Heart and Stroke Foundation of Canada [Heart & Stroke], n.d.). Heart & Stroke's patient guide tells people to call their health care provider if

their weight rises by more than 2 kg over 2 consecutive days or by more than 2.5 kg within a week. Some HF clinics set a different limit for an individual patient; the nurse teaches the limit written in that patient's plan.

An **action plan** is a written, personalized guide that tells the patient what to watch for and what to do. Heart & Stroke's guide organizes it in three colour zones (Heart & Stroke, n.d.):

- **Green (stable):** weight within the set limits; breathing, swelling and energy at the person's usual level.
- **Yellow (call the HF clinic or health care provider):** weight gain beyond the limit; more breathlessness than usual or needing extra pillows to sleep; more swelling of the feet, legs or abdomen; a dry cough; new dizziness; more fatigue; or vomiting or diarrhea that goes on for more than 2 days.
- **Red (call 9-1-1):** breathlessness at rest that does not settle, chest pain that rest or medicine does not relieve, a fast heartbeat that does not slow at rest, new confusion or fainting.

The nurse confirms that the patient owns a working scale, checks reading level, vision and preferred language (including French-language services), uses teach-back and includes a family caregiver. On a follow-up call, the nurse applies the Clinical Judgment Measurement Model (CJMM; section 1.4): recognizing a 2 kg rise plus new orthopnea as cues of early congestion and arranging prompt assessment.

Sodium, Fluids and Activity

Patients with HF were long told to follow a strict low-sodium diet, but the evidence for very strict limits is weak. The SODIUM-HF trial, an international randomized trial, assigned 806 adults with chronic HF to dietitian support aiming for less than 1,500 mg of sodium a day or to usual care (Ezekowitz et al., 2022). At 12 months, the combined rate of death, cardiovascular hospitalization and cardiovascular emergency visits did not differ significantly (about 15% versus 17%). The nurse therefore teaches an individualized plan: limiting high-sodium processed and restaurant foods, reading labels and working with a dietitian.

A fluid limit is not needed for everyone. The British Columbia HF guideline suggests one for people with symptoms or signs of fluid overload or who take diuretics, usually 1.5 to 2 L of total fluid a day (GPAC, 2023). The nurse teaches the limit in the patient's own plan and helps the patient count soups, ice and jelly as fluid.

Regular physical activity, balanced with rest, improves stamina and quality of life. Cardiac rehabilitation includes people with HF (Chapter 17). The patient stops and reports activity that brings on chest pain, marked breathlessness or dizziness.

Infections such as influenza can tip a stable patient into decompensation. The National Advisory Committee on Immunization (NACI) recommends yearly influenza vaccine for everyone 6 months of age and older without a contraindication, and lists adults with chronic health conditions among those at high risk (NACI, 2025). The nurse also checks that other vaccines recommended for the person's age and conditions, such as COVID-19 and pneumococcal vaccines, are up to date.

NSAIDs such as ibuprofen and naproxen blunt the effect of diuretics and can worsen kidney function (GPAC, 2023; section 18.3). The patient asks a pharmacist before buying any over-the-counter pain, cold or herbal product.

Leaving Hospital

Before the patient leaves, the nurse:

- completes medication reconciliation, comparing the home list, hospital orders and discharge prescriptions so the patient knows which drugs are new, changed or stopped;
- records the discharge weight as the patient's starting point for daily weights;
- gives a written action plan and confirms understanding with teach-back;
- confirms that a follow-up appointment within 1 to 2 weeks (section 18.2) and blood work for potassium and creatinine (section 18.3) are booked.

In an Ontario study of 34,519 adults discharged from emergency departments with HF between 2007 and 2014, only 47.1% saw a physician within 7 days; those seen within 7 days had lower 1-year mortality and fewer later hospital admissions than those first seen between days 8 and 30 (Atzema et al., 2018). Home care nursing, HF clinics and, in some regions, telemonitoring of weight, blood pressure and symptoms bridge this period.

Access is not equal. People in rural, remote and northern communities may live hours from an HF clinic or laboratory, which delays drug titration and potassium checks, and fresh, lower-sodium food costs more there. First Nations, Inuit and Métis patients may face long medical travel away from family and racism in health care, structural barriers described in Chapter 2. Nursing stations, virtual HF clinics, Indigenous patient navigators and culturally safe discharge planning help close these gaps.

A Palliative Approach

HF usually follows an unpredictable course: stable periods broken by sudden worsening, with a gradual overall decline. A **palliative approach** brings symptom relief, emotional support and planning into care early, alongside HF medicines and devices rather than in place of them (Chapter 10). The nurse assesses and treats breathlessness, fatigue, edema, pain, low mood and poor sleep, and supports caregivers.

Advance care planning helps the patient name a substitute decision-maker and discuss values and goals before a crisis (Chapter 1, section 1.5; Chapter 10). For a patient with an implantable cardioverter-defibrillator (ICD; section 16.7), planning includes whether to turn off the shock function near the end of life, when shocks can cause distress without changing the outcome. The nurse raises the topic, documents the patient's wishes and involves the cardiology and palliative care teams.

PATIENT EDUCATION

Daily Weights and Your Action Plan

- Weigh yourself every morning after you empty your bladder and before you eat breakfast.
- Use the same scale each day and wear about the same clothing.
- Write your weight on your chart or in an app and compare it with yesterday's.
- Call your heart failure clinic or health care provider if your weight goes up by more than 2 kg over 2 days in a row or by more than 2.5 kg within a week, or by the amount on your own plan.
- Also call if you are more short of breath, need more pillows to sleep, have more swelling, a new dry cough, new dizziness, or vomiting or diarrhea for more than 2 days.
- Call 9-1-1 if you cannot catch your breath at rest, have chest pain that does not go away, feel your heart racing at rest, become confused or faint.
- Bring your weight record and all your pill bottles to every appointment.
- Ask your pharmacist before taking any pain, cold or flu medicine, or any herbal product.

LIFESPAN CONSIDERATIONS

Older Adults With Heart Failure

- **Frailty:** many older adults with HF are frail; small changes in fluid or medicines can lead to falls, delirium or loss of independence (Chapter 8).
- **Atypical presentation:** worsening HF may appear as new confusion, a fall, poor appetite or reduced function rather than obvious breathlessness.
- **Polypharmacy:** older adults often take many drugs. The nurse reviews the full list, including over-the-counter products, at every transition.
- **Orthostatic hypotension and falls:** diuretics and other HF drugs can lower blood pressure on standing. The nurse checks lying and standing blood pressure, teaches the patient to rise slowly, and plans safe toileting when diuretics start working.
- **Hyponatremia and kidney function:** older adults are more prone to low sodium and changes in creatinine with diuretics; the nurse watches laboratory results and reports changes (Chapter 3).
- **Cognitive impairment:** memory problems make daily weights and complex regimens harder. Blister packs, simple written plans and caregiver involvement help.
- **Caregiver support:** caregivers need teaching, respite and a clear contact for questions.

18.5 Valvular Heart Disease

The four heart valves keep blood moving forward. When a valve is diseased, the heart must work harder, and over time this extra load can lead to HF, AF and sudden symptoms. In older adults, valve disease is common and easy to miss, because breathlessness and fatigue are often blamed on age.

Stenosis and Regurgitation

A valve can fail in two ways. In **stenosis**, the valve opening narrows and stiffens, so the chamber behind it must generate higher pressure to push blood through. This pressure load makes the muscle wall thicken. In **regurgitation** (also called insufficiency), the valve does not close fully and blood leaks backward. The chamber receiving the leak has to handle extra volume with every beat, so it gradually enlarges. A valve can have both problems at once.

Either disorder usually produces a murmur, heard with the stethoscope as described in section 16.2. Echocardiography confirms the diagnosis, measures severity and shows how the heart is coping (section 16.3). Decisions about repair or replacement are made by a **Heart Team** of cardiologists, cardiac surgeons, imaging specialists and nurses, together with the patient (Otto et al., 2021; Praz et al., 2025). Table 18.3 summarizes the common valve disorders.

Aortic Stenosis

Aortic stenosis is narrowing of the aortic valve that obstructs outflow from the left ventricle. In older adults the usual cause is gradual calcification of a valve that was once normal. A valve born with two leaflets instead of three (a bicuspid valve) tends to narrow at a younger age, and rheumatic heart disease is another cause.

Aortic stenosis may progress for years without symptoms while the left ventricle thickens to compensate. Once symptoms begin, they follow from a heart that cannot raise its output on demand:

- chest pain (angina), because the thickened muscle needs more oxygen than the coronary arteries can supply;
- fainting or near-fainting (syncope), often with exertion;
- breathlessness and other signs of HF.

New symptoms in a person with severe aortic stenosis are a signal to refer for valve replacement. No drug relieves the obstruction. The two options are **surgical aortic valve replacement (SAVR)**, an open-heart operation, and **transcatheter aortic valve implantation (TAVI)**, in which a collapsible valve is guided through an artery, usually the femoral artery, and expanded inside the diseased valve. The 2020 American College of Cardiology/American Heart Association (ACC/AHA) guideline favours SAVR for people younger than 65 with a long life expectancy, allows either approach between 65 and 80, and favours TAVI for people older than 80 (Otto et al., 2021). The 2025 European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS) guideline extends TAVI to anatomically suitable patients aged 70 or older with a three-leaflet valve, whatever their surgical risk, and keeps surgery as a key option for younger, lower-risk patients and for many with bicuspid valves (Praz et al., 2025). Both guidelines stress shared decision-making. For a patient with a very short life expectancy, the conversation includes palliative care. In Canada, TAVI is offered in larger cardiac centres, so rural and northern patients often travel for assessment and the procedure.

Nursing care of a patient with severe aortic stenosis centres on preload. Because the ventricle must push blood through a fixed narrow opening, it depends on adequate filling. Dehydration, bleeding, aggressive diuresis or drugs that dilate blood vessels (such as nitrates) can cause a sudden fall in blood pressure and syncope; the ACC/AHA guideline warns against abruptly lowering blood pressure in people with a narrowed valve (Otto et al., 2021). The nurse helps the patient change position slowly, monitors blood pressure closely after any new vasodilator or diuretic, and reports chest pain, syncope or new breathlessness at once.

Mitral Valve Disease

In **mitral regurgitation**, blood leaks back from the left ventricle into the left atrium with each contraction. It has two broad forms:

- **Primary (degenerative)** mitral regurgitation comes from disease of the valve itself, such as a floppy, prolapsing leaflet or a torn chord.

- **Secondary (functional)** mitral regurgitation occurs when the leaflets are normal but the left ventricle or atrium has enlarged, pulling the leaflets apart. It is common in HFrEF.

Sudden severe regurgitation, for example after rupture of a papillary muscle in myocardial infarction or destruction of a leaflet by endocarditis, causes abrupt pulmonary edema and shock, and needs urgent escalation (Chapter 6). For severe primary regurgitation, surgical repair is preferred; the 2025 ESC/EACTS guideline now recommends early repair even for some patients without symptoms, and supports **transcatheter edge-to-edge repair (TEER)**, a catheter-delivered clip that brings the leaflets together, for selected high-risk patients (Praz et al., 2025). For secondary regurgitation, HF medicines come first (section 18.3); TEER is then recommended for selected patients who remain symptomatic, to reduce HF hospitalizations and improve quality of life.

Mitral stenosis is narrowing of the mitral valve, and most often results from **rheumatic heart disease**: lasting valve damage after acute rheumatic fever, an immune reaction to a group A streptococcal throat infection. Blood backs up into the left atrium and lungs, causing breathlessness that worsens with exertion, fast heart rates or pregnancy. The enlarged left atrium favours AF, and AF with mitral stenosis carries a high risk of stroke (section 16.6).

Rheumatic heart disease is a disease of poverty and crowding. Worldwide, the World Health Organization (WHO) estimates that it affects about 55 million people and causes about 360,000 deaths a year, most of them in low- and middle-income countries; Indigenous and other marginalized communities are also affected (WHO, 2025). These are global figures; published national Canadian data are limited. In Canada, nurses most often meet rheumatic valve disease in adults who grew up where the disease is common. Prevention depends on prompt treatment of strep throat, adequate housing and, for people who have had rheumatic fever, long-term secondary prevention with long-acting penicillin injections every 3 to 4 weeks for many years (WHO, 2025). Barriers such as cost, distance and language can interrupt that prevention.

After Valve Replacement

Replacement valves are either mechanical or tissue. A **mechanical valve** is made of durable synthetic materials and can last a lifetime, but blood clots form on it unless the person takes an anticoagulant for life (Figure 18.5). A **bioprosthetic valve** (tissue valve) is made from animal tissue; it does not need lifelong anticoagulation but wears out over time and may later need a repeat procedure. The choice weighs age, bleeding risk, plans for pregnancy and the patient's preferences.

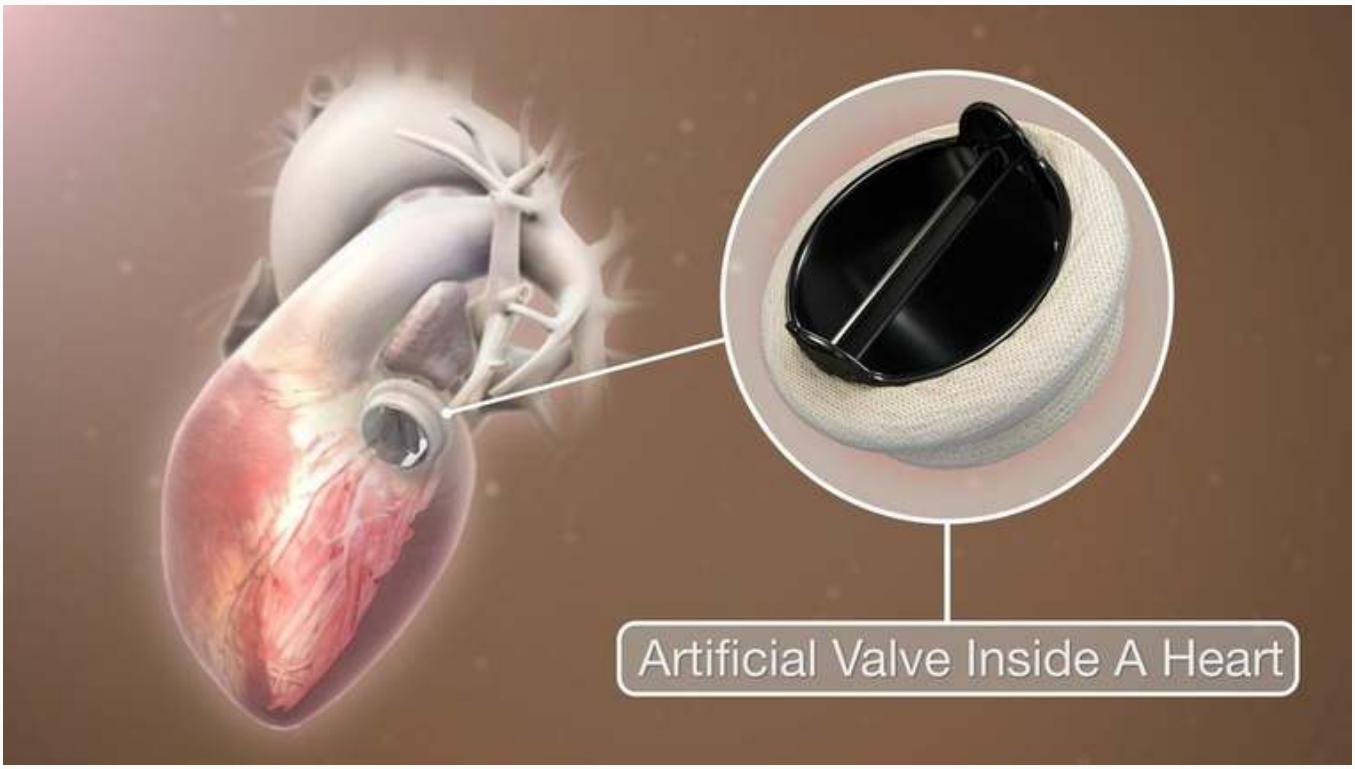

Figure 18.5 A mechanical heart valve shown in place in the heart (illustration). Clots can form on its surfaces, so lifelong anticoagulation is needed. (credit: "3D Medical Animation still shot Artificial Heart Valve" by Scientific Animations/Wikimedia Commons, CC BY-SA 4.0)

People with mechanical valves take warfarin, a vitamin K antagonist, adjusted to the **international normalized ratio (INR)**, a blood test that measures how long blood takes to clot. The ACC/AHA guideline sets a target INR of 2.5 for a current-generation mechanical aortic valve without added clotting risk factors, and 3.0 for a mechanical mitral valve or a mechanical aortic valve with risk factors or an older valve design (Otto et al., 2021). The cardiologist states each patient's target. Direct oral anticoagulants (DOACs), including dabigatran and the factor Xa inhibitors, are contraindicated with mechanical valves (Otto et al., 2021). After a bioprosthetic valve, the guideline supports low-dose ASA and, after surgical replacement, sometimes a few months of warfarin.

Care after SAVR follows the perioperative principles in Chapter 7 and the sternal care in Chapter 17. After TAVI, the nurse checks the femoral access site and distal pulses, as after percutaneous coronary intervention (Chapter 17), and watches the cardiac rhythm for new conduction problems (section 16.7). Every patient with a replacement valve has a lifelong higher risk of infective endocarditis, so daily oral hygiene and regular dental care are part of discharge teaching (section 18.6).

Table 18.3 Common valve disorders: causes, findings and treatment (Otto et al., 2021; Praz et al., 2025; WHO, 2025)

Disorder	Common causes	Key findings	Treatment
Aortic stenosis	Age-related calcification; bicuspid valve; rheumatic disease	Systolic murmur; angina, syncope with exertion, breathlessness; thick left ventricle on echocardiography	Valve replacement once severe and symptomatic (SAVR or TAVI, chosen with the Heart Team); careful volume and blood pressure management meanwhile
Aortic regurgitation	Bicuspid valve; enlarged aortic root; endocarditis; rheumatic disease	Diastolic murmur; gradual breathlessness; enlarged left ventricle	Monitoring with echocardiography; surgery when severe with symptoms or a weakening ventricle; urgent surgery if sudden
Primary mitral regurgitation	Prolapsing leaflet; torn chord; endocarditis; rheumatic disease	Systolic murmur; breathlessness; AF; sudden pulmonary edema if acute	Surgical repair preferred; TEER for selected high-risk patients
Secondary mitral regurgitation	Enlarged left ventricle or atrium, often with HFrEF	Murmur that may be soft; HF symptoms	HF medicines first; TEER for selected patients with persistent symptoms

Disorder	Common causes	Key findings	Treatment
Mitral stenosis	Rheumatic heart disease	Diastolic murmur; breathlessness worse with exertion or fast heart rate; AF; stroke risk	Rate control and anticoagulation for AF; balloon or surgical procedures when severe

CLINICAL SAFETY

Mechanical Valves and Anticoagulation

- Warfarin is lifelong with a mechanical valve. Missing doses raises the risk of valve thrombosis and stroke.
- INR checks are done on a regular schedule and more often when another medicine is started, stopped or changed, during illness, and after diet changes.
- Many drugs interact with warfarin, including some antibiotics, antifungals, amiodarone, NSAIDs and herbal products. The nurse checks every new order with the pharmacist.
- Sudden large changes in foods rich in vitamin K, such as leafy green vegetables, alter the INR. The goal is a steady intake, not avoidance.
- The nurse teaches the patient to report bleeding gums, nosebleeds, blood in the urine or stool, black stools, unusual bruising, severe headache or a fall with a head strike.
- A patient with a mechanical valve is never switched to a DOAC, even if a DOAC seems simpler; DOACs are contraindicated with mechanical valves (Otto et al., 2021). Any such order is questioned at once.
- Bridging and procedure planning, reversal and INR management in depth are covered in Chapter 19.

18.6 Infective Endocarditis

Infective endocarditis (IE) is infection of the inner lining of the heart, most often a heart valve or implanted material. It is uncommon but serious, and it needs weeks of treatment, a team approach and careful attention to the person's life outside hospital.

How It Develops and Who Is at Risk

Endocarditis starts where the endocardium is damaged or covered by foreign material. Platelets and fibrin collect on the rough surface, and bacteria in the bloodstream lodge there and multiply. The result is a **vegetation**, a mass of clot, bacteria and inflammatory cells. Vegetations destroy valve leaflets, causing regurgitation; spread into nearby tissue to form abscesses; and break off as infected emboli that travel to the brain, kidneys, spleen, limbs or, from right-sided valves, the lungs.

The 2023 Duke-International Society for Cardiovascular Infectious Diseases (Duke-ISCVID) criteria list the main predisposing conditions (Fowler et al., 2023):

- previous endocarditis;
- a prosthetic valve or previous valve repair;
- congenital heart disease;
- a valve that leaks or is narrowed more than mildly;
- an implanted cardiac device such as a pacemaker or ICD;
- hypertrophic obstructive cardiomyopathy;
- injection drug use.

Frequent access to the bloodstream, as with hemodialysis catheters and other central lines, also allows bacteria to enter.

In Ontario, a population-based study of 2006 to 2015 found that hospital admissions for endocarditis among people who inject drugs rose from a mean of 13.4 per quarter before late 2011 to 35.1 per quarter afterward, a rise that paralleled growth in hydromorphone prescribing (Weir et al., 2019). Structural factors shape this risk: an unpredictable drug supply, limited access to sterile equipment, unstable housing, criminalization and stigma that delays care. Harm reduction (Chapter 11) is part of endocarditis care.

Recognizing Endocarditis

The presentation ranges from a slow illness over weeks to a sudden, septic one. Cues include:

- fever (above 38.0 °C), chills, night sweats, fatigue, poor appetite and weight loss;
- a new murmur or a change in a known murmur;
- signs of HF from a newly leaking valve;
- embolic events: stroke symptoms, a cold painful limb, flank or left upper abdominal pain, or, with right-sided infection, cough, chest pain and breathlessness from septic lung emboli.

Figure 18.6 Janeway lesions on the palm of a man with staphylococcal endocarditis: small, flat, painless red spots. On darker skin they look purple to dark brown. (credit: "Janeway lesion" by Warfieldian/Wikimedia Commons, CC BY-SA 4.0)

Small signs in the skin, nails and eyes support the diagnosis, and the nurse looks for them in good light on every patient:

- **Splinter hemorrhages:** thin red-brown to dark lines under the nails. They are easier to see on pale nail beds; on darker skin the nurse checks every nail and compares with the person's usual nail colour.
- **Conjunctival hemorrhages or petechiae:** tiny red spots inside the lower eyelid. The conjunctiva is a useful site to inspect on all skin tones.
- **Janeway lesions:** painless, flat spots on the palms or soles that look red on lighter skin and purple to dark brown on darker skin (Figure 18.6).
- **Osler nodes:** small, painful, tender bumps on the pads of the fingers or toes, found by touch and by asking about pain.
- **Roth spots:** small retinal hemorrhages seen on eye examination.

Endocarditis can cause sepsis (Chapter 4). A falling blood pressure, rising respiratory rate, new confusion or sudden neurologic change means the nurse escalates at once (Chapter 6).

Diagnosis and Treatment

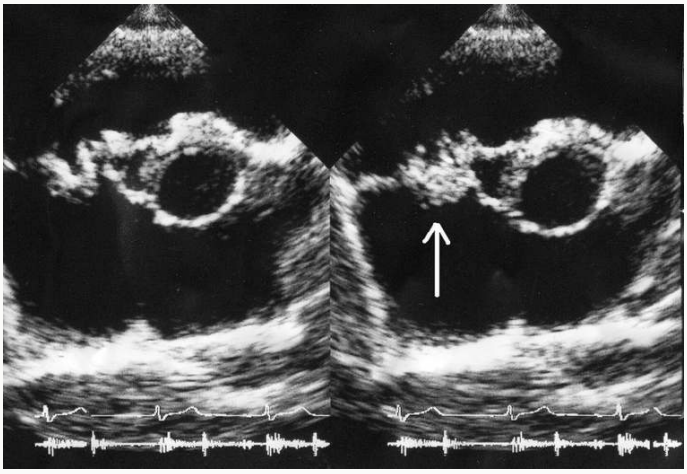

Figure 18.7 Echocardiogram showing a vegetation (arrow) on the tricuspid valve in infective endocarditis. (credit: "Endocarditis ultrasound" by Daisuke Koya, Kazuyuki Shibuya, Ryuichi Kikkawa and Masakazu Haneda; derivative work by Materialscientist/Wikimedia Commons, CC BY 2.0)

Blood cultures come first. Several separate sets are drawn before the first antibiotic dose, because cultures taken after antibiotics may not grow the organism (Otto et al., 2021). Growth of a typical organism in two or more separate sets is a major diagnostic criterion (Fowler et al., 2023). Transthoracic echocardiography is the first imaging test (Figure 18.7); transesophageal echocardiography (TEE) follows when the first study is negative but suspicion stays high, when a prosthetic valve or device leads are present, and before a switch from intravenous to oral antibiotics (Delgado et al., 2023; Otto et al., 2021). The **Duke-ISCVID criteria** combine microbiology, imaging and clinical findings to classify endocarditis as definite, possible or rejected (see the Going Deeper box in section 18.7).

Treatment is a long course of antibiotics chosen with infectious diseases specialists: commonly 2 to 6 weeks for a native valve and at least 6 weeks for a prosthetic valve. After about 2 weeks of inpatient intravenous therapy,

selected stable patients may finish treatment with oral antibiotics or with **outpatient parenteral antibiotic therapy (OPAT)**, once TEE shows no local spread (Delgado et al., 2023). Surgery is needed for HF caused by valve damage, infection that cannot be controlled, such as an abscess, or a large vegetation with a high risk of emboli.

For a person who uses drugs, admission is also a chance to treat substance use as a health condition. The 2023 ESC guideline recommends addiction treatment after endocarditis in people who inject drugs and a recovery plan developed with the patient (Delgado et al., 2023). The nurse uses person-first language, assesses and treats withdrawal and pain promptly, and advocates for an addiction medicine consultation and for starting or continuing opioid agonist treatment (Chapter 11). Whether a person finishes treatment with a peripherally inserted central catheter (PICC; Figure 18.8) and OPAT, or with oral step-down, is decided with the patient and the endocarditis team, taking housing and supports into account. Untreated withdrawal, pain and feeling judged are common reasons people leave before treatment ends. Preventing patient-directed discharge, and planning safely if it happens, is covered in Chapter 11.

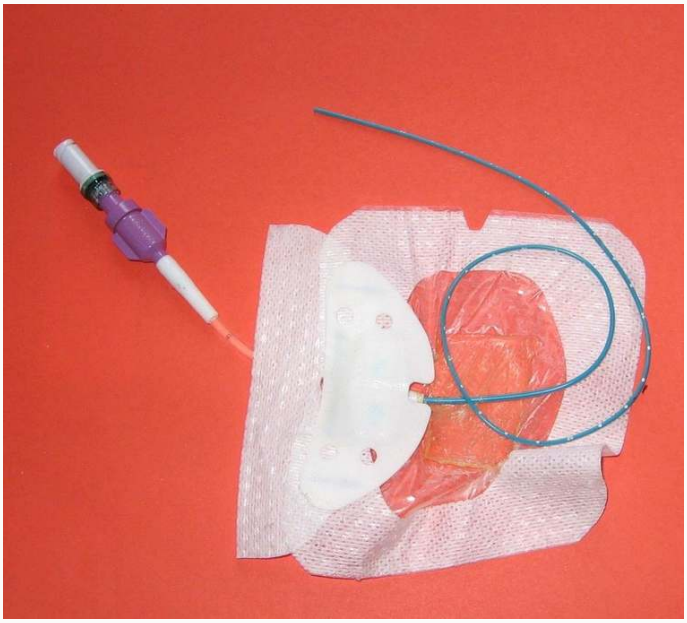

Figure 18.8 A peripherally inserted central catheter (PICC) after removal at the end of two months of treatment, with its hub and securement dressing. (credit: "Peripherally inserted central catheter (PICC or PIC line) after use in a patient for two months 2018 The Netherlands" by Hansmuller/Wikimedia Commons, CC BY-SA 4.0)

Prevention

Daily oral hygiene and regular dental care reduce the bacteria entering the blood every day. Antibiotic prophylaxis before dental procedures is recommended only for people at high risk: those with previous endocarditis, a surgical or transcatheter prosthetic valve or valve repair with prosthetic material, certain congenital heart disease and ventricular assist devices (Delgado et al., 2023). The nurse teaches these patients to tell every dentist about their heart condition. For people who inject drugs, sterile supplies and safer-injection teaching help lower the risk of a first or repeat infection (Chapter 11).

PATIENT EDUCATION

Protecting Your Heart Valves

- Brush your teeth twice a day, floss, and see a dentist regularly.
- Tell every dentist and health care provider that you have a heart valve problem or a replacement valve.
- If your care team says you need antibiotics before dental work, take them exactly as directed.
- Look after your skin: clean cuts well and get help early for redness, swelling or pus.
- If you inject drugs, use new sterile equipment every time, clean the skin first, never share equipment, and ask about local harm reduction services.
- Call your health care provider if you have a fever, chills, night sweats or unusual tiredness that lasts more than a few days.
- Call 9-1-1 if you have sudden weakness, trouble speaking, or chest pain.

PRACTICE STORY

Six Weeks Is a Long Time

Names and details are fictional; this is a composite story.

Nurse: Chantal Pelletier, RN. Years in practice: 9. Setting: medical unit, Ontario.

Tyler was 24 and had been admitted with fever and a new murmur. His blood cultures grew *Staphylococcus aureus*, and the TEE showed a vegetation on his tricuspid valve. The plan was six weeks of intravenous antibiotics. When I came in on his second day, he had his coat on.

I sat down instead of standing at the door. I asked what was making it hard to stay. He said he was "dope sick," his last nurse had looked at him "like garbage," and he was sure we would kick him out the moment we found out he'd used. I told him that withdrawal and pain were things we treat, not punishments, and that I would get the team to see him that morning.

I called the hospitalist and asked for an addiction medicine consult. By noon, Tyler had started buprenorphine–naloxone with a plan for his pain. I paged the social worker about his housing and his dog, which was being looked after by a friend for only a week.

I worked with Sana, the RPN on our team. Tyler's condition had settled, and our unit assigns RPNs to patients like him once they are stable. Sana knew him from a previous admission and was skilled in caring for patients on long IV antibiotic courses. We agreed she would call me right away for any fever spike, new breathlessness or neurologic change, since septic emboli were a real risk.

At rounds I asked whether OPAT or an oral step-down could be options later if his housing came together, and the team agreed to look at it after his next echo. We also set aside a daily time for Tyler to call his friend and step outside with a staff member. Two weeks later he was still with us, asking about a clinic near home that could continue his buprenorphine–naloxone.

Reflect: What cues suggested Tyler might leave before treatment ended, and how did each response address them? Using authority, competence and context, what parts of Tyler's care could the RPN provide, and when should she consult the RN?

18.7 Pericarditis, Myocarditis and Cardiomyopathies

The heart's muscle and its surrounding sac can be inflamed or structurally abnormal. The 2025 ESC guideline groups pericarditis and myocarditis under one umbrella term, **inflammatory myopericardial syndrome**, because they share causes and often overlap (Schulz-Menger et al., 2025).

Acute Pericarditis

The pericardium is a two-layered sac around the heart with a small amount of lubricating fluid between the layers. In **pericarditis**, those layers become inflamed. Common causes include viral infection, unknown (idiopathic) causes, injury after myocardial infarction or cardiac surgery, autoimmune disease, kidney failure and cancer.

The typical symptom is sharp chest pain that worsens with a deep breath, coughing or lying flat, and eases when the person sits up and leans forward. A **pericardial friction rub**, a high-pitched scratching or grating sound heard best with the stethoscope diaphragm at the left lower sternal border while the patient leans forward, is a classic finding. The 2025 ESC guideline diagnoses pericarditis when typical chest pain is accompanied by at least one more finding: a friction rub, compatible ECG changes, a raised C-reactive protein (CRP), a pericardial effusion, or compatible findings on cardiac magnetic resonance imaging (MRI) (Schulz-Menger et al., 2025). ECG changes may include ST elevation across many leads (Figure 18.9); the guideline notes that ST elevation suggests some involvement of the heart muscle but does not change management. Because pericarditis can mimic acute coronary syndrome, the patient with chest pain is assessed for both (Chapter 17).

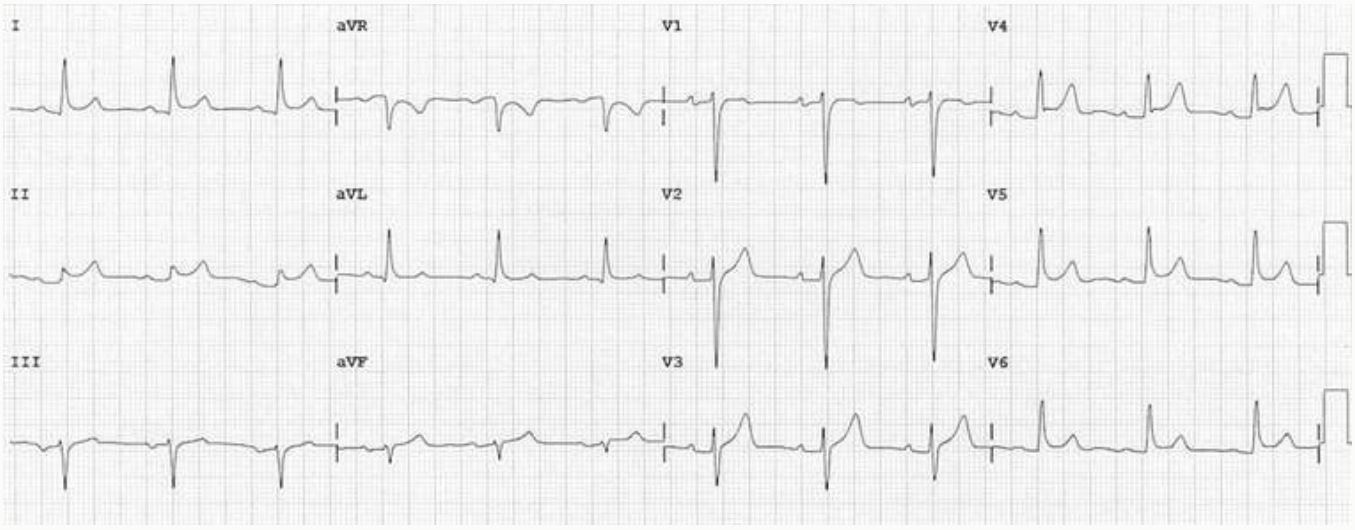

Figure 18.9 A 12-lead ECG in acute pericarditis, with ST elevation in many leads. Because pericarditis can mimic acute coronary syndrome, the patient with chest pain is assessed for both. (credit: "ECG Pericarditis" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

First-line treatment is ASA or an NSAID combined with colchicine (Schulz-Menger et al., 2025). Colchicine continues for months (at least 3 to 6) and is the last drug stopped once symptoms have settled. Corticosteroids are kept for people who do not respond to first-line treatment. Physical activity is restricted for an initial month and then adjusted to the individual. Pericarditis comes back in 15% to 30% of people, so teaching covers taking colchicine for the full course, reporting stomach upset or bleeding with NSAIDs, and returning if pain recurs.

Pericardial Effusion and Cardiac Tamponade

A **pericardial effusion** is extra fluid in the pericardial sac. Fluid that collects slowly can reach a large volume before it causes problems, because the sac stretches. Fluid that collects quickly, as with bleeding after cardiac surgery, trauma or a procedure, can be dangerous in small amounts.

Cardiac tamponade occurs when pressure in the sac squeezes the heart so that the ventricles cannot fill. Stroke volume and cardiac output fall, and the patient develops obstructive shock (Chapter 6). Cues include:

- breathlessness and tachycardia;
- low blood pressure;
- distended neck veins;
- muffled heart sounds;
- **pulsus paradoxus**, an exaggerated drop in systolic blood pressure during inspiration (see the Going Deeper box).

Low blood pressure, distended neck veins and muffled heart sounds together form **Beck's triad**, but all three may be absent, especially when tamponade develops from a medical cause (Roy et al., 2007). Tamponade is an emergency. The nurse who suspects it calls the rapid response team at once, stays with the patient, monitors vital signs continuously and prepares for urgent bedside echocardiography and drainage of the fluid by needle (**pericardiocentesis**) or surgery. Because the heart depends on filling, the nurse questions any order that would reduce preload, such as a diuretic or nitrate, until the team reassesses.

Myocarditis

Myocarditis is inflammation of the heart muscle. Viral infection is a common cause; others include immune and autoimmune disease, toxins and some medicines, including the immune checkpoint inhibitors used in cancer care (Chapter 9). Presentations vary widely: chest pain that resembles a heart attack, new HF, palpitations and dysrhythmias, or, rarely, fulminant illness with cardiogenic shock or sudden death. A recent flu-like illness is a common clue.

The 2025 ESC guideline recommends inflammatory markers, troponin, BNP or NT-proBNP and echocardiography for every patient with suspected myocarditis, and cardiac MRI to confirm the diagnosis (Schulz-Menger et al., 2025). Endomyocardial biopsy is reserved for high-risk presentations, such as acute HF or cardiogenic shock. The guideline advises hospital admission for all patients with myocarditis. Care is supportive: continuous cardiac monitoring, HF medicines when the ventricle is weak (section 18.3), treatment of dysrhythmias, and a period without strenuous exercise set by the cardiologist. Corticosteroids are not a routine first treatment.

Rare cases of myocarditis or pericarditis have followed mRNA COVID-19 vaccines, more often in males aged 12 to 29 years, after a second dose and usually within a week. Most people recover quickly with conservative treatment, and the risk with updated vaccine formulations is considerably lower (PHAC, 2026).

Cardiomyopathies

A **cardiomyopathy** is a disease of the heart muscle itself, not explained by coronary disease, hypertension or valve disease alone.

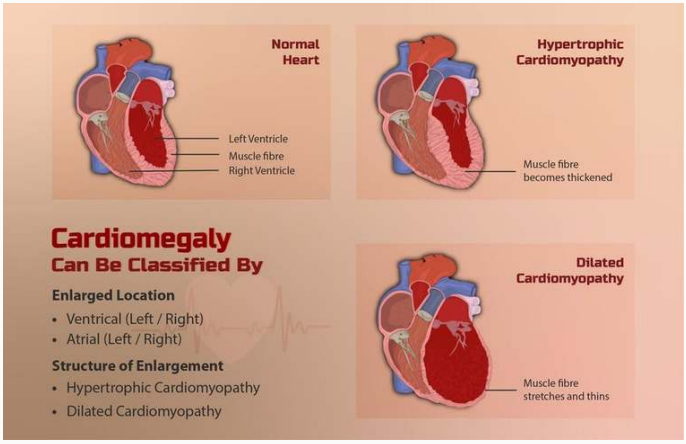

Figure 18.10 A normal heart compared with hypertrophic cardiomyopathy (thickened muscle) and dilated cardiomyopathy (enlarged chamber with thin, stretched muscle). (credit: "Illustration of an enlarged heart (Cardiomegaly)" by myUpchar/Wikimedia Commons, CC BY-SA 4.0)

- **Dilated cardiomyopathy:** the left ventricle enlarges and contracts weakly. Causes include inherited gene variants, alcohol, some cancer drugs, previous myocarditis and pregnancy. It presents as HFrEF and is treated as described in section 18.3, with devices as needed (section 16.7) (Figure 18.10).
- **Hypertrophic cardiomyopathy:** the ventricular wall thickens abnormally. It is a common inherited heart disease, often passed on in an autosomal dominant pattern through variants in sarcomere genes, although a family history is not always present (Ommen et al., 2024). In some people, the thick wall blocks outflow from the left ventricle (obstructive hypertrophic cardiomyopathy). That obstruction changes with heart rate, blood pressure, fluid status, activity, food, alcohol and medicines, so health advice includes staying well hydrated. Symptoms include breathlessness, chest pain, palpitations and fainting with exertion. Assessing the risk of sudden cardiac death is central to care and guides decisions about an ICD. First-degree relatives are offered screening with an ECG, echocardiography and, where available, genetic testing. A blanket ban on exercise is not recommended; activity is planned through shared decision-making (Ommen et al., 2024).
- **Restrictive cardiomyopathy:** stiff ventricles fill poorly, causing HF with a nonreduced ejection fraction. A key cause is **cardiac amyloidosis**, in which misfolded proteins, often transthyretin, deposit in the heart. Transthyretin amyloidosis may be inherited or may develop with age, so it should be considered in older adults with HF and thick ventricular walls. Tafamidis, a drug that stabilizes transthyretin, is authorized in Canada for adults with transthyretin amyloid cardiomyopathy, wild-type or inherited, to reduce cardiovascular death and cardiovascular hospitalization (Health Canada, n.d.).
- **Takotsubo (stress) cardiomyopathy:** sudden, temporary weakness of the left ventricle, set off in most cases by an emotional or physical stress. At first it can look exactly like a myocardial infarction, both in symptoms and in ECG and troponin changes (Ghadri et al., 2018).

Table 18.4 compares these conditions.

Table 18.4 Pericarditis, tamponade, myocarditis and the cardiomyopathies compared (Ommen et al., 2024; Roy et al., 2007; Schulz-Menger et al., 2025)

Condition	What happens	Key findings	Main treatment	Nursing focus

Condition	What happens	Key findings	Main treatment	Nursing focus
Acute pericarditis	Inflamed pericardial layers	Sharp chest pain eased by sitting forward; friction rub; ECG changes; raised CRP	ASA or NSAID plus colchicine; activity restriction	Pain and rub assessment; rule out acute coronary syndrome; teach full colchicine course; recurrence
Cardiac tamponade	Fluid under pressure stops ventricles filling	Hypotension; distended neck veins; muffled heart sounds; tachycardia; pulsus paradoxus	Urgent drainage by pericardiocentesis or surgery	Recognize early; call rapid response; continuous monitoring; avoid lowering preload
Myocarditis	Inflamed heart muscle	Chest pain; raised troponin; HF or dysrhythmias; MRI changes	Supportive care; HF medicines; dysrhythmia treatment	Cardiac monitoring; watch for HF and shock; activity limits
Dilated cardiomyopathy	Enlarged, weak left ventricle	HFrEF signs; low ejection fraction	HF medicines and devices	HF self-care teaching; device care
Hypertrophic cardiomyopathy	Abnormally thick ventricular wall, sometimes blocking outflow	Breathlessness; exertional fainting; family history; murmur	Beta-blocker or nondihydropyridine calcium channel blocker for obstruction symptoms; ICD when indicated	Hydration; family screening; sudden death risk
Cardiac amyloidosis (restrictive)	Protein deposits stiffen ventricles	HF with nonreduced ejection fraction; thick walls in an older adult	HF symptom care; tafamidis for transthyretin type	Fluid balance; gentle diuresis; falls and orthostatic hypotension
Takotsubo cardiomyopathy	Sudden stress-triggered left ventricular weakness	Mimics acute coronary syndrome	Supportive care; HF medicines while recovering	Monitoring; emotional support

GOING DEEPER

Tamponade, Pulsus Paradoxus and the Duke Criteria

Required for RN students; optional for PN students.

Systolic blood pressure normally falls slightly on inspiration. In tamponade, the right ventricle fills more on inspiration and, inside a tight sac, pushes the septum toward the left ventricle, so left-sided output drops further. To measure pulsus paradoxus, the nurse uses a manual cuff while the patient breathes normally, deflates slowly from above systolic pressure, and notes the pressure at which Korotkoff sounds are first heard, only during expiration. Deflation continues until sounds are heard with every beat; the difference between the two pressures is the pulsus paradoxus. When an effusion is present, a pulsus paradoxus above 10 mm Hg raises the likelihood of tamponade, although echocardiography is needed to confirm it (Roy et al., 2007).

The 2023 Duke-ISCVID criteria (Fowler et al., 2023) classify endocarditis using major and minor criteria:

- **Major:** a typical organism grown from two or more separate blood culture sets (three or more for organisms that rarely cause endocarditis), or certain molecular tests; imaging showing a vegetation, new valve leak or prosthetic valve separation; or endocarditis seen at surgery.
- **Minor:** a predisposing condition; temperature above 38.0 °C; embolic signs (such as arterial emboli, conjunctival hemorrhages, Janeway lesions); immune signs (Osler nodes, Roth spots, glomerulonephritis); or microbiology short of a major criterion.
- **Definite** endocarditis: two major, one major and three minor, or five minor criteria. **Possible:** one major and one minor, or three minor.

SCOPE IN PRACTICE

IV Diuretics, Telemetry and PICC Lines

the College of Nurses of Ontario's (CNO's) Scope of Practice standard asks every nurse to consider authority, competence and context (Chapter 1, section 1.3). Employer policy and province or territory matter.

- **Authority:** RNs and RPNs both have authority to give an ordered IV diuretic and to care for a PICC. Where a specific activity is restricted, the employer's policy sets the limit.

- **Competence:** interpreting telemetry rhythms, giving IV push medicines and managing OPAT infusions require education and practice. A nurse who lacks the competence seeks it or hands the task to a colleague who has it.
- **Context:** the patient's condition and the supports available matter. Many employers assign patients whose condition is stable and expected to remain so to RPNs; this is an employer practice, not a CNO rule. When a patient with HF or endocarditis needs more frequent assessment, rapid changes in treatment or complex decision-making, the RPN consults the RN, and care may be shared or transferred.
- **Deterioration:** any nurse who notices increasing breathlessness, a falling blood pressure, new confusion, a new rhythm on the monitor or signs of tamponade acts at once and escalates through rapid response (Chapter 6).
- **OPAT and PICC lines at home:** home care nurses teach patients and families line care and infusion, and follow the agency's policies and the prescriber's orders.

Chapter 18 Summary

Introduction

- Heart failure is a syndrome in which a heart problem causes symptoms and signs, supported by raised natriuretic peptides or evidence of congestion.
- Heart failure is one of the top reasons for hospital admission in Canada, and about 1 in 5 patients is readmitted within a month.
- The chapter also covers valvular heart disease, endocarditis, pericarditis, myocarditis and the cardiomyopathies.

18.1 Heart Failure: How It Develops

- Systolic dysfunction is weak contraction; diastolic dysfunction is poor filling of a stiff ventricle.
- Left-sided failure congests the lungs; right-sided failure congests the systemic veins; left-sided failure is the usual cause of right-sided failure.
- Sympathetic and RAAS activation support output at first but cause sodium and water retention, higher afterload and remodelling over time.
- Canadian guidelines use HFrEF (EF 40% or less), HF with improved EF and HF with nonreduced EF (above 40%); NYHA class describes symptom limits.
- About 670,000 Canadians aged 40 or older had diagnosed heart failure in 2012–2013; Métis people in Ontario had higher prevalence and hospitalization.

18.2 Recognizing and Managing Worsening Heart Failure

- Congestion shows as breathlessness, orthopnea, PND, crackles, a raised JVP, edema and weight gain; low output as fatigue, cool skin, confusion and low urine output.
- Cyanosis and pallor look different on darker skin; the nurse checks mucous membranes, temperature and capillary refill.
- In an acute setting, BNP below 100 ng/L or NT-proBNP below 300 ng/L makes heart failure unlikely; age, kidney function, obesity and sacubitril/valsartan affect results.
- Acute pulmonary edema is an emergency: stay, sit the patient up, give oxygen to target, call for help and give IV diuretics as ordered.
- Daily weights, intake and output, electrolytes, fall prevention and skin care guide ongoing care; cues of cardiogenic shock are escalated at once.

18.3 Medications and Devices

- Four drug classes change the course of HFrEF: ARNI (or ACE inhibitor or ARB), beta-blocker, MRA and SGLT2 inhibitor, started early and adjusted in parallel.
- Loop diuretics relieve congestion; in HFnrEF, SGLT2 inhibitors and MRAs are strongly recommended.
- The nurse checks blood pressure, heart rate, potassium and creatinine; watches for angioedema; and allows 36 hours between an ACE inhibitor and sacubitril/valsartan.

- MRAs need potassium and creatinine checks within 1 week; SGLT2 inhibitors need sick-day and genital hygiene teaching; NSAIDs are avoided.
- ICDs, CRT, LVADs and transplant help selected patients, with a palliative approach alongside.

18.4 Self-Management and Transitions

- Self-care in HF means keeping the condition stable, watching for change and acting on it; teaching starts on admission.
- Patients weigh daily after voiding and before breakfast and follow a written action plan; Heart & Stroke advises calling for a rise of more than 2 kg in 2 days or more than 2.5 kg in a week, or as the patient's plan states.
- Sodium teaching is individualized: the SODIUM-HF trial found that very strict restriction did not reduce clinical events. Fluid limits (often 1.5 to 2 L a day) are for selected patients.
- Annual influenza vaccine, other recommended vaccines, activity and cardiac rehabilitation, and avoiding NSAIDs support stability.
- Safe discharge includes medication reconciliation, an action plan and early follow-up; rural, remote and Indigenous patients face structural barriers to access.
- A palliative approach runs alongside HF treatment and includes advance care planning and discussion of ICD deactivation.

18.5 Valvular Heart Disease

- Stenosis obstructs forward flow and causes a pressure load; regurgitation causes backward leakage and a volume load.
- Aortic stenosis causes angina, syncope and HF; symptomatic severe disease is treated with SAVR or TAVI, chosen by the Heart Team with the patient.
- Patients with severe aortic stenosis depend on adequate preload; dehydration and vasodilators can cause sudden hypotension.
- Mitral regurgitation is primary or secondary; mitral stenosis usually results from rheumatic heart disease, a disease of poverty and crowding.
- Mechanical valves need lifelong warfarin with INR monitoring; DOACs are contraindicated with mechanical valves.

18.6 Infective Endocarditis

- Vegetations form on damaged or prosthetic valves and cause valve destruction, abscesses and emboli.
- Risk factors include previous endocarditis, prosthetic valves, congenital heart disease, cardiac devices and injection drug use; Ontario admissions for drug use–associated endocarditis have risen.
- Cues include fever, a new murmur, HF and embolic signs; skin, nail and eye signs are assessed carefully on every skin tone.
- Blood cultures are drawn before antibiotics; echocardiography and the 2023 Duke-ISCVID criteria guide diagnosis; treatment lasts weeks.
- Care for people who inject drugs is non-stigmatizing and harm-reduction-based, with treatment of withdrawal and opioid agonist treatment.
- Dental prophylaxis is limited to the highest-risk patients; oral hygiene matters for everyone.

18.7 Pericarditis, Myocarditis and Cardiomyopathies

- Acute pericarditis causes sharp chest pain eased by sitting forward and may cause a friction rub; first-line treatment is ASA or an NSAID with colchicine.
- Cardiac tamponade causes hypotension, distended neck veins, muffled heart sounds, tachycardia and pulsus paradoxus; the nurse escalates at once.
- Myocarditis ranges from chest pain to HF and shock; troponin, echocardiography and cardiac MRI support diagnosis.
- Hypertrophic cardiomyopathy is often inherited; care includes hydration, family screening and sudden death risk assessment.
- Cardiac amyloidosis and takotsubo cardiomyopathy are causes of HF that nurses should recognize.

Key Terms (60)

action plan: A written, personalized guide that tells a person with heart failure which signs to watch for and what to do, often organized in green, yellow and red zones.

acute decompensated heart failure (ADHF): Worsening of known heart failure that needs urgent treatment, usually in hospital.

acute heart failure: A sudden or gradual change in heart failure symptoms and signs that calls for urgent treatment.

acute pulmonary edema: An emergency in which fluid floods the alveoli, causing severe breathlessness and hypoxemia.

angioedema: Swelling of the lips, tongue, face or throat; an emergency that can follow ACE inhibitors, ARBs or an ARNI.

angiotensin receptor–neprilysin inhibitor (ARNI): A drug combining neprilysin inhibition with angiotensin II receptor blockade; sacubitril/valsartan.

aortic stenosis: Narrowing of the aortic valve that obstructs blood flow out of the left ventricle.

Beck's triad: Low blood pressure, distended neck veins and muffled heart sounds, a classic but often incomplete sign of cardiac tamponade.

bioprosthetic valve: A replacement heart valve made from animal tissue; it does not need lifelong anticoagulation but wears out over time.

cardiac amyloidosis: A restrictive cardiomyopathy in which misfolded proteins, often transthyretin, deposit in the heart muscle and stiffen it.

cardiac resynchronization therapy (CRT): Pacing of both ventricles so they contract together.

cardiac tamponade: Compression of the heart by fluid under pressure in the pericardial sac, preventing ventricular filling and causing obstructive shock.

cardiomyopathy: A disease of the heart muscle itself that is not explained by coronary disease, hypertension or valve disease alone.

diastolic dysfunction: A stiff ventricle that does not relax and fill normally, raising pressure behind it.

dilated cardiomyopathy: A cardiomyopathy in which the left ventricle enlarges and contracts weakly.

Duke-ISCVID criteria: The 2023 Duke-International Society for Cardiovascular Infectious Diseases criteria, which classify infective endocarditis as definite, possible or rejected using major and minor criteria.

ejection fraction (EF): The percentage of blood in the left ventricle pumped out with each beat, usually measured by echocardiography.

heart failure (HF): A clinical syndrome in which a structural or functional problem of the heart causes symptoms and signs, supported by raised natriuretic peptides or evidence of congestion.

heart failure with improved ejection fraction (HFimpEF): Heart failure in which a previously reduced ejection fraction has risen above 40% by at least 10 percentage points.

heart failure with mildly reduced ejection fraction (HFmrEF): An international term for heart failure with an ejection fraction of 41% to 49%.

heart failure with nonreduced ejection fraction (HFnrEF): The Canadian term for heart failure with an ejection fraction above 40%, combining HFmrEF and HFpEF.

heart failure with preserved ejection fraction (HFpEF): An international term for heart failure with an ejection fraction of 50% or more.

heart failure with reduced ejection fraction (HFrEF): Heart failure with an ejection fraction of 40% or less.

Heart Team: A multidisciplinary group, including cardiologists, cardiac surgeons, imaging specialists and nurses, that plans valve treatment with the patient.

hypertrophic cardiomyopathy: An often inherited cardiomyopathy in which the ventricular wall thickens abnormally and may block outflow from the left ventricle.

infective endocarditis (IE): Infection of the inner lining of the heart, usually a valve or implanted material.

inflammatory myopericardial syndrome: The 2025 ESC umbrella term for pericarditis and myocarditis, which share causes and often overlap.

international normalized ratio (INR): A standardized blood test of clotting time used to adjust warfarin.

left ventricular assist device (LVAD): An implanted pump that moves blood from the left ventricle into the aorta in advanced heart failure.

left-sided heart failure: Failure of the left ventricle, raising pressure in the pulmonary veins and causing lung congestion.

mechanical valve: A durable replacement heart valve made of synthetic materials that requires lifelong anticoagulation with warfarin.

mineralocorticoid receptor antagonist (MRA): A drug that blocks aldosterone, such as spironolactone or eplerenone; its main risk is hyperkalemia.

mitral regurgitation: Backward leakage of blood from the left ventricle into the left atrium through a mitral valve that does not close fully; primary when the valve itself is diseased and secondary when chamber enlargement pulls the leaflets apart.

mitral stenosis: Narrowing of the mitral valve, most often caused by rheumatic heart disease.

myocarditis: Inflammation of the heart muscle.

natriuretic peptides: Hormones (BNP and NT-proBNP) released by stretched heart muscle that promote sodium and water excretion; measured to help diagnose heart failure.

NYHA functional class: A four-level scale describing how much heart failure symptoms limit activity.

orthopnea: Breathlessness when lying flat that eases on sitting up.

outpatient parenteral antibiotic therapy (OPAT): Intravenous antibiotic treatment given outside hospital, at home or in a clinic.

palliative approach: Care that brings symptom relief, emotional support and advance care planning into the course of a chronic illness, alongside disease-directed treatment.

paroxysmal nocturnal dyspnea (PND): Waking from sleep suddenly short of breath and needing to sit up.

pericardial effusion: An abnormal collection of fluid in the pericardial sac.

pericardial friction rub: A scratching or grating sound produced by inflamed pericardial layers rubbing together.

pericardiocentesis: Removal of fluid from the pericardial sac with a needle.

pericarditis: Inflammation of the pericardium.

pulsus paradoxus: An exaggerated fall in systolic blood pressure during inspiration; when an effusion is present, a fall of more than 10 mm Hg suggests tamponade.

regurgitation: Backward leakage of blood through a valve that does not close fully.

remodelling: Changes in the size, shape and function of the heart caused by neurohormonal activation, cell loss and scarring.

renin–angiotensin–aldosterone system (RAAS): A hormone system activated by low kidney blood flow that constricts vessels and retains sodium and water.

rheumatic heart disease: Lasting heart valve damage after acute rheumatic fever, an immune reaction to group A streptococcal throat infection.

right-sided heart failure: Failure of the right ventricle, raising pressure in the systemic veins and causing edema, a raised JVP and organ congestion.

self-care: In heart failure, the daily activities of keeping the condition stable, watching for change and responding to it.

sodium–glucose cotransporter 2 (SGLT2) inhibitor: A drug that makes the kidneys excrete glucose and sodium; reduces heart failure hospitalization across ejection fraction categories.

stenosis: Narrowing and stiffening of a valve opening that obstructs forward blood flow.

surgical aortic valve replacement (SAVR): Open-heart surgery to replace the aortic valve.

systolic dysfunction: Weak contraction of the ventricle, so a smaller share of its blood is ejected with each beat.

takotsubo cardiomyopathy: Sudden, temporary weakness of the left ventricle, usually triggered by emotional or physical stress, that can mimic a myocardial infarction; also called stress cardiomyopathy.

transcatheter aortic valve implantation (TAVI): Placement of a replacement aortic valve through a catheter, usually inserted in the femoral artery.

transcatheter edge-to-edge repair (TEER): A catheter-delivered clip that joins the mitral valve leaflets to reduce regurgitation.

vegetation: A mass of clot, bacteria and inflammatory cells attached to a heart valve or other endocardial surface in infective endocarditis.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Henri Tremblay (Questions 1–6): Mr. Henri Tremblay, 76, has HFrEF (EF 30%) and is on a medical unit after 3 days of increasing breathlessness. At 0600 the nurse finds him sitting upright, saying he slept in a chair. Respiratory rate 26 breaths/min, heart rate 108 beats/min, blood pressure 148/88 mm Hg, SpO2 89% on room air. Crackles reach the mid-lung fields. His weight is 2.4 kg higher than at his clinic visit 5 days ago, and both ankles have pitting edema.

1. [CORE] Which finding is the strongest cue that Mr. Tremblay's left-sided congestion is worsening?

a. Resting heart rate of 108 beats/min, up from 84 yesterday
b. Pitting edema of both ankles extending up to the mid-shins
c. Crackles to the mid-lung fields with SpO2 89%
d. Blood pressure of 148/88 mm Hg

Answer: c — Crackles climbing to the mid-lung fields with low oxygen saturation show fluid in the lungs from high left-sided pressure (c) (section 18.2, Table 18.2). A rising heart rate (a) is nonspecific; it can come from anxiety, fever, AF or low output. Ankle and shin edema (b) reflects right-sided or systemic venous congestion, not the lungs. A blood pressure of 148/88 mm Hg (d) is a possible trigger to note but is not itself a sign of lung congestion.

2. [CORE] Which explanation best fits Mr. Tremblay's need to sleep in a chair?

a. Lying flat sends more blood to an overloaded heart, raising lung pressure.
b. Sitting up slows his heart rate and lowers the oxygen demand of the heart muscle.
c. A chair relieves the ankle edema that builds up when he lies flat in bed.
d. Lying flat presses the congested liver up against the diaphragm and compresses the lungs.

Answer: a — Orthopnea occurs because lying flat returns more venous blood to a heart that cannot handle it, raising pulmonary venous pressure (a) (section 18.2). Sitting up does not reliably slow the heart (b). Sitting in a chair lets edema collect in the legs rather than relieving it (c). Liver congestion (d) causes abdominal fullness, not orthopnea.

3. [CORE] The nurse considers several possible problems. Which should be addressed first?

a. Risk of falls related to nocturia and new diuretic therapy
b. Knowledge gap about the sodium plan and daily weights at home
c. Risk of pressure injury from ankle edema
d. Impaired gas exchange from pulmonary congestion

Answer: d — Hypoxemia from fluid in the lungs threatens oxygen delivery now and comes first (d) (section 18.2; Chapter 1, section 1.4). Fall risk (a) and skin risk (c) are real but less urgent than the airway and breathing. Teaching (b) waits until he is stable (section 18.4).

4. [CORE] What is the nurse's first action?

a. Restrict his fluids to 1 L for the day and explain the reason to him

b. Stay, keep him upright, give oxygen to target and call for help

c. Weigh him on the bed scale to confirm the size of the fluid gain

d. Give his regular morning dose of oral furosemide 2 hours early

Answer: b — The nurse stays, positions him upright, gives oxygen titrated to the target because SpO2 is below range, and escalates (b) (section 18.2; Chapters 6 and 12). Fluid restriction (a) is applied only when ordered and does not treat hypoxemia. A weight (c) is useful later but does not change the urgent plan. Changing the timing or route of a drug (d) needs an order; decongestion in this setting is usually IV, as ordered by the team.

5. [CORE] The physician orders IV furosemide. Thirty minutes after the dose, a registered practical nurse (RPN) caring for Mr. Tremblay finds him confused and clammy, with blood pressure 86/52 mm Hg. What should the RPN do?

a. Lower the head of the bed and recheck the blood pressure in 1 hour

b. Document the findings and report them at the end of the shift

c. Stay with him, call for immediate help and inform the RN

d. Give a 500 mL normal saline bolus to raise his blood pressure

Answer: c — New confusion, clammy skin and hypotension are cues of low output or cardiogenic shock; every nurse who notices deterioration escalates at once, and the RPN consults the RN as needs change (c) (section 18.2; Chapter 1, section 1.3; Chapter 6). Lying him flat and waiting an hour (a) worsens breathing and delays care. Reporting at shift end (b) is unsafe. A fluid bolus (d) needs an order and could worsen pulmonary congestion.

6. [CORE] After a rapid response assessment, Mr. Tremblay stabilizes. Which finding 6 hours later best shows that treatment of his congestion is working?

a. Urine output 1,400 mL, SpO2 94% on 2 L/min, crackles only at bases

b. Heart rate unchanged at 108 beats/min with blood pressure 140/84 mm Hg

c. Potassium 3.2 mmol/L after the second dose of IV furosemide

d. Ankle edema unchanged, but he says he feels a little less tired than at 0600

Answer: a — Good urine output after the diuretic, better oxygenation on less support and receding crackles show decongestion (a) (section 18.2). An unchanged fast heart rate (b) suggests the problem persists. Low potassium (c) is a diuretic adverse effect to report, not a sign of benefit. Edema in the legs (d) often clears more slowly and does not show improvement.

7. [CORE] A 79-year-old woman arrives at the emergency department breathless. Her NT-proBNP is 180 ng/L. How should the nurse interpret this result?

a. Heart failure is very likely and treatment should begin

b. Heart failure is an unlikely cause; another cause should be sought

c. The result cannot be interpreted, because age-specific cut-offs apply over age 75

d. She has HF with nonreduced ejection fraction

Answer: b — In the acute setting, an NT-proBNP below 300 ng/L makes heart failure unlikely, so another cause is sought (b) (section 18.2). A "very likely" result (a) requires a much higher, age-adjusted level. Age raises levels and changes the rule-in cut-offs, but the test is still useful (c). The peptide does not tell the EF category; echocardiography does (d).

8. [CORE] Which instruction about daily weights is correct for a patient with heart failure in hospital?

a. Weigh after breakfast and morning medications so the result reflects a normal day

b. Use whichever scale is closest on the unit, as long as it is calibrated each year

c. Weigh only on days when new edema is visible in the ankles or sacrum

d. Weigh each morning on the same scale after voiding, in similar clothing

Answer: d — Weighing at the same time, on the same scale, after voiding and in similar clothing makes the trend reliable (d) (section 18.2). Weighing after a meal (a) or on different scales (b) adds error. Weight gain from fluid often comes before visible edema, so waiting for edema (c) delays detection.

9. [CORE] A patient with HFrEF is starting spironolactone. Which result should the nurse report before the first dose is given?

a. Potassium 5.4 mmol/L

b. Sodium 138 mmol/L

c. Hemoglobin 128 g/L

d. eGFR 62 mL/min/1.73 m^2

Answer: a — An MRA is not started when potassium is above 5.0 mmol/L, because hyperkalemia is its main risk (a) (section 18.3). The sodium (b) and hemoglobin (c) values do not affect starting an MRA. Spironolactone is not started when eGFR is below 30 mL/min/1.73 m^2; 62 (d) does not prevent it.

10. [CORE] A patient with heart failure is going home on empagliflozin. Which statement shows the teaching was understood?

a. "I'll take an extra tablet on days when my ankles look more swollen than usual."

b. "I need to stop eating fruit because this pill raises my potassium."

c. "If I'm vomiting and can't keep fluids down, I'll pause it and call my clinic."

d. "Itching or discharge in the genital area is expected, so I won't mention it."

Answer: c — A pause of the SGLT2 inhibitor is considered on sick days with poor intake or fluid loss, and the patient contacts the clinic or prescriber (c) (section 18.3). Patients never change doses on their own (a). Raised potassium is the concern with MRAs and RAAS blockers, not SGLT2 inhibitors (b). Genital itching or discharge suggests a mycotic infection and should be reported (d).

11. [CORE] Which finding suggests right-sided rather than left-sided heart failure?

a. Paroxysmal nocturnal dyspnea that wakes the patient

b. Raised jugular venous pressure with ascites

c. Fine crackles heard at both lung bases

d. Breathlessness when lying flat in bed at night

Answer: b — A raised JVP and ascites come from high pressure in the systemic veins, the hallmark of right-sided failure (b) (section 18.1; Table 18.2). Paroxysmal nocturnal dyspnea (a), crackles (c) and orthopnea (d) all reflect fluid in the lungs from left-sided failure.

12. [CORE] An RPN on a medical unit is caring for a patient with heart failure who has been stable. At 1400, the patient's SpO2 has fallen from 95% to 89% on room air and new crackles are heard. What should the RPN do?

a. Recheck the SpO2 at the next scheduled vital signs
b. Ask the patient to walk in the hallway to clear the lungs
c. Wait for the RN to complete medication rounds before reporting
d. Stay with the patient, act within the RPN's competence and inform the RN promptly

Answer: d — Any nurse who notices deterioration acts and escalates at once; the RPN consults the RN as the patient's needs change, and employer policy guides the details (d) (section 18.2; Chapter 1, section 1.3). Waiting for scheduled checks (a) or until rounds end (c) delays care. Walking (b) increases oxygen demand in a hypoxemic patient.

13. [CORE] A patient says, "I wake up about two hours after falling asleep, gasping, and have to sit at the edge of the bed." How should the nurse document this?

a. Paroxysmal nocturnal dyspnea
b. Orthopnea
c. Obstructive sleep apnea with snoring
d. Exertional dyspnea

Answer: a — Waking suddenly from sleep short of breath and needing to sit up is paroxysmal nocturnal dyspnea (a) (section 18.2). Orthopnea (b) is breathlessness on lying flat that eases on sitting up, without waking from sleep. Obstructive sleep apnea (c) involves pauses in breathing, often with snoring, that a partner notices. Exertional dyspnea (d) occurs with activity.

14. [CORE] A patient has heart failure with an ejection fraction of 52%. Which term do the current Canadian guidelines use for this patient?

a. Heart failure with reduced ejection fraction
b. Heart failure with improved ejection fraction
c. Heart failure with nonreduced ejection fraction
d. Heart failure with mildly reduced ejection fraction

Answer: c — The 2025 CCS/CHFS update uses heart failure with nonreduced ejection fraction for heart failure with an EF above 40% (c) (section 18.1). Reduced EF (a) is 40% or less. Improved EF (b) applies only when a previously reduced EF has risen above 40%. Mildly reduced EF (d) is an international term for 41% to 49%; Canadian guidelines include it within HFnrEF.

15. [CORE] A patient taking ramipril is to switch to sacubitril/valsartan. The last ramipril dose was at 0800 today. When is the earliest the first dose of sacubitril/valsartan can be given?

a. At 2000 today
b. At 2000 tomorrow
c. At 0800 tomorrow
d. Immediately, because both drugs treat HFrEF

Answer: b — Sacubitril/valsartan must not be given until at least 36 hours after the last ACE inhibitor dose, because of the risk of angioedema; 0800 plus 36 hours is 2000 the next day (b) (section 18.3). Twelve hours (a), 24 hours (c) and no gap (d) are all too soon.

16. [CORE] Which findings suggest low cardiac output in a patient with heart failure? Select all that apply.

a. New confusion
b. Ascites
c. Cool hands and feet
d. Urine output falling over several hours
e. Weight gain of 2 kg in two days
f. Slow capillary refill

Answer: a, c, d, f — Confusion (a), cool extremities (c), falling urine output (d) and slow capillary refill (f) show too little blood reaching the brain, skin and kidneys (section 18.2, Table 18.2). Ascites (b) and rapid weight gain (e) are signs of congestion from fluid retention, not of low output.

17. [CORE] A patient with heart failure asks what to take for knee pain. Which response is best?

a. "Ibuprofen is fine as long as you take it with food."
b. "Naproxen is safer than ibuprofen for your heart."
c. "Any pain reliever you can buy without a prescription is safe to take alongside your heart medicines."
d. "Avoid anti-inflammatory pain relievers such as ibuprofen; ask your prescriber or pharmacist."

Answer: d — NSAIDs blunt diuretics, can worsen kidney function and add to hyperkalemia with an MRA, so patients avoid them and seek advice on alternatives (d) (section 18.3). Taking an NSAID with food (a) protects the stomach, not the heart or kidneys. Naproxen (b) is also an NSAID. Many nonprescription products contain NSAIDs (c).

18. [RN] A patient with acute heart failure has crackles, edema of both legs, cold hands and feet, new confusion and low urine output. Which profile does this describe?

a. Warm and wet
b. Warm and dry
c. Cold and wet
d. Cold and dry

Answer: c — Crackles and edema show congestion ("wet"); cold extremities, confusion and low urine output show poor perfusion ("cold") (c) (section 18.2, Going Deeper). Warm and wet (a) has congestion with adequate perfusion. Warm and dry (b) is compensated. Cold and dry (d) has poor perfusion without congestion.

19. [RN] For the patient in the previous question, which statement about inotropes is consistent with current guidance?

a. They are not used routinely unless cardiogenic shock is present.
b. They are first-line treatment for every patient admitted with acute decompensated heart failure.
c. They replace IV loop diuretics in patients who are warm and wet, because they work faster.
d. They are started on general medical units before discharge to help prevent readmission.

Answer: a — Inotropes are not recommended routinely in the absence of cardiogenic shock; a cold and wet patient needs critical care assessment, where they may be considered (a) (section 18.2, Going Deeper; Chapter 6). They are not first-line for all patients (b). Warm and wet patients need decongestion, usually with IV loop diuretics (c). Inotropes need critical care monitoring and do not prevent readmission (d).

20. [RN] A patient taking sacubitril/valsartan for 3 months has a rising BNP. The prescriber orders an NT-proBNP instead. What is the reason?

a. NT-proBNP is cheaper and faster to run in most Canadian hospital laboratories.

b. Neprilysin breaks down BNP, so sacubitril raises it; NT-proBNP is not affected.

c. BNP cannot be measured in patients with HFrEF.

d. Valsartan lowers NT-proBNP to normal, which confirms the drug is working.

Answer: b — BNP is a substrate of neprilysin, so blocking neprilysin raises BNP independent of heart failure status; NT-proBNP is the peptide to follow (b) (section 18.2). Cost and speed (a) are not the reason; the issue is the drug's effect on BNP. BNP can be measured in HFrEF (c). A normal NT-proBNP is not the treatment goal, and valsartan does not normalize it (d).

Case: Jordan (Questions 21–24): Jordan, 31, who injects opioids, is admitted to a medical unit with 5 days of fever, chills and fatigue. Temperature is 38.9 °C, heart rate 112 beats/min, blood pressure 108/64 mm Hg. A new murmur is heard. The admission orders include blood cultures and intravenous antibiotics.

21. [CORE] Which action should the nurse take first?

a. Give the first dose of the intravenous antibiotic, then draw the cultures.

b. Arrange transthoracic echocardiography.

c. Teach Jordan about dental hygiene.

d. Draw the ordered blood culture sets before the antibiotic.

Answer: d — Blood cultures are drawn before the first antibiotic dose because antibiotics can prevent the organism from growing (section 18.6). Giving the antibiotic first (a) risks a negative culture; it follows promptly after cultures. Echocardiography (b) is needed but does not come before cultures. Dental teaching (c) is important later, not first.

22. [CORE] While assessing Jordan's hands, the nurse notes thin dark red-brown lines under two fingernails. How should the nurse interpret this finding?

a. Expected trauma from manual work

b. Splinter hemorrhages, which support possible endocarditis

c. A sign of iron deficiency that needs a dietary referral

d. A normal variation in nail pigment that needs no follow-up

Answer: b — Thin red-brown to dark lines under the nails are splinter hemorrhages, a sign that supports endocarditis (section 18.6). Trauma (a) and normal pigment variation (d) should not be assumed in a febrile patient with a new murmur; the nurse compares with the person's usual nail colour. Iron deficiency (c) causes other nail changes, such as spoon-shaped nails.

23. [CORE] Jordan tells the nurse, "I'm getting sick from withdrawal and I'm going to leave." Which response by the nurse is most appropriate?

a. "Withdrawal is something we treat. I'll ask the team to see you now about medicine for it."

b. "If you leave, you will not be allowed to come back to this hospital."

c. "You should have thought about withdrawal before you used."

d. "I can't do anything about withdrawal until your infection has been fully treated."

Answer: a — Untreated withdrawal is a common reason people leave before treatment ends; prompt assessment, treatment and an addiction medicine consultation, including opioid agonist treatment, support staying (section 18.6; Chapter 11). Threats (b) and blame (c) are stigmatizing and increase the risk of patient-directed discharge. Withdrawal can be treated now (d), alongside the infection.

24. [CORE] On day 6, Jordan develops sudden weakness of the right arm and slurred speech. What should the nurse do first?

a. Document the findings and reassess in 1 hour.

b. Give acetaminophen and recheck the temperature.

c. Activate the stroke or rapid response protocol and stay with Jordan.

d. Ask Jordan whether he used any drugs on the unit before calling anyone.

Answer: c — Sudden focal neurologic signs in a person with endocarditis suggest an embolic stroke, an emergency that requires immediate escalation (section 18.6; Chapter 6). Waiting (a) delays time-sensitive treatment. Acetaminophen (b) does not address the cause. Questioning drug use (d) is not the priority and delays care.

25. [CORE] A patient with HF reports by phone that her weight has risen from 72.0 kg to 74.5 kg over the past 2 days and that she needed an extra pillow last night. What is the nurse's best action?

a. Arrange for the patient to be assessed by the HF team today.

b. Tell her to recheck her weight in 1 week.

c. Advise her to stop drinking fluids until her weight returns to normal.

d. Tell her to double her diuretic dose without consulting the prescriber.

Answer: a — A gain of more than 2 kg over two days plus new orthopnea are yellow-zone cues that call for prompt assessment by the HF team (section 18.4). Waiting a week (b) risks decompensation. Stopping all fluids (c) is unsafe and not part of the plan. Changing the dose without an order or a written plan (d) is unsafe.

26. [CORE] Which instruction about daily weights is correct?

a. Weigh yourself at any time of day as long as you do it daily.

b. Weigh yourself in the morning after you empty your bladder and before breakfast.

c. Weigh yourself after breakfast, wearing your shoes.

d. Weigh yourself once a week, using a different scale each time to compare readings.

Answer: b — Weighing each morning after voiding and before breakfast, on the same scale and in similar clothing, makes day-to-day changes meaningful (section 18.4). Varying the time (a), weighing after a meal in shoes (c) or weekly on different scales (d) adds error and misses early change.

27. [CORE] A patient with HF asks whether he must keep his sodium intake as low as possible. Which response reflects current evidence?

a. "You need to eat no sodium at all."

b. "Sodium doesn't matter in heart failure anymore."

c. "Very strict limits haven't been shown to prevent hospital stays, so we'll set a realistic goal with your dietitian."

d. "Sodium matters only if you also have high blood pressure, so we'll check that before setting any limit."

Answer: c — The SODIUM-HF trial found that targeting less than 1,500 mg a day did not significantly reduce death or cardiovascular hospital and emergency visits, so teaching is individualized (section 18.4). Zero sodium (a) is neither possible nor recommended. Sodium still matters (b, d), especially high-sodium processed foods.

28. [CORE] Which over-the-counter product should the nurse teach a patient with HF to avoid unless a prescriber approves it?

a. Acetaminophen

b. A saline nasal spray

c. A calcium supplement

d. Ibuprofen

Answer: d — NSAIDs such as ibuprofen blunt the effect of diuretics and can worsen kidney function, so people with HF avoid them (section 18.4). Acetaminophen (a), used as directed, does not have these effects. Saline spray (b) and calcium (c) are not linked to HF worsening in the same way, although the patient should still check with a pharmacist.

29. [CORE] An 84-year-old with HF is started on a loop diuretic. Which finding is the priority for the nurse to report?

a. A drop in systolic blood pressure from 128 to 98 mm Hg on standing, with dizziness

b. Increased urine output in the first few hours

c. A 0.5 kg weight loss the next morning

d. Mild thirst

Answer: a — Orthostatic hypotension with dizziness puts an older adult at high risk of falls and needs prompt reporting and a safety plan (section 18.4, Lifespan Considerations box). Increased urine output (b) and modest weight loss (c) are expected effects. Mild thirst (d) is common and less urgent.

30. [CORE] A patient with severe aortic stenosis is waiting for TAVI. Which new order should the nurse clarify with the prescriber before acting on it?

a. Daily weights before breakfast

b. Sublingual nitroglycerin as needed for chest pain

c. Continuous telemetry monitoring

d. A heart-healthy diet that is low in saturated fat and sodium

Answer: b — In severe aortic stenosis, the ventricle depends on adequate filling. Nitrates dilate blood vessels and can cause a sudden fall in blood pressure and syncope, and the ACC/AHA guideline warns against abruptly lowering blood pressure with a narrowed valve, so the nurse clarifies the order (section 18.5). Daily weights (a), telemetry (c) and a heart-healthy diet (d) do not pose this risk.

31. [CORE] A patient with a mechanical mitral valve asks to change from warfarin to "one of the new blood thinners that don't need blood tests." What is the nurse's best response?

a. "That's a good idea; I'll ask your provider to switch you."

b. "You can switch once your INR has stayed in your target range for a few months."

c. "Those drugs are not safe with a mechanical valve, so warfarin is still needed."

d. "You can take both drugs together for extra protection."

Answer: c — DOACs, including dabigatran and factor Xa inhibitors, are contraindicated with mechanical valves; warfarin with INR monitoring is required (section 18.5, Clinical Safety box). Options a and b would expose the patient to valve thrombosis. Combining anticoagulants (d) greatly increases bleeding risk without benefit.

32. [CORE] Which statement by a patient taking warfarin for a mechanical aortic valve shows correct understanding?

a. "I'll keep the amount of leafy greens I eat about the same each week."

b. "I'll stop eating all green vegetables."

c. "I'll take ibuprofen for my back pain."

d. "If I miss a dose, I'll take three tablets the next day to make up for it."

Answer: a — A steady intake of vitamin K–rich foods keeps the INR stable (section 18.5, Clinical Safety box). Avoiding all greens (b) is unnecessary and can make the INR unstable when intake changes. NSAIDs (c) increase bleeding risk. Tripling a dose (d) can cause a dangerously high INR; missed doses are managed as the prescriber directs.

33. [CORE] Two days after cardiac surgery, a patient becomes restless. Blood pressure has fallen from 118/70 to 84/66 mm Hg, heart rate is 128 beats/min, neck veins are distended and heart sounds are muffled. What should the nurse do first?

a. Give the scheduled furosemide.

b. Reposition the patient flat and recheck vital signs in 30 minutes.

c. Encourage deep breathing and coughing.

d. Call the rapid response team and stay with the patient.

Answer: d — Hypotension, distended neck veins, muffled heart sounds and tachycardia suggest cardiac tamponade, an emergency needing immediate escalation and drainage (section 18.7). A diuretic (a) lowers preload and could worsen shock. Waiting (b) delays care. Breathing exercises (c) do not address the cause.

34. [CORE] A patient with acute pericarditis is discharged on an NSAID and colchicine. Which teaching point is correct?

a. Stop taking the colchicine as soon as the chest pain has gone away completely, to avoid side effects.

b. Avoid strenuous activity for now; your team will tell you when to increase it.

c. Lying flat will relieve the pain.

d. Take the NSAID only if the pain becomes severe.

Answer: b — The 2025 ESC guideline restricts physical activity for an initial period, then individualizes it (section 18.7). Colchicine continues for months and is the last drug stopped (a), which helps prevent recurrence. Pain typically eases when sitting forward, not lying flat (c). The NSAID is given on a schedule as prescribed (d).

35. [CORE] An RPN caring for a stable patient receiving IV antibiotics for endocarditis notes a new fever of 39.2 °C, a respiratory rate of 26 breaths/min and new confusion. What should the RPN do?

a. Give acetaminophen and reassess at the end of the shift.

b. Wait for the RN to make rounds.

c. Document the findings for the next day's team.

d. Act at once to escalate, including rapid response, and inform the RN.

Answer: d — Every nurse who notices deterioration acts at once and escalates; the RPN also consults the RN as the patient's needs change (section 18.7, Scope in Practice box; Chapter 6). Treating the fever and waiting (a), waiting for rounds (b) or documenting only (c) delay care for possible sepsis.

36. [CORE] A nurse on a medical unit is asked to interpret a new telemetry rhythm but has not completed the unit's rhythm interpretation education. According to CNO's Scope of Practice standard, what should the nurse do?

a. Seek help from a colleague who has the competence and arrange the education.

b. Interpret the rhythm anyway, because nurses have authority to monitor patients.

c. Ignore the alarm until a physician arrives.

d. Refuse to care for any patient on telemetry.

Answer: a — Competence is one of the three considerations, with authority and context; a nurse who lacks it seeks help and gains it (section 18.7, Scope in Practice box). Authority alone (b) is not enough. Ignoring the alarm (c) is unsafe. Refusing all telemetry patients (d) does not address the immediate need.

37. [CORE] Which statements about hypertrophic cardiomyopathy should the nurse include when teaching a young adult who has just been diagnosed? Select all that apply.

a. "Your parents, siblings and children may be offered heart screening."

b. "It's important to stay well hydrated."

c. "Report any fainting, especially during exercise."

d. "You will never be able to exercise again."

e. "This condition is caused by a past viral infection."

f. "Your team will assess your risk of a dangerous heart rhythm."

Answer: a, b, c, f — First-degree relatives are offered screening (a); fluid status affects outflow obstruction, so hydration matters (b); exertional fainting is a warning sign (c); and sudden cardiac death risk assessment guides decisions about an ICD (f) (section 18.7). A blanket ban on exercise is not recommended (d); activity is planned through shared decision-making. The condition is usually inherited, not viral (e).

38. [RN] A nurse measures pulsus paradoxus in a patient with a known pericardial effusion. Korotkoff sounds are first heard during expiration only at 124 mm Hg and are heard with every beat at 108 mm Hg. How should the nurse interpret this?

a. Normal respiratory variation

b. A pulsus paradoxus of 16 mm Hg, supporting possible tamponade

c. A pulsus paradoxus of 8 mm Hg, ruling out tamponade

d. A measurement error, because the sounds should first appear at the same pressure throughout breathing

Answer: b — The difference between 124 and 108 mm Hg is 16 mm Hg; a value above 10 mm Hg when an effusion is present raises the likelihood of tamponade, and echocardiography confirms it (section 18.7, Going Deeper box). It is not normal variation (a). The calculation in (c) is wrong. Sounds normally appear at slightly different pressures during the breathing cycle (d).

39. [RN] Using the 2023 Duke-ISCVID criteria, which combination classifies a patient as having definite endocarditis?

a. One major criterion only

b. Three minor criteria

c. One major and one minor criterion

d. Two major criteria

Answer: d — Definite endocarditis requires two major, one major plus three minor, or five minor criteria (section 18.7, Going Deeper box). One major alone (a) is insufficient. Three minor (b) and one major plus one minor (c) classify endocarditis as possible.

40. [RN] Which finding counts as a major criterion in the 2023 Duke-ISCVID criteria?

a. Temperature of 38.6 °C

b. Osler nodes on the finger pads

c. Staphylococcus aureus grown from two separate blood culture sets

d. A history of injection drug use

Answer: c — A typical organism grown from two or more separate blood culture sets is a major microbiologic criterion (section 18.7, Going Deeper box). Fever above 38.0 °C (a), immunologic signs such as Osler nodes (b) and predisposing conditions such as injection drug use (d) are minor criteria.

19 Hypertension and Vascular Disorders

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Measure blood pressure accurately in clinic, hospital and home settings, and classify it using Hypertension Canada's 2025 thresholds.
2. Explain the causes and risk factors of hypertension using Canadian data, naming structural causes.
3. Support treatment of hypertension (lifestyle, drug classes, adherence and teaching), with attention to older adults.
4. Recognize a hypertensive emergency and an acute aortic syndrome, and escalate.
5. Assess and care for patients with peripheral arterial disease and acute limb ischemia, describing findings on a range of skin tones.
6. Recognize, prevent and help manage venous thromboembolism and chronic venous disease.
7. Give and monitor anticoagulants safely (heparins, warfarin and DOACs), including teaching, bleeding recognition and reversal.
8. Distinguish RN and RPN roles in vascular care and anticoagulation using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4, 5, 6	Clinician; Scholar	Foundations of Practice
3, 7	Clinician; Educator; Advocate	Foundations of Practice; Collaborative Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

High blood pressure is one of the most common long-term conditions nurses meet in adults. It rarely causes symptoms, yet over years it damages the arteries, heart, brain, kidneys and eyes. Nurses measure blood pressure in every setting, teach people to measure it at home, give the drugs that lower it and notice when it climbs high enough to harm organs within hours. Doing this well depends on accurate measurement and on knowing what Canada's current guideline says.

This chapter begins with hypertension: how blood pressure is regulated, how hypertension is defined and measured, and its causes and risk factors (section 19.1). It then covers lifestyle and drug treatment and care in hospital (19.2), followed by severe hypertension, hypertensive emergencies and acute aortic syndromes (19.3). The second half turns to the vessels themselves: peripheral arterial disease and acute limb ischemia (19.4), abdominal aortic aneurysm (19.5), and venous disease and venous thromboembolism (19.6). The chapter ends with anticoagulation (19.7). This chapter is the book's home for anticoagulant drugs, their monitoring, bleeding, reversal and patient teaching, so other chapters point here.

The chapter builds on cardiac output (section 16.1), focused cardiovascular assessment, including pulses (16.2), atherosclerosis and its risk factors (Chapter 17), and heart failure (Chapter 18). Venous thromboembolism prevention around surgery is taught in Chapter 7, and pulmonary embolism in Chapter 15. Recognizing deterioration and calling for help, which every section here relies on, is covered in Chapter 6.

19.1 Hypertension: Measurement and Risk

How Blood Pressure Is Regulated

Blood pressure is the force that blood exerts on artery walls. It depends on two things: cardiac output, which is the volume of blood the heart pumps each minute (section 16.1), and **systemic vascular resistance**, the resistance that small arteries and arterioles offer to that flow. A rise in either raises blood pressure.

Several systems adjust these two factors from moment to moment and over the long term:

- **Sympathetic nervous system:** baroreceptors in the carotid arteries and aortic arch sense stretch. When pressure falls, sympathetic activity rises, the heart beats faster and harder, and arterioles constrict. This fast response explains why pain, fear and a full bladder raise readings.
- **Renin–angiotensin–aldosterone system (RAAS):** when blood flow to the kidneys falls, the kidneys release renin. This leads to the formation of angiotensin II, which constricts arterioles and prompts the adrenal glands to release aldosterone. Aldosterone makes the kidneys hold sodium and water, which expands blood volume.
- **The kidneys and sodium:** over days and weeks, the kidneys set blood pressure by controlling how much sodium and water the body keeps. A diet high in sodium, or kidneys that cannot excrete it, keeps volume and pressure high.

In sustained hypertension, these controls reset at a higher level. Arterioles thicken and stiffen, which raises resistance further. Several drug classes in section 19.2 work by blocking one of these systems.

Defining Hypertension

Hypertension is a blood pressure persistently above the level at which the risk of heart attack, stroke, heart failure and kidney disease clearly rises. Hypertension Canada's 2025 guideline for adults in primary care defines hypertension as a blood pressure of 130/80 mm Hg or higher, taken with a validated device and standardized technique (Goupil et al., 2025). The guideline uses this single threshold for every measurement method; it does not give separate cut-offs for office, home or ambulatory readings (Table 19.1).

This is lower than Hypertension Canada's earlier advice. The 2020 guidelines used thresholds that differed by method, for example 135/85 mm Hg for automated office and home readings and 140/90 mm Hg for other office readings (Rabi et al., 2020). The 2025 authors note that more people will now be labelled as having hypertension (Goupil et al., 2025). Nurses will meet both sets of numbers in older charts and resources and should use the current one.

Table 19.1 Blood pressure thresholds by measurement method (Hypertension Canada, 2025; original wording)

Method	How it is done	Threshold for hypertension	Notes
Automated office blood pressure (AOBP)	A validated automated upper-arm device takes several readings at set intervals and averages them, with the patient seated and rested	130/80 mm Hg or higher	Validated automated devices are preferred to manual ones
Standardized office reading by other methods, including manual (auscultatory)	A trained person measures with a validated device or a manual sphygmomanometer and stethoscope, using standard technique	130/80 mm Hg or higher	Manual measurement is preferred when an arrhythmia makes automated readings unreliable
Home blood pressure monitoring (HBPM)	The person measures at home with a validated device, two readings each morning and evening for 1 week	130/80 mm Hg or higher	Confirms the diagnosis; detects white-coat and masked hypertension
Ambulatory blood pressure monitoring (ABPM)	A worn device records blood pressure every 20 to 30 minutes over a day and night	130/80 mm Hg or higher	Confirms the diagnosis; the 2025 guideline gives no separate daytime, night or 24-hour cut-offs

Measuring Blood Pressure Well

A diagnosis and every treatment decision rest on accurate readings. Hypertension Canada recommends a validated automated device and a standardized method (Goupil et al., 2025).

Automated office blood pressure (AOBP) uses a validated automated upper-arm device that takes several readings in a row and averages them. Hypertension Canada describes a seated rest of 1 to 5 minutes, if feasible, then 3 readings 1 minute apart that are averaged (Goupil et al., 2025). The patient sits with the back and feet supported, legs uncrossed, and the bare arm supported at heart level. The lower edge of a correctly sized cuff sits about 3 cm above the elbow crease. Caffeine, tobacco and exercise are avoided for 30 minutes beforehand.

Figure 19.1 An aneroid sphygmomanometer: an adult cuff with its size label and range marks, a dial gauge and an inflation bulb. The range marks show whether the cuff fits the arm.

When an office reading is raised, the guideline recommends confirming it out of the office before making the diagnosis (Goupil et al., 2025). **Home blood pressure monitoring (HBPM)** means the person measures at home with a validated device; the standard protocol is two readings, twice a day, for 1 week. Hypertension Canada keeps a list of recommended home devices (Hypertension Canada, n.d.). **Ambulatory blood pressure monitoring (ABPM)** uses a device worn for a day and night that inflates every 20 to 30 minutes. If neither is possible, standardized office readings are repeated at a separate visit (Goupil et al., 2025).

Nurses still use the manual (auscultatory) method (Figure 19.1), and the guideline prefers it when a persistent or frequent arrhythmia makes automated devices inaccurate (Goupil et al., 2025). The technique below follows a British Columbia guideline appendix based on earlier Hypertension Canada (Canadian Hypertension Education Program) recommendations (Guidelines and Protocols Advisory Committee, n.d.):

- **Prepare:** the patient rests quietly, seated, for about 5 minutes, with the back supported, feet flat and legs uncrossed. Neither the patient nor the nurse talks.
- **Size the cuff:** the bladder width is about 40% of the arm's circumference and its length covers 80% to 100% of it. The nurse measures the mid-upper arm rather than guessing (Figure 19.2).
- **Place the cuff:** on the bare arm, with the bladder centred over the brachial artery and the lower edge about 3 cm above the elbow crease. The arm is supported so the elbow crease is level with the heart.
- **Estimate the systolic pressure:** the nurse feels the radial pulse, inflates until it disappears, then inflates about 30 mm Hg higher. This avoids missing an auscultatory gap, a silent interval that can lead to a falsely low systolic reading.
- **Deflate slowly:** about 2 mm Hg per heartbeat. The first clear tapping sound is the systolic pressure; the point where sounds disappear is the diastolic pressure.
- **Repeat and record:** wait at least 1 minute between readings. Record the values, the arm used, the position and the pulse. Measure both arms at least once and use the arm that reads higher from then on.

An arm that hangs below heart level gives falsely high systolic and diastolic readings. A cuff of the wrong size, an unsupported back, crossed legs and talking also make readings unreliable, so each is avoided. Deflating too fast makes the exact systolic and diastolic points easy to miss. Leaving the cuff partly inflated too long fills the veins of the arm and makes the sounds hard to hear (Guidelines and Protocols Advisory Committee, n.d.).

Measuring outside the office reveals two patterns. **White-coat hypertension** is raised office blood pressure with normal out-of-office readings. **Masked hypertension** is the reverse: normal office readings with raised readings at home or on ambulatory monitoring (Rabi et al., 2020). Both are common. Hypertension Canada's 2020 guidelines put the prevalence of white-coat

Figure 19.2 Blood pressure cuffs come in many sizes, from neonatal to large adult and thigh cuffs. A cuff of the wrong size makes readings unreliable, so the arm is measured to choose the size. (credit: "Sizes of blood pressure cuffs" by Chippewa Valley Technical College, CC BY 4.0)

hypertension at between 9% and 30%, and suggested that masked hypertension may affect about 20% of untreated adults. Masked hypertension is more likely in people with high-normal office readings, diabetes, obesity, smoking or heavy alcohol use (Rabi et al., 2020). People with white-coat hypertension may be treated unnecessarily, while masked hypertension is missed unless someone checks. This is one reason the nurse encourages home readings rather than relying on a single clinic visit.

Causes and Risk Factors

Most adults have **primary hypertension**, which develops over time from a mix of genetic, ageing and lifestyle influences, with no single cause. **Secondary hypertension** has an identifiable cause that may be treatable. Causes include chronic kidney disease (Chapter 27), narrowing of a renal artery, **primary aldosteronism** (overproduction of aldosterone by the adrenal glands), sleep apnea and some drugs. Drugs that can raise blood pressure include nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, sympathomimetics such as some decongestants, stimulants such as amphetamines and cocaine, calcineurin inhibitors, erythropoietin and licorice (Rabi et al., 2020). Hypertension Canada advises screening for secondary causes when hypertension is resistant to treatment and checking aldosterone and renin for primary aldosteronism. Specialist referral is advised for unexplained, sudden worsening of blood pressure, low potassium or an adrenal nodule (Goupil et al., 2025).

In Canadian Health Measures Survey data, risk rose with age, overweight or obesity, low physical activity and eating fruit and vegetables fewer than five times a day; diabetes was the strongest predictor, and chronic kidney disease was a risk factor for women (Statistics Canada, 2019). In the Canadian Health Measures Survey (CHMS) for 2016 to 2019, 23% of adults aged 20 to 79 had what the survey called stage 2 hypertension: a measured reading of 140/90 mm Hg or higher, a diagnosis by a health care professional, or use of blood pressure medication in the past month. That included 51% of adults aged 60 to 79. About 29% of this group did not know they had it, and about 51% were treated with medication and controlled below 140/90 mm Hg (Statistics Canada, 2021). These figures predate the 130/80 mm Hg threshold, so they understate the share now defined as hypertensive.

Blood pressure is also shaped by where and how people live. Hypertension Canada notes that in a typical Western diet, more than 70% of sodium comes from processed foods rather than the salt shaker (Goupil et al., 2025), so food environments, food costs and time to cook matter as much as personal choice. Low income, racism, unstable housing and distance from primary care all make diagnosis, regular follow-up and medications harder to reach. The nurse names these causes rather than blaming the person, and looks for local supports (Chapter 2).

CANADIAN CONTEXT

Blood Pressure Across Canada

- About one in four adults aged 20 to 79 in the 2016 to 2019 CHMS had hypertension by the older 140/90 mm Hg definition. Among those aged 60 to 79, the figure was about half (Statistics Canada, 2021).
- Close to 3 in 10 people in that group were unaware of their hypertension. Of those with readings of 130 to 139 systolic or 80 to 89 diastolic, nearly three-quarters were unaware (Statistics Canada, 2021).
- In a 2017 health survey of 1,177 Inuit adults in Nunavik, 23% had hypertension (140/90 mm Hg or higher, or taking medication for it): 29% of men and 18% of women. About a third (34%) of those with hypertension were taking medication (Allaire et al., 2024). Remote location, travel for care and the cost and supply of fresh food affect both prevention and treatment in northern communities.
- Under the First Nations principles of OCAP® (ownership, control, access and possession), First Nations control how data about their communities are collected, used and shared (Chapter 2). The nurse uses distinctions-based data as each Nation or

organization publishes it.

- Under the 2025 threshold, more Canadians will meet the definition of hypertension, which increases demand for accurate measurement and follow-up in primary care (Goupil et al., 2025).

PATIENT EDUCATION

Measuring Your Blood Pressure at Home

- Buy a monitor that is validated and on Hypertension Canada's recommended list. An upper-arm cuff that fits your arm is best; ask the nurse or pharmacist to check the size.
- Measure in the morning and evening for 7 days before your next appointment or after your medication is changed.
- For 30 minutes before, do not smoke, drink coffee or other caffeine, or exercise. Empty your bladder first.
- Place the cuff directly on your skin, not over a sleeve. Sit quietly for 5 minutes with your back supported, feet flat on the floor and legs uncrossed. Rest your arm on a table so the cuff is level with your heart.
- Do not talk or look at your phone while the cuff inflates.
- Take two readings, 1 minute apart, each time.
- Write down every reading with the date and time, or use a monitor that stores them, and bring the record to your appointment.
- Tell your health care provider if your readings are often higher than usual. Call 9-1-1 right away for signs of a heart attack, such as chest discomfort or shortness of breath, or for signs of a stroke, whatever your reading.

(Goupil et al., 2025; Heart and Stroke Foundation of Canada, n.d.-a, n.d.-b; Hypertension Canada, n.d.)

19.2 Treating Hypertension

Lifestyle

Lifestyle change is recommended for every adult with hypertension, whether or not drugs are started (Goupil et al., 2025). The 2025 guideline cites these targets, several of them from the World Health Organization:

- **Sodium:** less than 2 g of sodium a day. Because most sodium comes from processed and restaurant food, teaching focuses on reading labels and cooking more meals from whole ingredients.
- **Potassium:** more than 3.5 g a day, mainly from vegetables and fruit. People with chronic kidney disease or taking an angiotensin-converting enzyme (ACE) inhibitor, an angiotensin receptor blocker (ARB) or a mineralocorticoid receptor antagonist need their potassium monitored, because their levels can rise too high (Chapter 3).
- **Physical activity:** 150 to 300 minutes of moderate aerobic activity each week.
- **Weight:** weight loss lowers blood pressure in people living with obesity. Glucagon-like peptide-1 (GLP-1) receptor agonists used for weight loss also lower blood pressure.
- **Alcohol:** cutting back lowers blood pressure in a dose-dependent way, with clear benefit in people who drink 3 or more drinks a day.
- **Smoking:** everyone with hypertension is counselled to quit (Chapter 14).

Teaching works best when it is practical. The nurse shows the person how to find sodium on a Nutrition Facts table, suggests swapping one high-sodium convenience food at a time, and explains that vegetables, fruit, beans and lentils supply potassium. Because high potassium is dangerous for some people, the nurse checks kidney function and the medication list before encouraging potassium-rich foods or salt substitutes made with potassium chloride. The nurse starts with what matters to the person and chooses one or two changes at a time. Cost, food access, shift work, disability and safe places to walk all shape what is realistic, so the nurse plans with the person rather than handing over a list.

Drug Treatment

Hypertension Canada recommends starting medication when blood pressure is 140/90 mm Hg or higher. When systolic pressure is 130 to 139 mm Hg, drugs are started only for people at high cardiovascular risk: those with established cardiovascular disease, diabetes, chronic kidney disease (estimated glomerular filtration rate below 60 mL/min/1.73 m² or albuminuria of 3 mg/mmol or

more), a 10-year Framingham risk score of 20% or more, or age 75 or older. Others focus on lifestyle and are reassessed in 3 to 6 months (Goupil et al., 2025).

The treatment target is a systolic pressure below 130 mm Hg, as long as treatment is well tolerated; the guideline sets no diastolic target. Exceptions include frailty, a high risk of falls, orthostatic hypotension and the person's goals of care. For these patients, the aim is the lowest systolic pressure that can reasonably be reached, decided case by case (Goupil et al., 2025).

The guideline names three first-line classes (Goupil et al., 2025):

- ACE inhibitors or ARBs, which block the RAAS;
- thiazide or thiazide-like diuretics, which increase sodium and water loss in the kidney;
- long-acting dihydropyridine calcium channel blockers, which relax arterial smooth muscle.

Treatment usually starts with low doses of two of these classes, ideally combined in one tablet. A **single-pill combination** contains two or more drugs in one tablet. It simplifies the routine, which helps adherence, and in Canada it usually costs less than the separate drugs. The guideline's preferred first pill combines irbesartan and hydrochlorothiazide; the panel chose it for reasons that included cost, drug-plan coverage and supply, and says the choice may be revisited. If the target is not reached, the third class is added. If blood pressure stays high on all three, spironolactone may be added, with potassium checked 2 to 4 weeks after it is started or the dose changes. An ACE inhibitor and an ARB are never combined. When a person is at high risk of symptomatic low blood pressure, starting with one drug is reasonable (Goupil et al., 2025).

Beta-blockers are not first-line for hypertension alone. They are used when there is another reason for them, such as heart failure, angina, a past myocardial infarction or heart rate control (Goupil et al., 2025). ACE inhibitors and ARBs must be avoided in pregnancy and stopped in people trying to become pregnant, so the nurse makes sure people who could become pregnant know this (Chapter 29).

Hypertension that stays above target despite three first-line drugs is usually called resistant hypertension. Before more drugs are added, the team checks that the person is taking the medications, that readings are accurate and that no other drug is raising the pressure. Hypertension Canada advises screening people with resistant hypertension for secondary causes, including primary aldosteronism, ideally before spironolactone is started (Goupil et al., 2025).

After an ACE inhibitor, ARB, diuretic or spironolactone is started or its dose changes, blood work for potassium, sodium and creatinine is commonly ordered; the nurse makes sure it is done and reports abnormal values (Chapter 3). Home readings brought to follow-up visits show whether the regimen is working. Hypertension Canada advises follow-up every 1 to 3 months until the target is reached, then every 6 to 12 months (Goupil et al., 2025). Many people stop their drugs because they feel well, have side effects or cannot afford them. The nurse asks about missed doses without judgment, checks whether a drug plan covers the medication, explains that the drugs work only while they are taken, and asks the prescriber or pharmacist about simpler or lower-cost options. Pill organizers, pharmacy blister packs, linking doses to a daily routine and home readings that show progress can all help people keep taking their medications.

MEDICATIONS

Antihypertensive Classes

Examples are generic names marketed in Canada. Doses follow the order and the Canadian product monograph.

- **ACE inhibitors** (for example, ramipril, perindopril): block the formation of angiotensin II. Check potassium and creatinine after starting. A dry cough can occur. Swelling of the lips, tongue or throat (angioedema) is an emergency.
- **ARBs** (for example, candesartan, irbesartan, telmisartan): block angiotensin II receptors. Check potassium and creatinine; cough is less common than with ACE inhibitors. Never given with an ACE inhibitor.
- **Thiazide and thiazide-like diuretics** (for example, hydrochlorothiazide, chlorthalidone, indapamide): increase sodium and water loss. Check sodium and potassium; watch for dizziness and dehydration, especially in heat or with vomiting or diarrhea.
- **Long-acting dihydropyridine calcium channel blockers** (for example, amlodipine): relax arterial smooth muscle. Ankle swelling, flushing and headache can occur.
- **Beta-blockers** (for example, bisoprolol, metoprolol): slow the heart and lower its force. Check apical pulse and blood pressure; teach not to stop suddenly. Not first-line for hypertension alone.

- **Spironolactone** (fourth drug for resistant hypertension): blocks aldosterone. Check potassium 2 to 4 weeks after starting or a dose change; counsel about possible breast enlargement (gynecomastia).
- **ACE inhibitors and ARBs in pregnancy:** must be avoided; teach people who could become pregnant.

(Goupil et al., 2025)

In Hospital

In hospital, the nurse checks blood pressure and heart rate before giving an antihypertensive and follows the hold parameters written in the order. If the order has none and the reading seems low for the patient, the nurse holds the dose and contacts the prescriber rather than guessing. Every hold is documented and reported. Patients who are acutely ill, vomiting, not eating or newly dehydrated may need their usual antihypertensives adjusted, so the nurse reports these changes rather than giving every home drug automatically. Whether to give antihypertensives on the morning of surgery is decided by the surgical and anesthesia teams (Chapter 7).

Patients newly started on antihypertensives, given diuretics or receiving several blood-pressure-lowering drugs need **orthostatic vital signs**. The nurse measures blood pressure and pulse after the patient has been lying down, then again after standing for up to 3 minutes. **Orthostatic hypotension** is a sustained fall of at least 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes of standing (Freeman et al., 2011). Dizziness on standing is a falls warning: the nurse has the patient sit on the edge of the bed first, stands with them and reports the finding (Chapter 8).

A single high reading in a patient who is in pain, anxious, short of breath or needing to void is usually a response to that stress. The nurse treats the cause, rechecks the reading with good technique after a rest and looks for symptoms, rather than calling for an extra antihypertensive dose straight away. A very high reading with symptoms such as headache, chest pain, shortness of breath, confusion or weakness is different and is escalated at once (section 19.3).

Admission and discharge are high-risk points for medication errors. The nurse compares the home list with what is ordered, including combination pills, over-the-counter drugs (such as NSAIDs and decongestants) and natural health products, and makes sure the patient leaves knowing which drugs to continue. If the patient owns a home monitor, the nurse can check the cuff size and the patient's technique before discharge.

LIFESPAN CONSIDERATIONS

Older Adults, Targets and Falls

- **Older adults:** hypertension is most common in later life. Age 75 or older counts as high cardiovascular risk in the 2025 guideline, so drug treatment is considered from a systolic pressure of 130 mm Hg (Goupil et al., 2025).
- The systolic target of under 130 mm Hg applies only when treatment is well tolerated. For a person living with frailty, a high falls risk or orthostatic hypotension, or whose goals of care point elsewhere, the target is set individually at the lowest level reasonably achievable (Goupil et al., 2025).
- Orthostatic hypotension, dehydration, several blood-pressure-lowering drugs and drugs taken for other conditions (such as for the prostate or for mood) can combine to cause falls. The nurse checks lying and standing readings and reviews the full medication list (Chapter 8).
- A fall, new confusion or dizziness after a dose change is reported, because the regimen may need to be simplified.
- **Younger adults:** in earlier CHMS data, about 65% of adults aged 20 to 39 with hypertension knew they had it, compared with 90% of those aged 70 to 79 (Statistics Canada, 2019). ACE inhibitors and ARBs need pregnancy counselling (Chapter 29).

19.3 Hypertensive Emergencies and Acute Aortic Syndromes

Urgency and Emergency

Very high blood pressure is not always an emergency. What matters is whether organs are being damaged now. Under Hypertension Canada's 2020 guidelines, an office reading with a systolic pressure of 180 mm Hg or higher or a diastolic pressure of 110 mm Hg or higher was enough on its own to diagnose hypertension (Rabi et al., 2020), and the 2024 European guideline recommends assessing anyone with a reading of 180/110 mm Hg or higher for a hypertensive emergency (McEvoy et al., 2024).

A **hypertensive emergency** is severe hypertension with new or worsening **target-organ damage**: acute injury to the brain, eyes, heart, kidneys or large arteries caused by the high pressure (van den Born et al., 2019). Examples are hypertensive encephalopathy, stroke, acute coronary syndrome, acute heart failure with pulmonary edema, acute kidney injury, retinal hemorrhage and aortic dissection. **Hypertensive urgency** is a common term for severe hypertension without acute organ damage. Some European experts discourage the term and describe it as a diagnosis reached only once organ damage is excluded; these patients can usually be treated with oral drugs and do not need rapid lowering (van den Born et al., 2019) (Table 19.2). The same document advises watching such patients for at least 2 hours after an oral dose before they leave. The nurse looks for a reason, such as missed or stopped home medications, pain or a drug that raises blood pressure, and makes sure follow-up is arranged.

In most hypertensive emergencies, blood pressure is lowered in a controlled way rather than to normal at once. The brain, heart and kidneys have adapted to the high pressure, and a sudden fall can starve them of blood. A European position document advises lowering mean arterial pressure by about 20% to 25% over several hours in malignant hypertension and warns that large falls have been linked with ischemic stroke and death (van den Born et al., 2019). The main exception is aortic dissection, where pressure and heart rate are lowered quickly. Stroke has its own targets (Chapter 31), as does severe hypertension in pregnancy (Chapter 29).

The nurse's role is recognition and escalation. The nurse repeats the measurement with correct technique, checks both arms, and assesses neurologic status, vision, chest pain, breathing, oxygen saturation and urine output. A neurologic check includes level of consciousness, orientation, speech, pupils and limb strength. The nurse asks about missed doses, pain and recent use of substances such as cocaine or amphetamines, which can raise blood pressure (Rabi et al., 2020). Readings in both arms and in a leg help reveal aortic disease, and an electrocardiogram (ECG) is recorded to look for ischemia (van den Born et al., 2019). Any sign of organ injury is reported immediately using the unit's escalation process (Chapter 6). Patients with a hypertensive emergency are moved to a monitored setting for IV treatment.

Table 19.2 Hypertensive urgency and emergency compared (van den Born et al., 2019; Rabi et al., 2020; McEvoy et al., 2024; original wording)

Feature	Urgency (severe hypertension without new organ damage)	Emergency (with acute organ damage)
Blood pressure	Severe, often 180/110 mm Hg or higher	Severe, often 180/110 mm Hg or higher; the level alone does not decide
Organ injury	None found after assessment	New or worsening injury to brain, eyes, heart, kidneys or aorta
Typical findings	May have mild headache or none; often missed or stopped medications	Severe headache, confusion, seizures, vision loss, chest pain, dyspnea, low urine output, new weakness
Setting	Usually outpatient or ward care with follow-up	Monitored unit such as emergency department resuscitation area or intensive care
Treatment	Oral drugs; restart or adjust usual regimen; gradual lowering	IV drugs titrated to targets; controlled lowering over hours except for aortic dissection
Nursing priority	Confirm readings, look for causes such as pain or missed doses, arrange follow-up	Escalate at once, frequent neurologic and vital sign checks, prepare for transfer

Acute Aortic Syndromes

Acute aortic syndromes are life-threatening injuries to the aortic wall. The best known is **aortic dissection**, in which a tear in the inner lining lets blood track between the layers of the wall. The dissection can extend along the aorta, block its branches or rupture. In an international registry of patients who had surgery for acute dissection of the ascending aorta, a history of hypertension was the most common predisposing condition (Berretta et al., 2016).

The 2022 American College of Cardiology and American Heart Association aortic guideline lists high-risk features (Isselbacher et al., 2022):

- pain that starts suddenly, is severe and feels ripping or tearing, in the chest, back or abdomen;
- a pulse deficit or a difference in systolic pressure of more than 20 mm Hg between limbs;

- new neurologic signs with the pain, such as stroke symptoms or paralysis of the legs.

Dissection is an emergency. The nurse stays with the patient, calls for help immediately and checks pulses and blood pressure in both arms (section 16.2). Treatment starts with IV beta-blockers to bring heart rate to 60 to 80 beats/min and systolic pressure below 120 mm Hg, or the lowest pressure that keeps organs perfused, plus pain relief; IV vasodilators are added if pressure is not controlled. A computed tomography (CT) scan usually confirms the diagnosis, and a dissection involving the ascending aorta needs emergency surgery (Isselbacher et al., 2022). Dissection can look like a heart attack or stroke. If it is mistaken for one and anticoagulants or thrombolytics are given, serious or fatal bleeding can follow (Zschaler et al., 2018). The nurse who notices tearing pain or unequal arm pressures says so before such drugs are given.

While help arrives, the nurse keeps the patient on bed rest, ensures IV access and continuous monitoring, gives pain relief as ordered and prepares the patient for urgent imaging. New limb pain or coldness, stroke signs, abdominal pain or falling urine output can mean the dissection is blocking branch arteries, and is reported at once. Abdominal aortic aneurysm is covered in section 19.5.

CLINICAL JUDGMENT

Headache and 220/130 on the Ward

Mrs. Leila Haddad, 66, was admitted 2 days ago with pneumonia. At 2300 she reports a severe headache and blurry vision. Her automated reading is 220/130 mm Hg.

- **Recognize cues:** the nurse rechecks manually with the correct cuff after she rests: 218/128 mm Hg in the right arm, 214/126 mm Hg in the left. Heart rate 92 beats/min, SpO2 95% on room air. She is slow to answer and unsure of the date, which is new. Her usual antihypertensive was not ordered on admission.
- **Analyze cues:** severe hypertension plus headache, vision change and new confusion suggests brain injury from the pressure, not a reaction to pain or anxiety. Similar pressures in both arms and no tearing pain make dissection less likely.
- **Prioritize hypotheses:** hypertensive emergency with possible encephalopathy or stroke comes first.
- **Generate solutions:** urgent assessment by the prescriber or rapid response team; controlled, not sudden, lowering in a monitored setting; neurologic checks.
- **Take action:** the nurse stays, raises the head of the bed, does a neurologic check including a stroke screen, and calls the rapid response team using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6). The nurse reports the missed home medication. No extra oral dose is given without an order.
- **Evaluate outcomes:** she transfers to the intensive care unit. Two hours later her pressure is 176/104 mm Hg and she knows the date.

GOING DEEPER

Titrated IV Antihypertensives and Arterial Lines

Required for RN students; optional for PN students.

Hypertensive emergencies are treated with short-acting IV drugs whose effect can be adjusted minute by minute. IV agents marketed in Canada include labetalol, esmolol, hydralazine and sodium nitroprusside (Health Canada, 2026). A European position document suggests labetalol as one of two drugs that can treat most hypertensive emergencies (the other, IV nicardipine, has no IV product listed in the Drug Product Database). For aortic dissection, an IV beta-blocker such as esmolol is given first, and a vasodilator such as nitroprusside is added if pressure stays above target (van den Born et al., 2019; Isselbacher et al., 2022).

Principles of titration:

- The prescriber sets the target and the time frame, such as a percentage fall in mean arterial pressure over the first hours, or a heart rate and systolic target for dissection.
- The nurse uses an infusion pump, increases or decreases the rate only within the ordered range, and checks blood pressure often enough to see each change take effect.
- Falling too far or too fast is as dangerous as staying too high. The nurse watches for new confusion, chest pain, low urine output and dizziness as pressure falls.

An **arterial line** gives continuous beat-to-beat pressure readings and is recommended in acute aortic syndromes (Isselbacher et al., 2022). The nurse keeps the transducer levelled and zeroed per unit policy, checks the waveform, compares it with a cuff reading when values seem wrong, and assesses circulation in the limb beyond the catheter.

19.4 Peripheral Arterial Disease

What Happens and Who Is at Risk

Peripheral arterial disease (PAD) is narrowing or blockage of the arteries that supply the limbs, most often the legs. The usual cause is atherosclerosis (Chapter 17). A narrowed artery may supply enough blood at rest but not during exercise; as narrowing worsens, the foot becomes short of blood even at rest.

The Canadian Cardiovascular Society (CCS) 2022 guideline describes PAD as often silent and as underdiagnosed, under-recognized and undertreated; lower-extremity PAD is common from age 50 (Abramson et al., 2022). Smoking, diabetes, chronic kidney disease, high blood pressure, abnormal lipids and older age raise the risk. Compared with people who have PAD alone, those who also have diabetes have about three to four times the mortality and about five times the amputation rate, the guideline reports.

Amputation is not shared equally in Canada. In an Ontario study of adults with diabetes from 1995/96 to 2014/15, First Nations people had revascularization rates similar to those of other Ontarians but three to five times their rate of lower-extremity amputation, and more than six times the rate at age 44 or younger (Shah et al., 2019). Risk rose with rurality in both groups and was highest in remote communities. The authors suggested that PAD may be underdiagnosed or undertreated in First Nations people. The study was designed with the Chiefs of Ontario and approved by its Data Governance Committee (First Nations data governance and OCAP®: Chapter 2). A second Ontario study of major (above-ankle) amputations linked to diabetes or PAD from 2007 to 2017 found regional rates that differed more than fourfold (de Mestral et al., 2020). The highest-rate regions had a larger share of patients who lived rurally or in the lowest income quintile, and rates were lower where more patients had seen a vascular surgeon or had revascularization. These gaps point to structural causes, such as distance from specialist care, poverty and health services shaped by colonial policy, rather than to biology (Chapter 2).

Recognizing PAD

The classic symptom is **intermittent claudication**: cramping or aching pain, usually in the calf, that comes on with walking at about the same distance each time and eases within about 10 minutes of rest (Abramson et al., 2022).

Chronic limb-threatening ischemia (CLTI) is the advanced stage: ischemic pain at rest, ulcers or gangrene (Abramson et al., 2022). Rest pain in the foot is often worse lying flat at night and eases when the leg hangs down. Arterial ulcers (Figure 19.3) form on the toes or below the ankle and look punched out, often with pale or dry, black tissue (Evans et al., 2025).

The nurse compares both legs (section 16.2):

- **Pulses:** weak or absent; a handheld Doppler can find pulses that cannot be felt.
- **Capillary refill and temperature:** slower refill and a cooler foot on the affected side.
- **Skin, hair and nails:** thin, shiny, dry, hairless skin, thickened nails and slow-healing cuts.
- **Colour with position: elevation pallor**, in which the foot blanches when raised, and **dependent rubor**, a dusky red colour when the leg hangs down.

Colour changes are harder to see on darker skin. Pallor may look ash-grey or yellow-brown and shows best in the conjunctiva and mucous membranes (Pusey-Reid et al., 2023). The nurse uses natural light, compares the limbs and relies on temperature, refill, pulses and symptoms, not colour alone.

Figure 19.3 A foot with peripheral arterial disease: a dry ulcer at the tip of the big toe and thickened nails. (credit: “Peripheral artery disease” by Milorad Dimić (Intermedichbo)/Wikimedia Commons, CC BY-SA 4.0)

The **ankle-brachial index (ABI)** compares ankle and arm systolic pressures. With the patient lying flat, systolic pressures are measured with a Doppler probe in both arms and at each ankle

(dorsalis pedis and posterior tibial arteries). For each leg, the higher ankle pressure is divided by the higher arm pressure (Abramson et al., 2022). The CCS states that an ABI below 0.9 suggests PAD. Calcified arteries, common in diabetes, kidney disease and older age, can give a falsely normal ABI or one above 1.4; a toe-brachial index or other tests are then used.

Treatment and Nursing Care

Treatment aims to prevent heart attack, stroke and death, and to save the limb. The CCS recommends (Abramson et al., 2022):

- **Smoking cessation** with counselling and medication (Chapter 14).
- **Supervised exercise** as first-line treatment for claudication, with walking preferred, at least twice a week for 30 minutes or more over at least 12 weeks; a structured home or community program is the alternative.
- **A statin** for every patient with PAD (Chapter 17).
- **Antithrombotic therapy for symptomatic PAD:** for most patients with low bleeding risk, low-dose (vascular-dose) rivaroxaban plus low-dose acetylsalicylic acid (ASA), especially with diabetes, heart failure, kidney impairment, disease in other arterial beds or a high-risk limb; a single antiplatelet drug for those at high bleeding risk. Routine antithrombotic therapy is not recommended when PAD causes no symptoms.

Because the vascular dose of rivaroxaban is much lower than the clot-treatment dose, the nurse checks that the dose matches the indication. Blood pressure (section 19.2), diabetes control and daily foot care (Chapter 22) also protect the limb.

When claudication stays disabling or CLTI threatens the limb, flow may be restored by **endovascular revascularization** (a balloon or stent passed through a catheter) or **bypass surgery** with a vein or synthetic graft. Afterward, the nurse:

- checks pulses, colour, warmth, capillary refill, sensation and movement against the pre-procedure baseline, and reports a lost pulse at once;
- inspects the access site or incision for bleeding or hematoma;
- reports rising pain, tense swelling or new numbness at once, because compartment syndrome can develop or worsen after revascularization (National Confidential Enquiry into Patient Outcome and Death [NCEPOD], 2025; Chapter 33).

In arterial disease, gravity helps blood reach the foot, so the legs stay level or slightly lower than the heart rather than raised; arterial pain worsens with elevation (Evans et al., 2025).

Acute Limb Ischemia

Acute limb ischemia is a sudden loss of blood flow to a limb, usually from an embolus (often from the heart in atrial fibrillation, section 16.6) or a clot in a diseased artery or graft. Its signs are remembered as the "six Ps": pain, pallor, pulselessness, paresthesia, paralysis and poikilothermia (a very cold limb); not all need be present (NCEPOD, 2025).

New numbness or weakness in a painful limb marks a limb in danger. A national review in the United Kingdom described a limb with sensory loss beyond the toes and some weakness as salvageable if revascularized promptly, ideally within 6 hours for full function; untreated, it progresses to irreversible nerve and muscle damage (NCEPOD, 2025). Every nurse who notices these signs escalates at once (Chapter 6), records when symptoms began, keeps the limb level and protected, and prepares for anticoagulation, imaging and transfer to the vascular team.

19.5 Abdominal Aortic Aneurysm

An **abdominal aortic aneurysm (AAA)** (Figure 19.4) is a weak area in the wall of the abdominal aorta that balloons outward as blood pressure pushes on it (Canadian Task Force on Preventive Health Care [CTFPHC], 2017). About 20,000 Canadians are diagnosed each year, and AAA caused about 1,244 deaths a year from 2009 to 2013. The strongest risk factors are male sex, smoking, older age and a family history of AAA; coronary artery disease, atherosclerosis, high cholesterol and hypertension are weaker ones, and AAA appears to be less common in people with diabetes. Among people aged 65 to 80, AAA is four to six times less common in women than in men, but women appear more likely to die after repair. Smoking promotes aneurysm formation,

growth and rupture, and current smoking roughly doubles the risk of rupture; even so, the Task Force made no separate recommendation for people who smoke.

An AAA usually causes no symptoms until it ruptures, so it is often found by chance on imaging or by screening. The CTFPHC (2017) recommends:

- one-time ultrasound screening for men aged 65 to 80 (weak recommendation, moderate-quality evidence);
- no screening for men older than 80 (weak recommendation, low-quality evidence);
- no screening for women (strong recommendation, very low-quality evidence).

Guidance outside Canada differs; the 2022 American College of Cardiology and American Heart Association guideline, for example, includes some women aged 65 or older who have ever smoked (Isselbacher et al., 2022). The nurse explains the Canadian recommendation and that the decision is shared with the primary care provider.

Figure 19.4 Contrast-enhanced CT of an abdominal aortic aneurysm measuring about 4.8 by 3.8 cm (green measurement lines). (credit: "Contrast-enhanced CT scan demonstrating abdominal aortic aneurysm" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

A small aneurysm is watched with repeat imaging; the 2022 guideline advises a scan every 3 years for one measuring 3.0 to 3.9 cm, and more often as it grows. Repair is generally offered once it reaches a size threshold, which the 2022 guideline sets at 5.5 cm for men and 5.0 cm for women, or when it causes symptoms (Isselbacher et al., 2022). Meanwhile the nurse supports smoking cessation, blood pressure control (section 19.2) and statin therapy when atherosclerosis is present.

Rupture

Rupture causes bleeding inside the abdomen that can cause death (CTFPHC, 2017). Warning signs include sudden, severe abdominal, back or flank pain; signs of shock, such as hypotension, a fast pulse, cool clammy skin and fainting; and sometimes a pulsating abdominal mass. A patient with a known AAA and new abdominal or back pain is treated as an emergency until proven otherwise. The nurse calls the rapid response team or 9-1-1 at once (Chapter 6), keeps the patient still, starts or prepares for large-bore intravenous (IV) access and blood work, and readies the patient for imaging and surgery. Section 19.3 covers aortic dissection, which can produce similar pain.

Care After Repair

Repair is done by **endovascular aneurysm repair (EVAR)**, in which a stent graft is passed through the femoral arteries to line the aneurysm from inside, or by open surgery through an abdominal incision. Perioperative care follows Chapter 7. After repair, the nurse also checks:

- **Limb perfusion:** pulses, colour, warmth, sensation and movement in both legs, because clot or debris can travel downstream.
- **Access sites:** groin wounds after EVAR for bleeding, swelling or hematoma.
- **Kidney function:** urine output and creatinine, because contrast dye and aortic clamping can injure the kidneys (Chapter 27).
- **The bowel after open repair:** pain, distension or bloody diarrhea, which can signal reduced blood flow to the colon.

After EVAR, the patient needs follow-up imaging on the schedule the vascular team sets. The nurse explains why missed scans matter and confirms that follow-up is booked.

19.6 Venous Disease and VTE

How Clots Form in Veins

Venous thromboembolism (VTE) includes **deep vein thrombosis (DVT)**, a clot in a deep vein, most often in the leg or pelvis, and **pulmonary embolism (PE)**, in which a clot travels to the lungs (Chapter 15). **Virchow's triad** names the three conditions that favour venous clotting: slow or stagnant blood flow (stasis), injury to the vein wall, and blood that clots more easily than usual (hypercoagulability).

Common risk factors map onto the triad:

- **Stasis:** surgery, bed rest, reduced mobility in hospital, a leg in a cast, paralysis and long travel.
- **Vein wall injury:** surgery or trauma to the leg or pelvis, and central venous catheters.
- **Hypercoagulability:** active cancer and some cancer treatments, estrogen-containing contraceptives and hormone therapy, pregnancy and the weeks after birth, and inherited clotting disorders.
- **Previous VTE**, which raises the risk of another.

Prevention in hospital, including risk assessment, early mobilization and prophylactic anticoagulants, is taught in Chapter 7.

Recognizing and Diagnosing DVT

A DVT typically causes swelling of one calf or the whole leg (Figure 19.5), pain or tenderness along the deep veins, warmth, and dilated superficial veins. Redness or a bluish colour is easy to see on light skin; on darker skin the change may look darker, purplish or be hard to see at all, so the nurse compares the two legs, feels for warmth and measures both calves at the same marked level. Many clots cause few or no signs, especially in patients in hospital, and these signs are also found in other conditions such as cellulitis or a ruptured cyst behind the knee. Examination alone therefore cannot confirm or rule out DVT.

Clinicians first estimate the **pretest probability**: how likely DVT is before any test. A validated clinical prediction rule, such as the Wells score, weighs features that make DVT more likely, such as active cancer, recent surgery or immobilization, a previous DVT and swelling or tenderness of the leg, against whether another diagnosis is as likely (Lim et al., 2018). The result places the patient in a lower or higher probability group, which sets the testing path.

- **Lower probability:** a **D-dimer** test comes first. D-dimer is a fragment released when cross-linked fibrin breaks down. A negative result rules out DVT without imaging; a positive result leads to ultrasound (Lim et al., 2018).
- **Higher probability: compression ultrasound** comes first. The sonographer presses on the vein with the probe; a vein that will not collapse contains clot. If the first scan is negative and no other cause is found, the scan is repeated, because one negative scan does not rule out DVT in this group.

D-dimer is less useful in patients in hospital, after surgery and in pregnancy, because levels are often raised without a clot (Lim et al., 2018). Levels also rise with age; for outpatients older than 50, the American Society of Hematology (ASH) reports that a cut-off adjusted for age is as safe as the standard cut-off (Lim et al., 2018). The nurse reports a suspected DVT promptly, does not massage the leg, and watches for sudden shortness of breath, chest pain or a fast heart rate, which may signal PE and call for immediate escalation (Chapter 15).

Treatment

Anticoagulation is the treatment for DVT (section 19.7). For most patients, ASH suggests a direct oral anticoagulant over warfarin, with exceptions such as severe kidney impairment, moderate to severe liver disease and antiphospholipid syndrome (Ortel et al., 2020). For uncomplicated DVT, ASH suggests that home treatment be offered in preference to hospital treatment (conditional recommendation); hospital care may benefit patients with a limb-threatening clot or a high risk of bleeding (Ortel et al., 2020).

Strict bed rest is no longer routine. In a meta-analysis of 13 studies with 3,269 patients receiving standard anticoagulation, walking early was not linked to more new PEs, clot extension or DVT-related deaths, and leg pain eased sooner in those with moderate or severe pain (Liu et al., 2015). The nurse encourages walking once anticoagulation has started, unless the prescriber orders otherwise.

Some patients go on to develop **post-thrombotic syndrome (PTS)**: lasting pain, swelling, heaviness and skin changes in the leg after a DVT. A Canadian-led trial randomly assigned 806 patients after a first proximal DVT to active or placebo compression stockings for 2 years; PTS developed in 14.2% and 12.7%, respectively (Kahn et al., 2014). The American College of Chest Physicians (CHEST) advises against routine compression stockings for preventing PTS (Stevens et al., 2021).

Superficial Thrombophlebitis and Chronic Venous Disease

Superficial vein thrombosis (SVT), also called superficial thrombophlebitis, is a clot with inflammation in a vein near the skin surface. It causes a tender, warm, firm cord along the vein, with redness on lighter skin or darker discoloration on darker skin. A leg SVT can extend, so the prescriber may order an ultrasound to look for clot progression or DVT. For SVT of the leg at increased risk of progression, CHEST suggests 45 days of anticoagulation, with fondaparinux preferred and rivaroxaban as an alternative for patients who cannot use injections (Stevens et al., 2021).

Varicose veins are swollen, twisted, bluish surface veins, common on the calf and inner leg (Evans et al., 2025; Figure 19.6). **Chronic venous insufficiency (CVI)** develops when vein valves fail or veins stay blocked after a DVT, so pressure in the leg veins stays high. Risk factors include older age, previous DVT, obesity, long periods of standing or sitting, several pregnancies, a weak calf-muscle pump and a family history. Findings include:

Figure 19.5 Deep vein thrombosis of the right leg (arrow): the leg is swollen and redder than the other. On darker skin, the change may look darker or purplish, or be hard to see. (credit: "Deep vein thrombosis of the right leg" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

Figure 19.6 Varicose veins: raised, twisted surface veins over the lower leg and ankle.

- ankle edema that worsens when the leg hangs down and improves with elevation;
- **hemosiderin staining**, a grey-brown discoloration around the lower calf and ankle from iron pigment left by broken-down red blood cells; on darker skin it may appear as darker brown or black patches that blend with the person's skin tone, so the nurse compares legs and asks about change;
- hard, tight skin above the ankle, itchy scaling (stasis dermatitis) and, eventually, venous ulcers around the ankle (Chapter 35; Figure 19.7).

Care centres on **compression** and **elevation** (Figure 19.8). Compression lowers venous pressure, but only after an arterial assessment, because compression can harm a leg with poor arterial flow; Wounds Canada advises against compression when the ABI is below 0.5 and reserves high compression for an ABI of 0.9 or higher (Evans et al., 2025). After a venous ulcer heals, compression is generally continued for life to prevent it from returning. Raising the legs above heart level (for example, for 30 minutes three times a day), walking and ankle exercises that work the calf-muscle pump also help. This is the opposite of arterial

disease, in which the legs are not elevated (Table 19.3). A patient with both arterial and venous disease needs a full vascular assessment before compression is used.

Figure 19.7 Chronic venous insufficiency on darker skin: dark hyperpigmentation and thickened skin above the ankle, with an open venous ulcer. (credit: "Chronic venous insufficiency & Venous ulcer" by Ahmed Shawky Mohammedin, MD (Ashashyou)/Wikimedia Commons, CC BY-SA 4.0)

Figure 19.8 Medical compression stockings come in different lengths, strengths and colours; the type is prescribed after an arterial assessment. (credit: "Medizinische Kompressionsstrümpfe" by Enter/Wikimedia Commons, CC BY-SA 3.0)

Table 19.3 Arterial and venous disease compared at the bedside (Abramson et al., 2022; Evans et al., 2025; original wording)

Feature	Arterial disease	Venous disease
Main problem	Too little blood reaching the tissues	Blood pooling in the leg veins
Typical pain	Cramping with walking; rest pain in the foot, worse when the leg is raised	Aching or heaviness, worse at the end of the day, eased by raising the leg
Pulses	Weak or absent	Usually present
Skin and hair	Thin, shiny, dry, hairless; cool	Brownish staining, thickened skin, scaling; warm
Colour with position	Pale when raised; dusky when hanging down	Swelling and darker colour when hanging down

Feature	Arterial disease	Venous disease
Edema	Usually little	Common, around the ankle
Ulcers	Toes or below the ankle; punched out, often pale or dry, black tissue	Around the ankle; shallow, irregular, with moderate to heavy drainage
Positioning	Legs level or slightly lower than the heart	Legs raised above heart level
Compression	Avoided until arterial flow is assessed	Main treatment once arterial flow is confirmed

19.7 Anticoagulation

How Anticoagulants Work

Anticoagulants slow clot formation. They stop existing clots from growing and new clots from forming while the body's own fibrinolytic system gradually breaks the clot down; they do not dissolve clots themselves (thrombolytics are covered in Chapter 15). All of them increase the risk of bleeding.

- **Unfractionated heparin (UFH)** boosts antithrombin, which inactivates thrombin and factor Xa. It is given IV by continuous infusion or subcutaneously, acts quickly and wears off within hours, which makes it useful when a procedure may be needed or kidney function is poor.
- **Low-molecular-weight heparins (LMWHs)**, such as enoxaparin, dalteparin and tinzaparin, act mainly against factor Xa. They are injected subcutaneously at weight-based doses, have a predictable effect and are cleared by the kidneys.
- **Fondaparinux** is a synthetic injectable that blocks factor Xa through antithrombin. It is not recommended for treating DVT or PE when creatinine clearance (CrCl) is 30 mL/min or less (Aspen Pharmacare Canada, 2019).
- **Warfarin**, a vitamin K antagonist, lowers the liver's production of the vitamin K–dependent clotting factors. Its full effect takes several days, so a heparin is often given alongside it at first.
- **Direct oral anticoagulants (DOACs)** act directly on one clotting factor: apixaban, rivaroxaban and edoxaban block factor Xa, and dabigatran blocks thrombin. They work within hours, are taken at fixed doses and do not need routine blood tests of their effect.

Monitoring

- **International normalized ratio (INR):** the standardized measure of warfarin's effect. For most indications, including VTE and atrial fibrillation, the target is 2.5 within a range of 2.0 to 3.0 (Guidelines and Protocols Advisory Committee [GPAC], 2023); mechanical heart valves need different targets (section 18.5). The INR is checked every 2 to 4 days when warfarin is started or its dose is changed, at longer intervals once stable, and more often with illness, new medications or supplements, or a major change in diet.
- **Activated partial thromboplastin time (aPTT) or anti-Xa level:** used to adjust a heparin infusion according to the hospital's protocol (Table 19.4).
- **Platelet count:** watched in patients on heparin for heparin-induced thrombocytopenia (HIT; see the Going Deeper box).
- **Kidney function:** For apixaban, CrCl is estimated with the Cockcroft-Gault formula before the drug starts and checked at least once a year, and more often with dehydration, worsening heart failure or more diuretic use (Pfizer Canada & Bristol-Myers Squibb Canada, 2025). The other DOACs, LMWHs and fondaparinux also depend on the kidneys.
- **Hemoglobin:** a falling value in grams per litre (g/L) can be the first clue to hidden bleeding.

The INR does not measure the effect of apixaban (Pfizer Canada & Bristol-Myers Squibb Canada, 2025), so a normal INR does not mean a patient on a DOAC is not anticoagulated.

Table 19.4 Anticoagulants compared: monitoring, key cautions and reversal (sources in text; original wording)

Drug or class	How it is given	Monitoring	Key cautions	Reversal

Drug or class	How it is given	Monitoring	Key cautions	Reversal
Unfractionated heparin	IV infusion or subcutaneous	aPTT or anti-Xa per protocol; platelets; hemoglobin	High-alert drug; infusion errors; HIT	Protamine
LMWHs (enoxaparin, dalteparin, tinzaparin)	Subcutaneous	Platelets; creatinine; hemoglobin	Builds up when the kidneys fail; spinal or epidural hematoma with neuraxial procedures	Per hospital protocol, with expert advice
Fondaparinux	Subcutaneous	Creatinine; hemoglobin	Not recommended for treatment with CrCl 30 mL/min or less	No specific reversal agent
Warfarin	Oral	INR	Many drug, supplement and food interactions; slow onset and offset; generally avoided in pregnancy	Vitamin K; prothrombin complex concentrate for life-threatening bleeding
Apixaban, rivaroxaban, edoxaban	Oral	Creatinine; hemoglobin; INR is not a guide	Missed doses; interacting drugs; kidney function	Prothrombin complex concentrate (off-label; usual Canadian care)
Dabigatran	Oral	Creatinine; hemoglobin	Strongly dependent on the kidneys	Idarucizumab

Bleeding and Reversal

Some bleeding is obvious: nosebleeds, bleeding gums, blood in the urine, heavy menstrual periods, large bruises, or vomit that is bloody or looks like coffee grounds. Other bleeding is hidden and must be suspected:

- black, tarry stools from bleeding in the gut;
- headache, drowsiness, confusion or vomiting after a fall or head knock, which may signal bleeding inside the skull, even when the patient first seems well (Chapter 8);
- back, flank or groin pain, especially after a femoral procedure, which may signal bleeding behind the abdomen;
- dizziness, fainting, a rising pulse, falling blood pressure or a falling hemoglobin.

When bleeding is suspected, the nurse first stops a running anticoagulant infusion or holds the next dose as policy directs, applies pressure to any visible bleeding site and assesses airway, breathing, circulation and level of consciousness. The nurse then escalates using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6), reporting the drug, dose and time of the last dose, because these determine which reversal agent is used. Blood work is sent as ordered, and blood products are given according to Chapter 20.

Reversal depends on the drug:

- **Warfarin:** vitamin K, given orally for a high INR and IV in emergencies, plus **prothrombin complex concentrate (PCC)**, a concentrate of vitamin K–dependent clotting factors, for life-threatening bleeding (GPAC, 2023).
- **Heparin:** protamine neutralizes heparin within minutes of IV administration; given too fast, it can cause severe hypotension and anaphylactoid reactions (Fresenius Kabi Canada, 2016).
- **Dabigatran:** idarucizumab, an antibody fragment that binds only dabigatran and reverses no other anticoagulant (Boehringer Ingelheim Canada, 2019).
- **Factor Xa inhibitors (apixaban, rivaroxaban, edoxaban):** in Canada, usual care for major bleeding is PCC, used off-label, together with stopping the drug, resuscitation, local measures and blood products (Canadian Agency for Drugs and Technologies in Health [CADTH], 2024). Andexanet alfa, a specific reversal agent for apixaban and rivaroxaban, received conditional Health Canada authorization in 2023 and is listed as marketed, but CADTH recommended against public reimbursement and Canadian Blood Services decided not to list it (Canadian Blood Services, 2024). Experts consulted for the CADTH review noted that PCC and blood products are not available in every clinical setting (CADTH, 2024), which matters for patients far from a hospital.

CLINICAL SAFETY

Anticoagulants as High-Alert Medications

The Institute for Safe Medication Practices Canada (ISMP Canada) lists anticoagulants among **high-alert medications**: drugs that are not necessarily involved in more errors, but that carry a greater risk of serious harm when an error happens (ISMP Canada, 2016). ISMP Canada has reported a patient death after a home LMWH was continued on admission while a heparin infusion was also started; the duplication was not caught before both were given. System safeguards work better than vigilance alone:

- Reconcile medications on admission and transfer, and look for duplicate anticoagulants, including a home LMWH or DOAC alongside a hospital heparin.
- Use standard concentrations and pre-mixed bags, and programmed infusion pumps with dose limits.
- Check heparin vials and bags carefully, because products with very different strengths can look alike.
- Complete an independent double check before starting an infusion or changing its rate when policy requires it; the second nurse checks the order, product, concentration, pump settings and patient on their own, not by reading out the first nurse's work.
- Document the product, concentration, rate, laboratory result and time of each change.
- Act on aPTT or anti-Xa results promptly and adjust the infusion only as the protocol directs.

MEDICATIONS

Anticoagulants and Their Reversal

- **UFH:** IV or subcutaneous; aPTT or anti-Xa monitoring per protocol; reversed by protamine.
- **LMWHs (enoxaparin, dalteparin, tinzaparin):** subcutaneous; check platelets and creatinine; follow the product's injection instructions.
- **Fondaparinux:** subcutaneous; avoid for treatment when CrCl is 30 mL/min or less.
- **Warfarin:** oral; INR guides dosing; many interactions; reversed with vitamin K and PCC.
- **Apixaban, rivaroxaban, edoxaban:** oral factor Xa inhibitors; kidney function checked; PCC is the usual reversal approach in Canada.
- **Dabigatran:** oral thrombin inhibitor; strongly kidney-dependent; reversed with idarucizumab.
- **All:** watch for bleeding, ask about falls, and check for spinal or epidural hematoma (leg numbness or weakness, bowel or bladder changes) after neuraxial anesthesia or lumbar puncture (Pfizer Canada & Bristol-Myers Squibb Canada, 2025).

Teaching and Transitions

Anticoagulants are safe only when taken as directed. Stopping early raises the risk of clots (Pfizer Canada & Bristol-Myers Squibb Canada, 2025), so the nurse explains why the drug is needed and for how long, and checks that the patient can get and afford the next supply. Teaching covers:

- **Missed doses:** instructions differ by drug and by once- or twice-daily schedule. For apixaban, the patient takes the missed dose as soon as remembered and continues the usual twice-daily schedule, without doubling a dose (Pfizer Canada & Bristol-Myers Squibb Canada, 2019). For other drugs, the nurse uses that product's patient information or asks the pharmacist.
- **Interactions:** other anticoagulants and antiplatelet drugs, ASA, NSAIDs such as ibuprofen, and some antidepressants increase bleeding. Some antifungals and human immunodeficiency virus (HIV) drugs raise apixaban levels, and rifampin, some seizure medications and St. John's wort lower them (Pfizer Canada & Bristol-Myers Squibb Canada, 2025). Warfarin interacts with many antibiotics, acetaminophen in higher doses, alcohol binges and supplements such as fish oil, garlic and ginseng (GPAC, 2023).
- **Vitamin K and warfarin:** no food is forbidden. The patient keeps vitamin K intake steady from week to week rather than avoiding green vegetables, and reports large diet changes or nutritional supplement drinks (GPAC, 2023).
- **Falls and injuries:** removing fall hazards (Chapter 8), and seeking same-day assessment after any head injury.
- **Procedures:** telling dentists, surgeons and pharmacists about the anticoagulant before any procedure (Chapter 7).
- **Identification and pregnancy:** wearing medical alert identification; warfarin is generally avoided in pregnancy, so people who could become pregnant discuss contraception and plans (GPAC, 2023).

Older adults need extra attention. Kidney function falls with age and with dehydration or acute illness, many older adults take several interacting drugs, and falls are common, so the nurse reviews creatinine, the medication list and fall risk at every transition (Pfizer Canada & Bristol-Myers Squibb Canada, 2025; Chapter 8).

Cost is a real barrier. Drug coverage differs by province or territory and by private plan, and DOACs cost more than warfarin. The nurse asks directly about cost, involves the pharmacist or social worker, and checks that patients in rural, remote and northern communities can reach INR testing or pharmacy services (Chapter 2).

PATIENT EDUCATION

Living Safely With an Anticoagulant

- Take your anticoagulant at the same time every day. Use a pill organizer or phone reminder.
- If you miss a dose, follow the instructions for your medicine. Never take two doses to catch up. Ask your pharmacist if you are unsure.
- Do not stop taking it unless your health care provider tells you to.
- Check with your pharmacist before taking any new medicine, pain reliever, vitamin or herbal product. Avoid ibuprofen and naproxen unless your provider approves them.
- If you take warfarin, keep your diet steady from week to week, and go for every INR test.
- Use a soft toothbrush and an electric razor.
- Get medical help the same day if you hit your head, even if you feel fine.
- Call 9-1-1 if you have a sudden severe headache, vomit blood, have black stools or bleeding that will not stop.
- Tell every dentist, surgeon and pharmacist that you take an anticoagulant.
- Wear medical alert identification.

GOING DEEPER

Heparin-Induced Thrombocytopenia and Anti-Xa Monitoring

Required for RN students; optional for PN students.

Heparin-induced thrombocytopenia (HIT) is an immune reaction in which antibodies form against heparin bound to a platelet protein. The antibodies activate platelets, so the platelet count falls while the risk of clotting rises sharply. ASH describes HIT as a profoundly hypercoagulable state in which one-third to one-half of patients develop venous, arterial or small-vessel thrombosis (Cuker et al., 2018). A platelet fall of more than 50% that begins 5 to 10 days after heparin is started points most strongly to HIT.

Clinicians estimate the probability of HIT with the **4Ts** score, which considers how far the platelets have fallen, when the fall began in relation to heparin exposure, whether new thrombosis is present, and whether another cause of a low platelet count is more likely. A low score makes HIT unlikely, and laboratory testing is not recommended. With an intermediate or high score, all heparin is stopped and a non-heparin anticoagulant such as argatroban, fondaparinux or a DOAC is started. Routine platelet transfusion is avoided, and warfarin is not started until the platelet count recovers.

UFH infusions are adjusted using either the aPTT, a clotting time affected by many factors, or an anti-Xa level, which measures heparin's activity directly. Each hospital chooses one method and a protocol with set targets; the nurse follows that protocol.

SCOPE IN PRACTICE

Heparin Infusions, Injections and Doppler Checks

Whether a nurse performs a task depends on **authority, competence and context** (Chapter 1, section 1.3); employer policy and the province or territory also matter.

- **Subcutaneous LMWH:** registered nurses (RNs) and registered practical nurses (RPNs) commonly give it and teach self-injection once they have the authority (an order) and competence.
- **IV heparin infusions:** many hospitals assign titrated heparin infusions to RNs, or require added education before RPNs manage them. The rule comes from employer policy, not from any College of Nurses of Ontario (CNO) classification of patients.
- **Doppler pulse checks and ABI:** handheld Doppler pulse checks are within both RN and RPN practice when the nurse is competent and the employer supports it. ABI is often done by vascular laboratory staff or nurses with added training.

- **Escalation:** every nurse who notices bleeding, a pulseless limb or signs of PE acts at once and escalates. The RPN consults the RN as the patient's needs change, for example when a stable patient on an LMWH develops melena or a falling hemoglobin.

PRACTICE STORY

A Sunday Morning Visit

Names and details are fictional; this is a composite story.

Nurse: Maya Nwosu, RPN. Years in practice: 6. Setting: home and community care, Ontario.

Mrs. Rose Thibault is 84 and lives alone in a small town. She takes apixaban for atrial fibrillation, and I visit twice a week to manage her leg wound. On Sunday her daughter, Claire, met me at the door. "Mom tripped on the bath mat last night. She bumped her head on the sink, but she says she's fine."

Mrs. Thibault was in her chair doing the crossword. She knew the day and the date, her speech was clear and her grips were equal. There was a small swelling above her right eyebrow. Her blood pressure was 148/82 mm Hg and her pulse was 78 and irregular, her usual rhythm. She had no headache and no nausea.

It would have been easy to feel reassured. But I knew her anticoagulant meant she could be bleeding inside her skull without any signs yet, and that a bleed can show up hours after a fall. Her normal assessment did not rule that out.

I explained to Mrs. Thibault and Claire that she needed to be seen in the emergency department that morning. Mrs. Thibault said she didn't want to "make a fuss." I told her plainly why the visit mattered, and she agreed. Claire drove her to the hospital, and I made sure the apixaban bottle and medication list went with her.

I called the emergency department and gave a short report: anticoagulant, time of her last dose, time of the fall and my findings. I then called the on-call RN for our agency and left a message for the care coordinator, so her visits and wound care could be adjusted. I documented my assessment, advice and calls.

Claire phoned that evening. The scan showed no bleeding, and her mother was home. The next week we talked about removing the bath mat and adding grab bars.

Reflect: Which cues told the nurse that a normal assessment was not enough? Which actions were within the RPN's scope, and when should the RPN involve the RN?

Chapter 19 Summary

Introduction

- Hypertension is one of the most common chronic conditions in adults; it is usually silent but damages arteries and organs over time.
- This chapter covers hypertension, acute aortic syndromes, arterial and venous disease, venous thromboembolism and anticoagulation, the book's main section on anticoagulants.

19.1 Hypertension: Measurement and Risk

- Blood pressure depends on cardiac output and systemic vascular resistance, regulated by the sympathetic nervous system, the RAAS and the kidneys' handling of sodium.
- Hypertension Canada's 2025 guideline defines hypertension as 130/80 mm Hg or higher by any validated method; the 2020 guidelines used higher, method-specific thresholds.
- AOBP and out-of-office readings (home or ambulatory) are preferred; manual technique is used when arrhythmias make automated readings unreliable.
- Cuff size, arm position, rest, silence and slow deflation all affect accuracy; white-coat and masked hypertension are found only by measuring outside the office.
- Secondary causes include kidney disease, primary aldosteronism, sleep apnea and drugs such as NSAIDs and decongestants; food environments, income and access to care make diagnosis and control harder for some people.

19.2 Treating Hypertension

- Lifestyle targets include sodium under 2 g a day, potassium over 3.5 g a day from food, 150 to 300 minutes of moderate activity a week, less alcohol and quitting smoking.
- Drugs start at 140/90 mm Hg, or at a systolic of 130 to 139 mm Hg in high-risk people; the systolic target is below 130 mm Hg if tolerated.
- First-line treatment is two of three classes (ACE inhibitor or ARB, thiazide-type diuretic, long-acting dihydropyridine calcium channel blocker), ideally as a single-pill combination.
- In hospital, the nurse follows hold parameters, checks orthostatic vital signs, treats pain or anxiety before reacting to a single high reading, and reconciles home medications.
- For older adults with frailty, falls or orthostatic hypotension, targets are individualized.

19.3 Hypertensive Emergencies and Acute Aortic Syndromes

- A hypertensive emergency is severe hypertension with acute damage to the brain, eyes, heart, kidneys or aorta; without organ damage, oral drugs and gradual lowering are used.
- In most emergencies, pressure is lowered in a controlled way over hours, because a sudden fall can cause ischemia.
- The nurse rechecks readings, assesses neurologic status, chest pain, breathing and urine output, and escalates at once.
- Aortic dissection causes sudden tearing pain and unequal pulses or arm pressures; heart rate and systolic pressure are lowered quickly, and anticoagulants or thrombolytics given in error can cause fatal bleeding.

19.4 Peripheral Arterial Disease

- PAD is usually atherosclerosis of the leg arteries; smoking, diabetes, kidney disease and age raise the risk, and it signals high cardiovascular risk.
- In Ontario, First Nations people with diabetes had three to five times the amputation rate of other Ontarians, and amputation rates were highest in rural, remote and lower-income regions, reflecting structural barriers to care.
- Claudication, rest pain, ulcers, weak pulses, elevation pallor and dependent rubor are key findings; colour changes are assessed with care on darker skin.
- The CCS states that an ABI below 0.9 suggests PAD; calcified arteries can give falsely normal or high values.
- Care includes smoking cessation, supervised exercise, a statin, antithrombotic therapy, foot care, checks after revascularization, and keeping the legs level or slightly lowered.
- Acute limb ischemia, especially with new sensory or motor loss, is an emergency; the nurse escalates at once.

19.5 Abdominal Aortic Aneurysm

- An AAA is usually silent until it ruptures; male sex, smoking, age and family history are the strongest risk factors.
- The CTFPHC recommends one-time ultrasound screening for men aged 65 to 80, not for older men or for women.
- Sudden abdominal, back or flank pain with signs of shock in a patient with an AAA is treated as rupture and escalated immediately.
- After repair, the nurse checks limb perfusion, access sites, kidney function and the bowel; EVAR needs imaging follow-up as the vascular team directs.

19.6 Venous Disease and VTE

- Virchow's triad of stasis, vein wall injury and hypercoagulability explains VTE risk factors.
- DVT signs are unreliable; pretest probability guides testing, with D-dimer first when probability is lower and compression ultrasound first when it is higher.
- Most patients start anticoagulation, often at home, and walk early; routine compression stockings are not recommended to prevent post-thrombotic syndrome.

- Chronic venous insufficiency causes edema, staining and ulcers; compression after arterial assessment and leg elevation are central, unlike in arterial disease.

19.7 Anticoagulation

- UFH, LMWHs, fondaparinux, warfarin and DOACs act at different points in clotting and differ in route, monitoring and reversal.
- The INR target for most warfarin indications is 2.0 to 3.0; heparin infusions follow aPTT or anti-Xa protocols; kidney function and hemoglobin are checked for all.
- The nurse recognizes hidden bleeding, holds the drug, assesses and escalates; reversal agents include vitamin K and PCC for warfarin, protamine for heparin and idarucizumab for dabigatran, with PCC as usual Canadian care for factor Xa inhibitors.
- Anticoagulants are high-alert medications that need system safeguards, and teaching covers adherence, missed doses, interactions, vitamin K consistency, falls, procedures, identification and cost.

Key Terms (44)

abdominal aortic aneurysm (AAA): a weak area in the wall of the abdominal aorta that balloons outward.

acute aortic syndrome: A life-threatening injury to the wall of the aorta, such as aortic dissection, that causes sudden severe pain.

acute limb ischemia: sudden loss of blood flow to a limb that threatens its survival and needs emergency treatment.

ambulatory blood pressure monitoring (ABPM): Blood pressure measured automatically every 20 to 30 minutes over a day and night by a device the person wears.

ankle-brachial index (ABI): the ratio of ankle to arm systolic pressure; the CCS states that a value below 0.9 suggests PAD.

anticoagulant: a drug that slows clot formation and stops existing clots from growing.

aortic dissection: A tear in the inner lining of the aorta that lets blood track between the layers of its wall.

automated office blood pressure (AOBP): Several readings taken and averaged by a validated automated upper-arm device in a health care setting.

chronic limb-threatening ischemia (CLTI): advanced PAD with ischemic rest pain, ulcers or gangrene.

chronic venous insufficiency (CVI): persistently high pressure in the leg veins from failed valves or blocked veins, causing edema, skin changes and ulcers.

compression ultrasound: ultrasound in which a vein that will not collapse under probe pressure shows a clot.

D-dimer: a fragment released when cross-linked fibrin breaks down; a negative result helps rule out DVT when pretest probability is low.

deep vein thrombosis (DVT): a clot in a deep vein, most often in the leg or pelvis.

dependent rubor: dusky red colour of the foot when the leg hangs down, a sign of advanced arterial disease.

direct oral anticoagulant (DOAC): an oral drug that directly blocks factor Xa (apixaban, rivaroxaban, edoxaban) or thrombin (dabigatran).

elevation pallor: blanching of the foot when the leg is raised, a sign of arterial disease.

endovascular aneurysm repair (EVAR): repair of an aneurysm with a stent graft placed through the femoral arteries.

hemosiderin staining: grey-brown or dark discoloration of the lower leg from iron pigment left by broken-down red blood cells.

heparin-induced thrombocytopenia (HIT): an immune reaction to heparin that lowers the platelet count and greatly increases the risk of clotting.

high-alert medication: a drug that carries a high risk of serious harm when an error occurs.

home blood pressure monitoring (HBPM): Readings taken by the person at home with a validated device, using a set schedule such as two readings morning and evening for 1 week.

hypertension: Blood pressure persistently at or above 130/80 mm Hg, taken with a validated device and standardized technique (Goupil et al., 2025).

hypertensive emergency: Severe hypertension with new or worsening damage to the brain, eyes, heart, kidneys or large arteries.

hypertensive urgency: Severe hypertension without acute target-organ damage; treated with oral drugs and gradual lowering.

intermittent claudication: cramping or aching leg pain that comes on with walking at a predictable distance and eases with rest.

international normalized ratio (INR): the standardized test of warfarin's effect; the usual target range is 2.0 to 3.0.

low-molecular-weight heparin (LMWH): a subcutaneous heparin, such as enoxaparin, dalteparin or tinzaparin, that acts mainly against factor Xa.

masked hypertension: Normal blood pressure in the office with raised readings at home or on ambulatory monitoring.

orthostatic hypotension: A sustained fall of at least 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes of standing.

peripheral arterial disease (PAD): narrowing or blockage of the arteries that supply the limbs, usually from atherosclerosis.

post-thrombotic syndrome (PTS): lasting pain, swelling, heaviness and skin changes in a leg after DVT.

pretest probability: the estimated likelihood of a disease before testing, used to choose the testing path.

primary aldosteronism: Excess aldosterone production by the adrenal glands, a cause of secondary hypertension.

primary hypertension: Hypertension without a single identifiable cause.

prothrombin complex concentrate (PCC): a concentrate of vitamin K–dependent clotting factors used to reverse warfarin and, in Canadian practice, for major bleeding on factor Xa inhibitors.

secondary hypertension: Hypertension caused by an identifiable condition or drug.

single-pill combination: A tablet that contains two or more blood-pressure-lowering drugs.

superficial vein thrombosis (SVT): a clot with inflammation in a vein near the skin surface.

systemic vascular resistance: The resistance that small arteries and arterioles offer to blood flow.

target-organ damage: Injury to the brain, eyes, heart, kidneys or large arteries caused by high blood pressure.

unfractionated heparin (UFH): an anticoagulant given IV or subcutaneously that boosts antithrombin; monitored by aPTT or anti-Xa level.

venous thromboembolism (VTE): deep vein thrombosis, pulmonary embolism or both.

Virchow's triad: stasis of blood flow, vein wall injury and hypercoagulability, the three conditions that favour venous clotting.

white-coat hypertension: Raised blood pressure in the office with normal readings at home or on ambulatory monitoring.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Samuel Mensah (Questions 1–6): Mr. Samuel Mensah, 58, is on a medical unit with cellulitis of the left leg. He has a history of hypertension and ran out of his home medication 5 days ago. At 2200 he reports a severe headache, nausea and blurred vision. Repeat readings with a correctly sized cuff are 224/132 mm Hg in the right arm and 220/130 mm Hg in the left. Heart rate 96 beats/min, respiratory rate 20 breaths/min, SpO2 96% on room air, temperature 37.4 °C. He is unsure of the date. Serum creatinine is 171 µmol/L today; it was 94 µmol/L on admission. He has passed 90 mL of urine in the past 4 hours.

1. [CORE] Which findings suggest acute target-organ damage in Mr. Mensah? Select all that apply.

- **a.** Severe headache with blurred vision
- **b.** New uncertainty about the date
- **c.** Creatinine rise from 94 to 171 µmol/L
- **d.** Heart rate of 96 beats/min
- **e.** Running out of medication 5 days ago
- **f.** SpO2 of 96% on room air

Answer: a, b, c — Headache with vision change (a) and new confusion (b) point to the brain and eyes, and a rapid rise in creatinine with low urine output (c) points to kidney injury (section 19.3). A heart rate of 96 beats/min (d) is mildly raised and not specific. Missed medication (e) explains why the pressure rose but is not organ damage. SpO2 of 96% (f) is within the expected range.

2. [CORE] Which interpretation best fits Mr. Mensah's findings?

- **a.** Hypertensive emergency with signs of brain and kidney injury
- **b.** Hypertensive urgency caused by pain and stress from the cellulitis
- **c.** White-coat hypertension triggered by the hospital setting
- **d.** Expected rebound that will settle once he sleeps

Answer: a — Severe hypertension with new neurologic signs and acute kidney injury meets the definition of a hypertensive emergency (a) (section 19.3, Table 19.2). Urgency (b) means no acute organ damage, which is not the case here. White-coat hypertension (c) is a diagnosis made by comparing office and home readings, not an explanation for symptoms. Waiting for him to sleep (d) would delay care for an emergency.

3. [CORE] Which concern has the highest priority for Mr. Mensah right now?

- **a.** Risk of falls from nausea and blurred vision
- **b.** Worsening infection in the left leg
- **c.** Knowledge gap about refilling his prescriptions
- **d.** Injury to the brain from severely raised pressure

Answer: d — New confusion with severe hypertension signals possible encephalopathy or stroke, which can progress quickly (d) (section 19.3). Falls (a) are a real risk, but they follow from the neurologic problem. The cellulitis (b) is being treated and is not the immediate threat. Teaching about refills (c) matters before discharge but not during an emergency.

4. [CORE] The nurse anticipates the team's plan. Which approach to lowering Mr. Mensah's blood pressure is expected?

- **a.** An extra dose of his usual oral antihypertensive now, with a recheck of the pressure in the morning
- **b.** Controlled lowering with IV medication in a monitored setting over hours
- **c.** Rapid lowering to below 120/80 mm Hg within the first 30 minutes
- **d.** No treatment until a CT scan of the head is completed

Answer: b — Most hypertensive emergencies are treated with titrated IV drugs in a monitored area, lowering pressure gradually because a sudden fall can cause ischemia (b) (section 19.3). An oral dose with a morning recheck (a) fits urgency, not emergency. Rapid lowering to normal (c) risks stroke and other ischemic injury; fast lowering is reserved for aortic dissection. Imaging may be part of the work-up, but treatment of a hypertensive emergency is not simply withheld until it is done (d).

5. [CORE] Mr. Mensah's nurse is a registered practical nurse (RPN). What should the RPN do first?

a. Stay with him and call the rapid response team or the most responsible provider

b. Give the PRN acetaminophen ordered for headache and recheck the blood pressure in 1 hour

c. Ask the RN on the next unit to come and assess him before calling anyone else

d. Document the readings and report them to the night supervisor at the end of the shift

Answer: a — Every nurse who notices deterioration acts at once and escalates, using the unit's process (a) (section 19.3; Chapter 6; Chapter 1, section 1.3). Treating the headache alone (b) delays care for a hypertensive emergency. Waiting for another nurse to assess (c) wastes time; the RPN can call directly and involve the RN as the patient's needs change. Reporting at the end of the shift (d) is unsafe.

6. [CORE] Mr. Mensah is transferred to the intensive care unit and IV treatment is started. Which finding 2 hours later best shows that care is working safely?

a. Blood pressure 118/74 mm Hg with new drowsiness

b. Blood pressure 210/126 mm Hg with the headache unchanged since the infusion began

c. Blood pressure 120/80 mm Hg and urine output 10 mL/h

d. Blood pressure 178/106 mm Hg and he now states the date correctly

Answer: d — A gradual fall with improving orientation shows the brain is being protected (d) (section 19.3). A fall to 118/74 mm Hg with new drowsiness (a) suggests the pressure dropped too far, too fast. Unchanged pressure and symptoms (b) show treatment is not yet effective. A normal pressure with very low urine output (c) may mean the kidneys are underperfused.

7. [CORE] The nurse measures the mid-upper arm of a patient as 40 cm. Which cuff bladder width is closest to correct for a manual reading?

a. 10 cm

b. 16 cm

c. 24 cm

d. 32 cm

Answer: b — The bladder width should be about 40% of arm circumference, so about 16 cm for a 40 cm arm (b) (section 19.1). A 10 cm bladder (a) is too narrow for this arm, so the reading would be inaccurate. Widths of 24 cm (c) and 32 cm (d) are far too wide; 32 cm is closer to the bladder length needed, which covers 80% to 100% of the arm.

8. [CORE] A student takes a manual blood pressure while the patient sits with the arm hanging at the side, below heart level. What effect does the nurse expect this error to have?

a. The reading will underestimate the true pressure.

b. There is no effect as long as the cuff is the right size.

c. Only the diastolic value will be affected.

d. The reading will overestimate the true pressure.

Answer: d — An arm below heart level gives falsely high systolic and diastolic readings (d) (section 19.1). It does not lower the reading (a). A correctly sized cuff does not make up for poor arm position (b). Both the systolic and the diastolic values are affected, not only the diastolic (c).

9. [CORE] A patient is learning home blood pressure monitoring. Which statement shows the teaching has been understood?

a. "I'll take two readings 1 minute apart each morning and evening for a week."

b. "I'll check my pressure right after my morning walk, when I feel most awake."

c. "I'll take one reading a day, whenever I remember, for the next month."

d. "I'll keep my sweater on so the cuff fits snugly over the sleeve."

Answer: a — Hypertension Canada advises two readings, 1 minute apart, morning and evening for 7 days (a) (section 19.1). Exercise in the 30 minutes before (b) raises readings. Single random readings (c) do not follow the protocol. The cuff goes on the bare arm (d).

10. [CORE] A patient's home readings over 1 week average 134/82 mm Hg. According to Hypertension Canada's 2025 guideline, how should the nurse interpret this average?

a. Normal, because home readings use a threshold of 135/85 mm Hg

b. Normal, because hypertension starts at 140/90 mm Hg

c. In the hypertensive range, because the threshold is 130/80 mm Hg for all methods

d. Not interpretable, because only readings taken in an office can be used to diagnose hypertension

Answer: c — The 2025 guideline uses 130/80 mm Hg for every validated method, so this average is in the hypertensive range (c) (section 19.1, Table 19.1). The 135/85 mm Hg home threshold (a) comes from the older 2020 guidelines. A threshold of 140/90 mm Hg (b) is the level at which drug treatment is generally started, not the definition. Home readings are recommended to confirm the diagnosis (d).

11. [CORE] Lying, a patient's blood pressure is 142/84 mm Hg. Which standing reading at 3 minutes meets the definition of orthostatic hypotension?

a. 134/80 mm Hg

b. 120/80 mm Hg

c. 138/78 mm Hg

d. 130/76 mm Hg

Answer: b — Orthostatic hypotension is a fall of at least 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes of standing; 142 to 120 is a 22 mm Hg systolic fall (b) (section 19.2). The falls in (a) (8 systolic, 4 diastolic), (c) (4 and 6) and (d) (12 and 8) are all below those amounts.

12. [CORE] Which teaching statement about sodium matches Hypertension Canada's 2025 guideline?

a. "Using less salt at the table is the main way to cut the sodium you eat."

b. "Sea salt is a low-sodium choice you can use freely."

c. "Aim for under 2 grams of sodium a day; most comes from processed foods."

d. "Sodium matters only if you also have kidney disease."

Answer: c — The guideline sets a target of under 2 g of sodium a day and notes that in a typical Western diet more than 70% of sodium comes from processed foods (c) (section 19.2). Table salt (a) is a smaller source than processed food. Sea salt (b) is still sodium. Sodium reduction is advised for all adults with hypertension (d).

13. [CORE] Which patient's blood pressure is most likely to reflect white-coat hypertension?

a. Office readings of 148/92 mm Hg with home readings averaging 122/76 mm Hg

b. Office readings of 124/78 mm Hg with home readings averaging 142/88 mm Hg

c. Office and home readings both averaging 150/94 mm Hg

d. Office readings of 118/74 mm Hg with home readings averaging 116/72 mm Hg

Answer: a — White-coat hypertension is raised office pressure with normal out-of-office readings (a) (section 19.1). Option (b) shows masked hypertension. Option (c) shows sustained hypertension. Option (d) is normal in both settings.

14. [CORE] An RPN is about to give amlodipine at 0900. The order says, "Hold if systolic BP below 100 mm Hg." The patient's systolic pressure is 92 mm Hg, and he says he feels light-headed. What should the RPN do?

a. Give the dose because amlodipine works slowly and will not lower the pressure today

b. Give half the tablet and recheck the pressure in 1 hour

c. Ask the patient whether he wants to take the dose

d. Hold the dose, keep him safe from falls, and report and document the finding

Answer: d — The order gives a hold parameter, and the patient is symptomatic, so the RPN holds the dose, protects him from falls and reports to the prescriber, documenting the action (d) (section 19.2; Chapter 1, section 1.3). Giving the full dose (a) ignores the order. Splitting a tablet (b) changes the dose without an order. A patient may refuse a medication, but asking him to decide (c) does not replace the nurse's duty to follow the hold order and report.

15. [CORE] A patient admitted for a knee replacement has a blood pressure of 176/98 mm Hg on the first postoperative evening. He rates his pain as 8 out of 10 and is grimacing. He has no headache, chest pain or neurologic change. What is the nurse's best first action?

a. Call the prescriber at once to request an IV antihypertensive for the reading

b. Treat his pain as ordered, then recheck the pressure after he rests

c. Give his usual morning antihypertensive dose now

d. Activate the rapid response team for a hypertensive emergency

Answer: b — A high reading in a patient in severe pain, without signs of organ damage, is usually a stress response; the nurse treats the cause and rechecks (b) (section 19.2). An IV antihypertensive (a) is not indicated without organ damage. Giving a scheduled dose early (c) needs an order. There are no features of a hypertensive emergency (d), although the nurse escalates if symptoms appear or the pressure stays high.

16. [CORE] A patient with long-standing hypertension suddenly reports severe chest pain "like something ripping" that moves to his back. Which finding most strongly supports the nurse's concern about aortic dissection?

a. Right arm 168/94 mm Hg; left arm 136/80 mm Hg

b. Pain that eases when he leans forward

c. Pain that is worse with deep breathing and coughing

d. A heart rate of 88 beats/min that is regular

Answer: a — A systolic difference of more than 20 mm Hg between arms, with tearing pain, is a high-risk feature of acute aortic syndrome (a) (section 19.3). Pain eased by leaning forward (b) suggests pericarditis (Chapter 18). Pain worse with breathing (c) suggests a pleural cause. A regular heart rate of 88 (d) is not specific.

17. [CORE] The nurse suspects aortic dissection in the patient above. The emergency physician has not yet seen him, and a colleague suggests starting the heparin order set for a possible heart attack. What should the nurse do?

a. Start the heparin order set, because early anticoagulation improves outcomes in a heart attack

b. Give ASA from the chest pain order set now and start heparin once the ECG is done

c. Tell the physician about the tearing pain and unequal arm pressures before any anticoagulant

d. Wait for the physician to arrive and complete the assessment before reporting findings

Answer: c — Dissection can resemble a heart attack, and anticoagulants or thrombolytics given in error to a patient with dissection can cause serious or fatal bleeding; the nurse reports the features of dissection before any such drug is given (c) (section 19.3). Starting heparin (a) or giving ASA (b) without that information is unsafe. Waiting to report (d) delays emergency care.

18. [RN] A patient in a hypertensive emergency has a blood pressure of 220/130 mm Hg. The order is to lower the mean arterial pressure (MAP) by no more than 25% in the first hour. What is the lowest MAP the nurse should accept at 1 hour?

a. 98 mm Hg

b. 160 mm Hg

c. 120 mm Hg

d. 140 mm Hg

Answer: c — MAP is about (systolic + 2 × diastolic) ÷ 3, so (220 + 260) ÷ 3 = 160 mm Hg; a 25% fall gives 120 mm Hg (c) (section 19.3, Going Deeper). A MAP of 98 mm Hg (a) is a fall of nearly 40%, which risks ischemia. A MAP of 160 mm Hg (b) is the starting value. A MAP of 140 mm Hg (d) is within the limit but is not the lowest acceptable value.

19. [RN] A patient with aortic dissection is receiving IV esmolol. The prescriber plans to add sodium nitroprusside. Which statement about the order of these drugs is correct?

a. Esmolol is started first so that nitroprusside can share its IV line.

b. Once esmolol is running, an arterial line is no longer needed.

c. Esmolol is expected to bring systolic pressure to target within 5 minutes.

d. Heart rate is controlled first; a vasodilator is added if needed.

Answer: d — The 2022 ACC/AHA guideline recommends an IV beta-blocker as initial management, aiming for a heart rate of 60 to 80 beats/min, with an IV vasodilator added if blood pressure is not controlled (d) (section 19.3, Going Deeper). The order of drugs has nothing to do with sharing an IV line (a). Continuous arterial pressure monitoring is still recommended (b). The aim is controlled lowering to the ordered targets, not a set number of minutes (c).

20. [RN] A patient receiving a titrated IV antihypertensive has an arterial line reading 88/50 mm Hg. Twenty minutes ago it read 150/90 mm Hg. The patient is alert and talking, and a cuff reading on the other arm is 148/88 mm Hg. What should the nurse do first?

a. Stop the infusion and call the rapid response team for hypotension

b. Check the arterial line set-up, including transducer level, zero and waveform

c. Increase the infusion rate, because the cuff reading is still above target

d. Remove the arterial line, because it is clearly malfunctioning

Answer: b — An alert patient with a cuff reading that matches the earlier trend suggests a technical problem; the nurse checks the transducer level, zero and waveform first (b) (section 19.3, Going Deeper). Stopping the infusion (a) based on a suspect reading could cause a rebound rise. Increasing the rate (c) before resolving the discrepancy is unsafe. Removing the line (d) needs an order and is not the first step.

Case: Gordon (Questions 21–24): Gordon, 71, is admitted to a medical unit with a left-leg DVT. He has started apixaban. He also takes ASA for a past heart attack and ibuprofen for knee pain, and he lives alone in a rural community.

21. [CORE] Which finding should the nurse report first?

a. Mild bruising at a former IV site

b. A black, tarry stool this morning

c. Persistent swelling of the left calf

d. A blood pressure of 136/84 mm Hg

Answer: b — Black, tarry stool suggests gastrointestinal bleeding, a serious hidden bleed in a patient on an anticoagulant plus ASA and an NSAID (section 19.7). Minor bruising is expected and less urgent. Calf swelling persists for days after DVT treatment begins. The blood pressure is acceptable and not a sign of bleeding.

22. [CORE] Gordon asks whether he will need regular blood tests to check that apixaban is working, as his brother does with warfarin. What is the nurse's best response?

a. "You will need an INR test every 2 to 4 days at first."

b. "Apixaban needs an aPTT test before each dose."

c. "The INR will tell us if the dose is right for you."

d. "Its effect is not checked routinely, but your kidney function will be."

Answer: d — DOACs are given at fixed doses without routine tests of their effect, but kidney function is checked before starting and at least yearly (section 19.7). INR testing every 2 to 4 days applies to warfarin. aPTT is used for heparin infusions. The INR does not measure apixaban's effect.

23. [CORE] Which statement by Gordon shows that teaching about pain relief has been effective?

a. "I'll take ibuprofen only when my knee is very sore."

b. "I'll ask the pharmacist before I take any pain medicine."

c. "I'll switch from ibuprofen to naproxen instead."

d. "I can take extra ASA for my knee because it is only a mild pain reliever."

Answer: b — NSAIDs and extra ASA increase bleeding with an anticoagulant, so checking with the pharmacist before taking any pain reliever shows understanding (section 19.7). Occasional ibuprofen still adds risk. Naproxen is also an NSAID. Extra ASA increases bleeding risk.

24. [CORE] Before discharge, which action best addresses Gordon's risk of not continuing apixaban at home?

a. Confirming that he can afford and obtain the medication locally

b. Giving him a printed list of foods high in vitamin K

c. Booking weekly INR tests at the laboratory closest to his home community

d. Teaching him to take two tablets if he misses a dose

Answer: a — Cost, coverage and access to a pharmacy are real barriers, especially in rural communities, and stopping early raises clot risk (section 19.7). Vitamin K lists apply to warfarin, and even then consistency matters, not avoidance. INR testing does not guide apixaban. Doubling a dose is unsafe.

25. [CORE] A patient with intermittent claudication asks how to position the legs in bed. What should the nurse advise?

a. Raise both legs on two pillows so they rest above the level of the heart.

b. Keep the legs level or slightly lower than the heart.

c. Alternate raising each leg every 2 hours.

d. Elevate the foot of the bed at night.

Answer: b — In arterial disease, gravity helps blood reach the foot, so the legs stay level or slightly dependent (section 19.4). Raising the legs reduces arterial flow and can worsen ischemic pain; elevation is used for venous disease. Alternating elevation and raising the foot of the bed still elevate the legs.

26. [CORE] A patient's ankle-brachial index is 0.7 in the right leg. How should the nurse interpret this result?

a. It suggests PAD in the right leg.

b. It is within the normal range.

c. It suggests stiff, calcified arteries.

d. It confirms a DVT in the right leg.

Answer: a — The CCS states that an ABI below 0.9 suggests PAD (section 19.4). A value of 0.7 is not normal. Calcified arteries give falsely normal values or values above 1.4. The ABI assesses arterial flow, not venous clots.

27. [CORE] Which finding in a patient with acute limb ischemia shows that the limb is becoming threatened and needs the most urgent treatment?

a. A cool foot with a weak pulse
b. Pain in the calf at rest
c. Pallor of the foot when it is raised and a dusky colour when it is lowered
d. New numbness above the toes and weak foot movement

Answer: d — New sensory loss beyond the toes and motor weakness mark an immediately threatened limb that is salvageable only with prompt revascularization (section 19.4). Coolness, a weak pulse, rest pain and elevation pallor are ischemic signs, but none shows the nerve and muscle threat that sensory and motor loss do.

28. [CORE] A 74-year-old man with a known AAA reports sudden severe back pain. His blood pressure is 86/50 mm Hg and his pulse is 124. What should the nurse do first?

a. Give the ordered analgesic and reassess in 30 minutes.
b. Call the rapid response team.
c. Help him walk to the bathroom.
d. Palpate the abdomen firmly for a mass.

Answer: b — Sudden back pain with hypotension and tachycardia in a patient with an AAA suggests rupture, an emergency that needs immediate escalation (section 19.5). Treating pain alone delays care. Walking increases risk. Firm palpation delays help and is not needed to act.

29. [CORE] Which patient meets the Canadian Task Force on Preventive Health Care recommendation for AAA screening?

a. A 70-year-old man who has never been screened
b. A 68-year-old woman who smoked for 30 years
c. An 84-year-old man with high blood pressure
d. A 55-year-old man with a family history of AAA

Answer: a — The Task Force recommends one-time ultrasound screening for men aged 65 to 80 (section 19.5). It recommends against screening women and men over 80. A 55-year-old is below the recommended age range.

30. [CORE] A patient in hospital 4 days after hip surgery has new swelling and warmth of one calf. What is the nurse's best action?

a. Massage the calf gently to ease the discomfort.
b. Wait for the next scheduled assessment.
c. Apply a compression stocking to the affected leg.
d. Report the findings promptly to the prescriber.

Answer: d — One-sided calf swelling and warmth after surgery suggest DVT, which needs prompt reporting and diagnostic testing (section 19.6). Massage is avoided. Compression does not treat a DVT and is not a substitute for assessment. Waiting delays diagnosis.

31. [CORE] A patient with a suspected DVT is in the lower-probability group. Which test is usually done first?

a. Compression ultrasound of both legs
b. International normalized ratio
c. D-dimer
d. Ankle-brachial index

Answer: c — In the lower-probability group, a negative D-dimer rules out DVT without imaging (section 19.6). Compression ultrasound comes first when probability is higher. The INR measures warfarin's effect. The ABI assesses arterial disease.

32. [CORE] A patient taking warfarin for VTE asks about diet. Which response is accurate?

a. "Avoid all green vegetables while you take warfarin."
b. "Eat as many green vegetables as you like each day."
c. "Keep the amount of vitamin K you eat about the same from week to week."
d. "Vitamin K in food has no effect on warfarin."

Answer: c — Consistent vitamin K intake keeps the INR stable; no food is forbidden (section 19.7). Avoiding greens is unnecessary. Large swings in intake change warfarin's effect, so unlimited variation is unsafe and vitamin K does matter.

33. [CORE] A patient taking warfarin for a DVT has an INR of 2.4. How should the nurse interpret this result?

a. Within the usual target range of 2.0 to 3.0
b. Too low for VTE treatment, so the weekly dose should be increased
c. Too high for VTE treatment, so the next dose should be held and the prescriber called
d. The target for a mechanical valve

Answer: a — For most indications, including VTE, the target INR is 2.5 within a range of 2.0 to 3.0 (section 19.7). The value is neither low nor high. Mechanical valves have different targets (section 18.5).

34. [CORE] A patient who takes apixaban twice daily realizes at noon that the morning dose was missed. What should the nurse advise?

a. Take two tablets with the evening dose.
b. Skip the missed dose and wait until tomorrow.
c. Take the missed dose now, then continue the usual schedule.
d. Stop apixaban for the rest of the day and call the prescriber in the morning.

Answer: c — The Canadian patient information for apixaban says to take the missed dose as soon as remembered and continue twice daily without doubling (section 19.7). Doubling raises bleeding risk. Skipping leaves the patient unprotected. Stopping raises clot risk.

35. [CORE] An 80-year-old resident of a long-term care home who takes rivaroxaban slipped and hit her head. She is alert and has no headache. Which action should the nurse take?

a. Apply ice and recheck her tomorrow.
b. Hold rivaroxaban for one week.
c. Arrange urgent medical assessment.
d. Document the fall and continue routine care.

Answer: c — A head injury in a person on an anticoagulant can cause bleeding inside the skull that appears hours later, so urgent assessment is needed even without symptoms (section 19.7; Chapter 8). Waiting until the next day delays diagnosis. Holding the anticoagulant is a prescriber decision and does not replace assessment. Routine care misses the risk.

36. [CORE] On a medical unit, an RPN is caring for a patient receiving enoxaparin for DVT. The patient's hemoglobin has fallen from 128 g/L to 101 g/L, and the patient feels dizzy on standing. What should the RPN do?

a. Give the next dose and recheck the hemoglobin tomorrow.

b. Encourage oral fluids, help the patient back to bed and continue to monitor the vital signs.

c. Ask the patient to stay in bed until morning.

d. Hold the next dose and consult the RN and prescriber now.

Answer: d — A falling hemoglobin with dizziness suggests bleeding; every nurse acts at once, holds the next dose per policy and escalates, and the RPN consults the RN as the patient's needs change (section 19.7). Giving the dose risks more bleeding. Fluids and bed rest do not address the cause.

37. [CORE] Which statement about scope for heparin therapy reflects how role differences are explained in Ontario?

a. CNO rules state that only RNs may care for any patient receiving an anticoagulant.

b. CNO classifies patients on heparin as unstable, so RPNs may not care for them.

c. Whether a nurse manages a heparin infusion depends on authority, competence, context and employer policy.

d. RPNs may manage heparin infusions without an order if they are competent.

Answer: c — Role differences are explained by authority, competence and context, and employer policy shapes who manages titrated infusions (section 19.7, Scope in Practice box). CNO has no rule limiting all anticoagulant care to RNs and does not classify patients this way. An order is part of authority.

38. [RN] A patient receiving IV unfractionated heparin for 7 days has a platelet count that has fallen from 240 × 10^9/L to 95 × 10^9/L, and the left arm is newly swollen. Which action should the nurse anticipate?

a. Stop all heparin and start a non-heparin anticoagulant.

b. Switch from the heparin infusion to a subcutaneous LMWH such as enoxaparin.

c. Give a platelet transfusion before any other treatment.

d. Start warfarin today to prevent further clots.

Answer: a — A fall of about 60% beginning within days 5 to 10, with new thrombosis, points strongly to HIT; all heparin stops and a non-heparin anticoagulant starts (Going Deeper box). Switching to an LMWH still exposes the patient to heparin. Routine platelet transfusion is not recommended. Warfarin waits until the platelet count recovers.

39. [RN] Which features does the 4Ts score consider when estimating the probability of HIT? Select all that apply.

a. How far the platelet count has fallen

b. When the fall began in relation to heparin exposure

c. Whether new thrombosis has occurred

d. Whether another cause of a low platelet count is likely

e. The patient's hemoglobin level

f. The heparin infusion rate

Answer: a, b, c, d — The 4Ts score weighs the size of the platelet fall, its timing, new thrombosis and other possible causes (Going Deeper box). Hemoglobin and the infusion rate are not part of the score.

40. [RN] A hospital adjusts heparin infusions using anti-Xa levels instead of the aPTT. What best explains the difference?

a. Anti-Xa measures the effect of warfarin, whereas the aPTT measures the effect of heparin.

b. Anti-Xa measures heparin's activity directly; the aPTT is affected by many factors.

c. The aPTT is used only for LMWH.

d. Anti-Xa monitoring removes the need for a protocol.

Answer: b — The anti-Xa level measures heparin activity directly, whereas the aPTT is a clotting time influenced by many factors; each hospital chooses one with a protocol (Going Deeper box). Warfarin is monitored with the INR. The aPTT is used for UFH. A protocol is always needed.

V Hematologic, Immunologic & Endocrine Care

UNIT CLINICAL SCOPE & INTEGRATION

Explores hematologic assessment, anemias, sickle cell vaso-occlusive crisis, Canadian Blood Services transfusion safety, hematologic malignancies, immune deficiency, HIV care, anaphylaxis, Diabetes Canada clinical practice guidelines (DKA, HHS, inpatient glycemic targets), and thyroid, parathyroid, adrenal, and pituitary disorders.

Contents of UNIT V

Chapter	Chapter Title	Visual Assets	Page
Chapter 20	Hematologic Disorders and Transfusion	8 Figs • 4 Tbls	p. 569
Chapter 21	Immunity, Allergy and HIV	7 Figs • 4 Tbls	p. 601
Chapter 22	Diabetes	6 Figs • 4 Tbls	p. 635
Chapter 23	Thyroid, Parathyroid, Adrenal and Pituitary Disorders	5 Figs • 3 Tbls	p. 665

20 Hematologic Disorders and Transfusion

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how blood cells are made, and interpret the complete blood count, iron studies and basic clotting tests in SI units, recognizing that reference ranges vary by laboratory.
2. Recognize and care for adults with iron deficiency, vitamin B12 and folate deficiency and other anemias, describing findings on a range of skin tones and in older adults.
3. Provide safe, equitable care for people with sickle cell disease and thalassemia, including timely pain management in a vaso-occlusive crisis and early recognition of complications.
4. Recognize and respond to bleeding and clotting disorders (thrombocytopenia, immune thrombocytopenia, hemophilia, von Willebrand disease and DIC), and teach bleeding precautions.
5. Describe leukemia, lymphoma and multiple myeloma, and manage the infection, bleeding and anemia risks common to blood cancers.
6. Give blood components safely: pre-transfusion checks, bedside identification, monitoring, and recognition of and first actions for transfusion reactions, using the CJMM.
7. Distinguish RN and RPN roles in transfusion and hematologic care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5	Clinician; Scholar	Foundations of Practice
3, 6	Clinician; Advocate; Educator	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Blood problems show up on every unit. A low hemoglobin can explain why an older adult is short of breath after a few steps, why a patient feels faint when standing after surgery, or why chest pain appears in someone with narrowed coronary arteries. Disorders of bleeding and clotting shape decisions about procedures and medications. Blood products are given on medical, surgical, oncology and critical care units every day. Whatever the setting, the nurse reads results, follows trends, links numbers to what is seen at the bedside, and acts when a value or a patient changes.

This chapter starts with how blood cells are made and how to read the complete blood count, iron studies and basic clotting tests in SI units (section 20.1). It then covers the anemias (20.2) and two inherited hemoglobin disorders, sickle cell disease and thalassemia (20.3). The second half turns to bleeding and clotting disorders (20.4); leukemia, lymphoma and multiple myeloma (20.5); and blood components and transfusion, including consent, bedside checks and transfusion reactions (20.6).

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1. Pain assessment and opioid principles are in Chapter 5, and recognizing deterioration in Chapter 6. Cancer treatment, including febrile neutropenia, is covered in Chapter 9. Anticoagulants and the monitoring that goes with them are taught in Chapter 19, and the anemia of chronic kidney disease in Chapter 27.

20.1 Blood and Its Tests

How Blood Cells Are Made

Hematopoiesis is the production of blood cells. In adults it takes place in the bone marrow, the soft tissue inside bones. All blood cells come from a small pool of stem cells that can both renew themselves and mature into each cell line. One branch produces red blood cells, platelets and most white blood cells. The other produces lymphocytes, the cells of specific immunity. Because all the lines share this origin, diseases of the marrow, such as aplastic anemia or leukemia, often lower more than one cell count at once (sections 20.2 and 20.5) (Figure 20.1).

Red blood cell production responds to oxygen delivery. When the kidneys sense that tissues are receiving too little oxygen, they release the hormone erythropoietin, which signals the marrow to make more red cells. This is why chronic kidney disease so often causes anemia (Chapter 27). Building a red cell needs iron to make hemoglobin, and vitamin B12 and folate to copy DNA as precursor cells divide. A shortage of any of these produces one of the anemias in section 20.2.

Young red cells leave the marrow as **reticulocytes**, which mature in the bloodstream. A mature red cell normally survives about 120 days (Phillips & Henderson, 2018). Old cells are removed mainly in the spleen, and their iron is recycled. Platelets are fragments of large marrow cells called megakaryocytes; they start clot formation at sites of vessel injury. White cells defend against infection: neutrophils respond first to bacteria, lymphocytes direct immune responses, monocytes become tissue macrophages, and eosinophils and basophils take part in allergic and parasitic responses (Chapter 21).

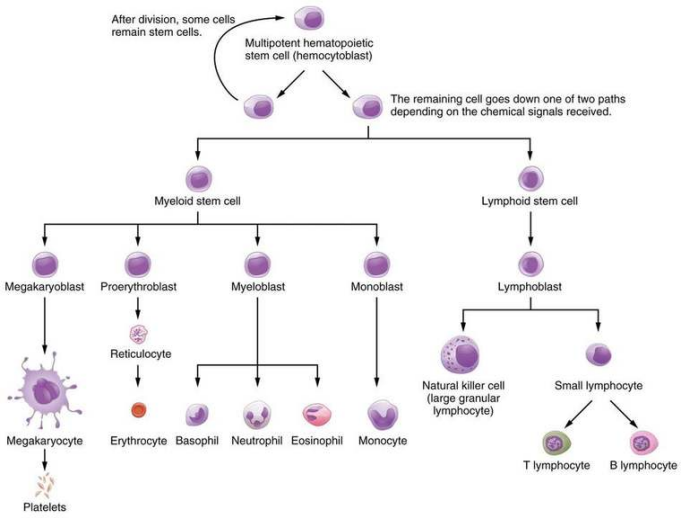

Figure 20.1 Hematopoiesis: one stem cell population in the bone marrow gives rise to two lines. The myeloid line makes red cells, platelets and most white cells; the lymphoid line makes lymphocytes. (credit: Figure 18.4, "Hematopoietic System of Bone Marrow," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The Complete Blood Count

The **complete blood count (CBC)** is the most common blood test in hospital. It reports:

- **Hemoglobin:** the oxygen-carrying protein in red cells, reported in grams per litre (g/L). It is the main value used to define anemia.
- **Hematocrit:** the fraction of blood volume made up of red cells, reported in litres per litre (L/L), for example 0.40.
- **Red blood cell count:** reported as $\times 10^{12}$/L.
- **White blood cell count and differential:** the total count and the count of each type, reported as $\times 10^{9}$/L.
- **Platelet count:** reported as $\times 10^{9}$/L.

The nurse looks at the absolute count of each white cell type, not only the total. A patient with a normal total white count can still have too few neutrophils, the cells most needed to fight bacterial infection.

The CBC also reports **red cell indices**, which describe the cells themselves. The **mean corpuscular volume (MCV)** is the average size of red cells in femtolitres (fL). The mean corpuscular hemoglobin (MCH) is the average amount of hemoglobin in each cell, and the mean corpuscular hemoglobin concentration (MCHC) is how concentrated that hemoglobin is. The red cell distribution width (RDW) shows how much cell size varies. Together these help sort anemias into small-cell, normal-cell and large-cell patterns (Going Deeper box). A reticulocyte count shows whether the marrow is responding to anemia.

Iron studies answer a different question: how much iron the body has stored. **Ferritin** is the storage form of iron, and serum ferritin is the screening test laboratories prefer when iron deficiency is suspected (Alberta Precision Laboratories [APL] & DynaLIFE Medical Labs, 2021). Serum iron alone cannot show iron stores. Ferritin also rises with inflammation and acute illness, so a normal ferritin in a sick patient does not rule out iron deficiency. Vitamin B12 and folate levels are ordered when red cells are large or nerve symptoms suggest deficiency.

Reference ranges vary by laboratory, by the patient's age and sex, and sometimes by the instrument used. Nurses always read results against the range printed on the patient's own report. Table 20.1 gives example adult ranges from Alberta's provincial laboratory system to show typical units and size of values. Laboratories also set **critical values** that are phoned to the care team at once. In the same Alberta system, for example, a hemoglobin below 70 g/L and a platelet count below 10×10^9/L in an inpatient are critical (Alberta Health Services, 2023). The nurse who receives a critical value repeats it back, assesses the patient, notifies the prescriber promptly and documents according to employer policy.

Table 20.1 The complete blood count, ferritin and vitamin B12 in SI units, and what changes may mean (Alberta Health Services, 2023; APL, 2020; APL & DynaLIFE Medical Labs, 2021; Phillips & Henderson, 2018; Weiss et al., 2019)

Test	Unit	Example adult range (varies by laboratory)	Low may mean	High may mean
Hemoglobin	g/L	Female 120–160; male 135–175	Anemia from blood loss, low production or red cell destruction	Dehydration (concentration) or too many red cells
Hematocrit	L/L	Female 0.36–0.48; male 0.40–0.52	Same as for low hemoglobin	Same as for high hemoglobin
Red blood cell count	$\times 10^{12}$/L	Female 3.80–5.20; male 4.30–6.00	Anemia	Too many red cells, or many small cells as in thalassemia trait
White blood cell count	$\times 10^9$/L	4.0–11.0	Marrow suppression (for example after chemotherapy) or marrow failure; higher infection risk	Infection, inflammation, physiological stress, some leukemias
Neutrophils	$\times 10^9$/L	1.8–7.5	Neutropenia; high risk of serious infection	Bacterial infection, inflammation, corticosteroids
Lymphocytes	$\times 10^9$/L	0.5–4.5	Some infections, immune suppression	Viral infection, some leukemias and lymphomas
Platelets	$\times 10^9$/L	140–400	Thrombocytopenia; bleeding risk rises as the count falls (section 20.4)	Reactive rise with inflammation, iron deficiency or bleeding; marrow disorders
Mean corpuscular volume (MCV)	fL	80–100	Small cells: iron deficiency, thalassemia trait	Large cells: vitamin B12 or folate deficiency, high reticulocyte count
Mean corpuscular hemoglobin concentration (MCHC)	g/L	310–360	Pale cells, as in iron deficiency	Some inherited red cell membrane disorders
Red cell distribution width (RDW)	%	Below 16.0	Not usually significant	Mixed cell sizes, as in early iron deficiency or a recent response to treatment
Ferritin	µg/L	Female 20–300; male 30–500	Depleted iron stores; values below about 30–45 are linked to iron deficiency	Inflammation, acute illness, liver disease, iron overload
Vitamin B12	pmol/L	160 or higher	Possible deficiency; confirm with clinical picture and further testing	Not usually a concern

Clotting Tests

Clotting tests measure how long plasma takes to form a clot, or the amount of key clotting proteins.

- **International normalized ratio (INR):** a standardized form of the prothrombin time. It rises with warfarin, liver disease and vitamin K deficiency; warfarin monitoring is taught in Chapter 19.
- **Activated partial thromboplastin time (aPTT):** a clotting time in seconds that rises with heparin, some factor deficiencies such as hemophilia (section 20.4) and some inhibitors. Its range depends on the reagent: when one Alberta laboratory changed reagent lots, its range moved from 26.0–36.0 to 28.0–38.0 seconds (APL, 2019).
- **Fibrinogen:** the protein that becomes the fibrin mesh of a clot. It falls when clotting factors are used up, as in disseminated intravascular coagulation and massive bleeding (sections 20.4 and 20.6).
- **D-dimer:** a fragment released when a fibrin clot breaks down. It rises with venous thromboembolism but also after surgery, with infection and in many other states, so a raised value is not specific (Chapter 19).

The platelet count belongs with these tests. A low count raises the risk of bleeding, and the link between platelet levels, bleeding and platelet transfusion is discussed in sections 20.4 and 20.6.

GOING DEEPER

Reading Red Cell Indices

Required for RN students; optional for PN students.

The MCV sorts anemia into three patterns that narrow the search for a cause.

- **Microcytic (MCV below the reference range):** most often iron deficiency. Thalassemia trait also causes small cells, often with a normal or high red cell count and a normal ferritin. Anemia of inflammation is usually normocytic but can become microcytic.
- **Normocytic:** acute blood loss, anemia of inflammation, chronic kidney disease, hemolysis and marrow failure (Phillips & Henderson, 2018; Weiss et al., 2019).
- **Macrocytic (MCV above the range):** vitamin B12 or folate deficiency, a high reticulocyte count (reticulocytes are larger than mature cells) and some drugs; hydroxyurea, for example, causes macrocytosis (Eugia Pharma, 2024).

The RDW adds detail. A high RDW means cells of mixed sizes, as when new small iron-deficient cells mix with older normal ones.

The reticulocyte count shows whether the marrow is keeping up. A low count in an anemic patient points to a production problem: missing iron, B12 or folate, low erythropoietin, or marrow failure. A high count points to loss or destruction of red cells, as in bleeding or hemolysis (Phillips & Henderson, 2018). After treatment of a deficiency starts, the reticulocyte count rises first. The cyanocobalamin monograph, for example, advises checking reticulocytes before treatment and again around days 5 to 7 (Eugia Pharma, 2023).

20.2 Anemias

Anemia is a hemoglobin below the lower limit of the reference range for the person's age and sex. It is a sign with a cause, not a diagnosis on its own. Anemia results from one of three processes: blood loss, too little red cell production, or early red cell destruction. Table 20.2 compares the main types.

Recognizing Anemia

With less hemoglobin, each litre of blood carries less oxygen. The body compensates by raising heart rate and cardiac output and by breathing faster. Symptoms depend on how low the hemoglobin is, how fast it fell and how much reserve the heart and lungs have. A person whose hemoglobin drifted down over months may adapt surprisingly well. A sudden fall from bleeding causes hypovolemia as well as anemia and can lead to shock (Chapter 6).

Common findings are fatigue, weakness, reduced exercise tolerance, dyspnea on exertion, tachycardia and, in more severe cases, low blood pressure (Phillips & Henderson, 2018). Patients may report dizziness when standing, palpitations or headaches. In a person with coronary artery disease, anemia can trigger angina; in a person with heart failure, it can worsen breathlessness and fluid retention (Chapters 17 and 18).

Assessing pallor on a range of skin tones: pallor is easy to see in the face and skin of people with light skin and much harder to see in medium and dark skin. The nurse looks where pigment does not hide colour: the inner lower eyelid (conjunctiva), the lips and inside of the mouth, the nail beds and the palms. Comparing with the patient's usual colour, or asking the patient or family whether

they look different, also helps. Even so, no single site is accurate enough on its own; a pooled review of studies in children found that palm, conjunctival and nail bed pallor were each only moderately useful for detecting anemia (Chalco et al., 2005). Pallor prompts a hemoglobin level, and a normal-looking patient can still be anemic. Pulse oximetry measures the saturation of the hemoglobin that is present, not the amount, so oxygen saturation can be normal in severe anemia; its reduced accuracy on darker skin is discussed in Chapter 12.

When to escalate: the nurse reports at once a critical hemoglobin value, a fall from the patient's baseline, chest pain, syncope, new confusion, rising heart rate with falling blood pressure, or signs of bleeding such as black or bloody stools or vomiting blood. These findings are communicated with a structured tool such as Situation, Background, Assessment, Recommendation (SBAR) (Chapter 6).

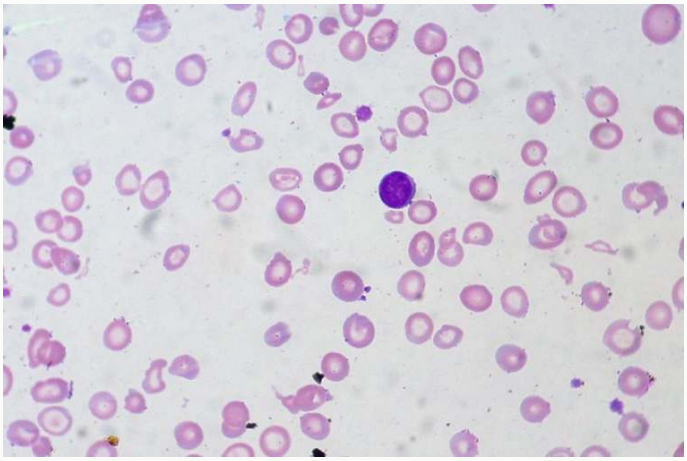

Figure 20.2 A blood smear in severe iron deficiency anemia: the red cells are small (microcytic) and pale (hypochromic), with wide pale centres. (credit: “Iron-deficiency Anemia, Peripheral Blood Smear” by Ed Uthman/Wikimedia Commons, CC BY 2.0)

Iron Deficiency Anemia

Iron deficiency anemia develops in stages. Iron stores, measured by ferritin, fall first. Next, the marrow runs short of iron for new red cells. Finally, the hemoglobin falls and the red cells become small and pale (Cooper et al., 2012; Figure 20.2). Long-standing iron deficiency can also make the nails thin and spoon-shaped, a change called koilonychia (Figure 20.3).

Figure 20.3 Koilonychia: thin nails that curve up at the edges into a spoon shape, a sign of long-standing iron deficiency. Nail and skin changes are useful cues on every skin tone. (credit: “Koilonychia iron deficiency anemia” by CHeitz/Wikimedia Commons, CC BY 2.0)

Iron is lost mainly through bleeding. Common causes are heavy menstrual bleeding, slow bleeding from the gastrointestinal tract (for example from ulcers, polyps, cancer or anti-inflammatory drugs), the extra demands of pregnancy, poor absorption after gastric surgery or with celiac disease or inflammatory bowel disease, and diets low in absorbable iron (Ko et al., 2020). Iron from plant foods is harder to absorb than iron from meat, poultry and fish (Health Canada, 2025).

Canadian data: using Canadian Health Measures Survey data from 2012 to 2019, Health Canada (2025) reports that low iron affects about 1 in 4 women (ages 14 to 50) and that the chance of low iron is twice as high among people new to Canada; the infographic does not name the comparison group. In the 2009 to 2011 survey cycle, about 3% of Canadians aged 3 to 79 had anemia; people in the lowest household income quartile had a slightly lower mean hemoglobin than those in the highest (140 versus 143 g/L) (Cooper et al., 2012). That survey did not include people living on First Nations reserves or Crown lands, people in institutions or people in certain remote regions, so it cannot describe iron status in those communities.

Finding the cause: a diagnosis of iron deficiency always raises the question of where the iron went. In a person with anemia, a ferritin below 45 µg/L (equal to 45 ng/mL) supports iron deficiency; ferritin is less reliable with chronic inflammation or chronic kidney disease (Ko et al., 2020). The American Gastroenterological Association recommends upper endoscopy and colonoscopy for men and postmenopausal women with iron deficiency anemia, because a bleeding lesion, including cancer, may be the cause. It also

recommends blood testing for celiac disease (Ko et al., 2020). In older adults especially, starting iron without looking for the source can let a cancer progress.

Nursing care using the CJMM: the nurse *recognizes cues* such as fatigue, exertional dyspnea, pallor, tachycardia and dark stools, and *analyzes* them against the CBC and ferritin. The *priority hypotheses* are usually reduced activity tolerance, risk of falls and the possibility of ongoing bleeding. The nurse *generates solutions and takes action*: pacing activity, helping with mobility, checking stools, teaching about iron, and reporting signs of active bleeding. To *evaluate outcomes*, the nurse follows symptoms, the reticulocyte count and hemoglobin. Hemoglobin should rise after about a month of oral iron; if it does not, poor adherence, poor absorption or ongoing blood loss is considered (Ko et al., 2020).

Oral and intravenous iron: oral iron is inexpensive and easy to take, but nausea and constipation are common (Black et al., 2024). Teaching focuses on timing and absorption (Patient Education box). Intravenous (IV) iron is used when oral iron is not tolerated or not working, when absorption is poor, as after gastric surgery or with inflammatory bowel disease or chronic kidney disease (Ko et al., 2020; Health Canada, 2024).

Hypersensitivity, including anaphylaxis, is a known risk with every IV iron product. The risk is higher in people with known allergies, severe asthma or eczema, and a reaction can occur even after earlier doses were uneventful (Health Canada, 2024). The nurse takes baseline vital signs, keeps emergency equipment and medications at hand, watches closely during the infusion and repeats vital signs afterward. One Alberta order set asks for observation for 30 minutes after the infusion and describes milder reactions to free iron (flushing, chest tightness, joint aches) that are managed by pausing the infusion and calling the prescriber (Black et al., 2024). Local policy sets the exact monitoring. With ferric carboxymaltose, low blood phosphate has been reported, sometimes with serious outcomes such as softened bones and fractures (Health Canada, 2024).

PATIENT EDUCATION

Taking Iron by Mouth

- Take your iron exactly as your prescriber or pharmacist told you. More is not better.
- Ask your pharmacist the best time of day to take it. If it upsets your stomach, ask whether you can take it with a little food.
- Foods and drinks with vitamin C, such as fruits and vegetables, help your body absorb iron.
- Tea, coffee and high amounts of calcium lower how much iron you absorb. Have tea or coffee, or take calcium or antacids, 1 to 2 hours after eating rather than with the meal (Health Canada, 2025).
- Nausea and constipation are common (Black et al., 2024). Drink fluids, stay active and tell your provider if they bother you; another form or schedule may help.
- Tell your provider right away if your stools are black and sticky like tar, or if you vomit blood or feel faint, because these can be signs of bleeding.
- Keep iron locked away from children. An overdose can be very dangerous for a child.
- Keep your follow-up blood tests. They show whether the iron is working.

Vitamin B12 and Folate Deficiency

Vitamin B12 and folate are needed to copy DNA when red cell precursors divide. When either is missing, the precursors grow but divide poorly, so the red cells that reach the blood are large: a **macrocytic** or megaloblastic anemia.

Absorbing B12 from food depends on intrinsic factor, a protein made in the stomach (Eugia Pharma, 2023). **Pernicious anemia** is an autoimmune disease in which antibodies damage the stomach lining and intrinsic factor, so B12 cannot be absorbed. Other causes of B12 deficiency include gastric surgery or removal of the stomach, disease of the last part of the small bowel (such as Crohn disease), long-term metformin, proton pump inhibitors, low dietary intake and older age (Patel & McGuirk, 2025). Low folate usually reflects low intake or higher needs.

Vitamin B12, unlike folate, is also needed for healthy nerves. Deficiency can cause fatigue, "brain fog", depression, peripheral neuropathy (numbness and tingling in the hands and feet) and ataxia, an unsteady gait (Patel & McGuirk, 2025). If deficiency goes untreated for more than about three months, spinal cord damage can become permanent (Eugia Pharma, 2023). For this reason, both B12 and folate are checked before treatment. Folic acid given alone can improve the anemia while nerve damage from B12 deficiency continues.

The nurse assesses sensation, balance, gait and cognition, and asks about metformin and acid-suppressing drugs. Vitamin B12 can be replaced by injection or by mouth. Injection is the traditional route for pernicious anemia, and the Canadian monograph states that people with pernicious anemia need it for life (Eugia Pharma, 2023). A recent review notes that high-dose oral B12 works as well as injection for most people, with injection preferred when deficiency is severe or there are neurologic signs (Patel & McGuirk, 2025). The prescriber chooses the route. As red cell production restarts, potassium can fall sharply, so potassium is monitored closely in the first 48 hours of treatment for severe deficiency (Eugia Pharma, 2023). People taking metformin long term may need periodic B12 checks (Patel & McGuirk, 2025).

Other Anemias in Brief

- **Anemia of inflammation:** the anemia seen most often in people who are hospitalized or chronically ill. During infection, autoimmune disease or cancer, inflammatory signals raise the hormone hepcidin, which blocks iron absorption and traps iron inside storage cells. The marrow cannot use the iron the body has. Serum iron is low but ferritin is normal or high. Treatment targets the underlying disease (Weiss et al., 2019).
- **Anemia of chronic kidney disease:** damaged kidneys make too little erythropoietin. This anemia and its treatment are covered in Chapter 27.
- **Hemolytic anemia:** red cells are destroyed before their normal lifespan ends. Causes include inherited disorders (sickle cell disease, thalassemia, glucose-6-phosphate dehydrogenase deficiency, hereditary spherocytosis) and acquired ones (autoimmune hemolysis, some drugs, transfusion reactions and red cell fragmentation in disseminated intravascular coagulation) (Phillips & Henderson, 2018). Hemoglobin released from destroyed cells is broken down to bilirubin, which causes **jaundice**. Jaundice is easiest to see in the sclera on every skin tone; on darker skin the nurse also checks the hard palate and the palms. Urine may be dark from bilirubin or hemoglobin. Laboratory signs include a high reticulocyte count, raised lactate dehydrogenase and unconjugated bilirubin, and low haptoglobin (Phillips & Henderson, 2018).
- **Aplastic anemia:** the marrow fails to make enough of all three cell lines. Patients have anemia, infections from low neutrophils and bleeding from low platelets. Treatment, in specialized centres, includes immune-suppressing therapy and stem cell transplant (Young, 2018). Nursing care resembles care for any patient with very low blood counts (Chapter 9).

Table 20.2 Types of anemia compared (Ko et al., 2020; Patel & McGuirk, 2025; Phillips & Henderson, 2018; Weiss et al., 2019; Young, 2018)

Type	Common causes	Typical red cell pattern	Key findings	Treatment focus
Iron deficiency	Blood loss (menstrual, gastrointestinal), pregnancy, poor absorption, low intake	Small, pale cells; RDW often high	Low ferritin; fatigue, exertional dyspnea, pallor	Find and treat the source; oral or IV iron
Vitamin B12 deficiency	Pernicious anemia, gastric or ileal surgery or disease, metformin, proton pump inhibitors, low intake	Large cells	Low B12; numbness, tingling, unsteady gait, cognitive change	B12 by injection or by mouth; monitor potassium early
Folate deficiency	Low intake, higher needs	Large cells	Low folate; no nerve damage from folate lack alone	Folic acid after B12 deficiency is ruled out
Anemia of inflammation	Chronic infection, autoimmune disease, cancer	Usually normal size; sometimes small	Low serum iron with normal or high ferritin	Treat the underlying disease
Anemia of chronic kidney disease	Too little erythropoietin	Normal size	Reduced kidney function	See Chapter 27
Hemolytic	Inherited red cell disorders, autoimmune, drugs, transfusion reaction	Usually normal or large size	Jaundice, dark urine, high reticulocytes, raised lactate dehydrogenase and bilirubin, low haptoglobin	Treat or remove the cause

Type	Common causes	Typical red cell pattern	Key findings	Treatment focus
Aplastic	Marrow failure, often immune	Normal or large size	Low red cells, white cells and platelets; infections, bleeding	Specialist care: immune suppression, stem cell transplant

MEDICATIONS

Iron, Vitamin B12 and Hydroxyurea

- **Oral iron** (iron salts taken by mouth; the prescriber or pharmacist recommends the product): first-line for most iron deficiency. Check the timing of other drugs and of tea, coffee, calcium and antacids; ask about constipation and nausea.
- **IV iron** (iron sucrose; ferric carboxymaltose): for intolerance, failure or poor absorption of oral iron. Check for previous reactions and allergies, take baseline vital signs, have emergency drugs and equipment ready, monitor during and after the infusion as policy states, and know that anaphylaxis can occur with any IV iron (Health Canada, 2024).
- **Vitamin B12 (cyanocobalamin):** by injection or by mouth. Ask about cobalt or B12 allergy; monitor potassium closely early in treatment of severe deficiency; teach that pernicious anemia needs lifelong treatment (Eugia Pharma, 2023).
- **Folic acid:** for confirmed folate deficiency, after B12 deficiency has been ruled out.
- **Hydroxyurea:** a disease-modifying oral drug used in sickle cell disease (section 20.3). The Canadian product monograph lists only cancer indications; use in sickle cell disease follows hematology guidance (CanHaem, 2014). It suppresses the marrow, so blood counts are monitored. Because it can harm a fetus, the monograph advises reliable birth control while it is taken and afterward: at least 6 months after the last dose for women and at least 1 year for men. It is handled as a hazardous drug: gloves for anyone handling capsules, hand washing, and no opening of capsules without precautions (Eugia Pharma, 2024; Chapter 9).

LIFESPAN CONSIDERATIONS

Anemia in Older Adults

- **Older adults:** anemia is common in older people living in the community, but it is not harmless. Studies link it to higher death rates, more hospital admissions, loss of physical function and frailty, and to worse outcomes in heart failure (Patel & Guralnik, 2009). A low hemoglobin is a finding to explain, not something to accept as part of aging.
- In Canada, anemia among people aged 65 to 79 rose between the 1970s and 2009 to 2011, and the authors suggested that causes other than iron deficiency, including B12 deficiency, may play a part (Cooper et al., 2012).
- In older adults, anemia may first show as fatigue, a fall, worsening angina or heart failure, or confusion. The nurse treats dizziness and weakness as fall risks (Chapter 8).
- New iron deficiency in an older adult calls for a search for gastrointestinal bleeding, including cancer (Ko et al., 2020).
- Medications matter: anti-inflammatory drugs and anticoagulants can cause bleeding, and metformin and proton pump inhibitors can lower B12. A medication review is part of the work-up (Chapter 8).
- **Younger adults:** heavy menstrual bleeding and pregnancy are common causes of iron deficiency in people who menstruate.

20.3 Sickle Cell Disease and Thalassemia

What Happens in Sickle Cell Disease

Sickle cell disease is a group of inherited disorders caused by an abnormal hemoglobin called hemoglobin S. When hemoglobin S gives up its oxygen, its molecules link into long, stiff chains. The red cell becomes rigid and distorts into a crescent or sickle shape that can be trapped in small vessels (Alberta Health Services, 2019; Figure 20.4). Two problems follow:

- **Hemolysis:** sickled cells are fragile and break down early, which causes chronic anemia, jaundice and, over time, gallstones.
- **Vaso-occlusion:** rigid cells block small blood vessels. The tissue downstream becomes ischemic, causing sudden severe pain and, over years, organ damage.

Sickle cell disease is inherited when a person receives a hemoglobin S gene from each parent, or hemoglobin S from one parent and another hemoglobin variant, such as hemoglobin C or beta thalassemia, from the other (Canadian Haemoglobinopathy Association

[CanHaem], 2014). A person who inherits only one hemoglobin S gene has **sickle cell trait**. People with the trait are carriers and generally do not have the disease, but they can pass the gene to their children.

Newborn screening finds the disease before symptoms start, so that infection prevention and family teaching begin early. Programs differ by province and territory (Canadian Context box). Screening also identifies infants with the trait, and families need clear, respectful counselling about what that means (Canadian Institute of Child Health, n.d.).

Complications

- **Vaso-occlusive crisis:** an episode of acute pain from blocked blood flow, often in the back, chest, arms or legs. It is the most common reason people with sickle cell disease come to an emergency department or are admitted (Ontario Health, 2023).
- **Acute chest syndrome:** a new infiltrate on chest X-ray plus one or more of fever, chest pain, rapid breathing, wheezing or cough (Pastore et al., 2017). Infection, fat emboli from damaged marrow and sickled cells trapped in the lungs contribute. It is an emergency that can develop during a pain crisis and progress to respiratory failure. Management includes admission, close monitoring, oxygen to keep saturation at or above 95%, careful fluid balance, urgent hematology input and sometimes transfusion (CanHaem, 2014; Pastore et al., 2017).
- **Infection and functional asplenia:** repeated sickling damages the spleen so that it no longer filters bacteria well. This **functional asplenia** brings a lifelong risk of overwhelming bloodstream infection from encapsulated bacteria. The *Canadian Immunization Guide* recommends all routine vaccines including yearly influenza vaccine, plus pneumococcal, meningococcal and *Haemophilus influenzae* type b vaccines, and hepatitis B vaccine for people who need repeated transfusions (Public Health Agency of Canada [PHAC], 2026). Fever is treated as an emergency: CanHaem (2014) advises giving antibiotics by injection or infusion within 30 minutes of arrival, without waiting for blood cultures.
- **Stroke:** sudden weakness or trouble speaking needs emergency care (Ontario Health, 2023; Chapter 31). Children at high risk are screened and may receive regular transfusions to prevent stroke (CanHaem, 2014).
- **Splenic sequestration:** sickled cells pool in the spleen, which enlarges and becomes painful while the hemoglobin drops quickly (CanHaem, 2014).
- **Priapism:** a sustained, often painful erection lasting 4 hours or more is an emergency (Ontario Health, 2023).
- **Acute anemia:** a hemoglobin that drops 20 g/L or more below the patient's usual (baseline) level (Ontario Health, 2023).
- **Chronic organ damage:** over years, many organs can be affected, and life expectancy is shorter than in people without the disease (Ontario Health, 2023).

Care During a Pain Crisis

Ontario Health's (2023) quality standard sets clear expectations for a vaso-occlusive crisis. Pain is assessed promptly with an age-appropriate pain tool. The patient is triaged at Canadian Triage and Acuity Scale (CTAS) level 2 or a more urgent level. Treatment starts **within 30 minutes of triage or within 60 minutes of arrival**. CanHaem's (2014) consensus statement likewise calls for management to start ideally within 30 minutes. Opioid principles and pain assessment are covered in Chapter 5.

Care during the crisis includes:

- **Following the individualized care plan:** many patients have a written plan from their sickle cell centre; the nurse asks for it and uses it (Ontario Health, 2023).
- **Reassessing often:** pain, sedation, respiratory rate and oxygen saturation are rechecked frequently so that doses are adjusted promptly and opioid-related hypoventilation is caught early (CanHaem, 2014).
- **Hydration:** by mouth if tolerated. Overhydration is avoided because it can cause pulmonary edema (CanHaem, 2014).
- **Oxygen only when needed:** oxygen has no proven benefit in an uncomplicated pain crisis. It is given when saturation is low or respiratory symptoms appear (CanHaem, 2014).
- **Incentive spirometry:** advised once a patient is admitted, and particularly with chest or back pain, to help prevent acute chest syndrome (CanHaem, 2014).
- **Comfort measures:** heat and massage may help alongside medication (Ontario Health, 2023).
- **Watching for acute chest syndrome:** new chest pain, fever, cough, faster breathing or falling saturation are reported immediately.
- **Planning for home:** before discharge, the patient helps write a plan for pain at home, whom to call and follow-up (Ontario Health, 2023).

Stigma and racism: in Canada, sickle cell disease mostly affects racialized people, particularly Black people (Ontario Health, 2023). Patients describe racism and anti-Black racism in health care, long waits, lack of respect and being falsely accused of "drug-seeking", and many delay or avoid emergency care as a result (Ontario Health, 2023). An Ontario study of emergency visits for sickle cell pain crises from 2006 to 2018 found that adults waited on average about 90 minutes to be seen by a physician, longer than the guideline target of a first analgesic dose within 60 minutes of arrival, and that adults and people from lower-income neighbourhoods received poorer-quality care (Chan et al., 2020). Labels such as "frequent flyer" or "drug-seeking" are not assessments. The nurse believes the patient's report of pain, gives analgesia on time, documents objectively and challenges biased comments from colleagues (Chapter 2).

Long-Term Care and Thalassemia

Hydroxyurea is the main disease-modifying drug for sickle cell disease. It raises the level of fetal hemoglobin, which does not sickle, and so reduces sickling. CanHaem (2014) advises that adults with the most severe forms of the disease who have three or more pain crises a year be strongly encouraged to start it, and that it be considered after even one episode of acute chest syndrome. Blood counts are monitored regularly (Medications box). Regular transfusion is used to prevent stroke in high-risk children and for some patients in whom hydroxyurea has not worked (CanHaem, 2014). Each unit of red cells adds about 200 to 250 mg of iron, and the body loses only about 1 mg a day, so repeated transfusion leads to **iron overload** (CanHaem, 2014). Stem cell transplant can cure sickle cell disease in selected patients. Section 20.6 covers transfusion.

The move from pediatric to adult care is a vulnerable time. Ontario Health (2023) recommends that young people aged 15 to 24 have a designated provider who coordinates care until the transition is complete.

Thalassemia is a group of inherited disorders in which the body makes too little of one of the protein chains of hemoglobin. Beta thalassemia is the most common form, and it is classed as major, intermedia or minor (trait). In Canada it mainly affects people of South Asian, Mediterranean or North African descent (Canadian Agency for Drugs and Technologies in Health [CADTH], 2016). People with **thalassemia trait** have small red cells and mild or no anemia. People with transfusion-dependent thalassemia need regular transfusions for life, starting in early childhood (CADTH, 2016); others, with non-transfusion-dependent thalassemia, need transfusion only occasionally.

For transfusion-dependent patients, iron overload is unavoidable: iron comes from transfusions and from increased absorption. Excess iron damages the heart, liver and endocrine glands, causing heart failure, dysrhythmias, cirrhosis, diabetes and hypothyroidism (CADTH, 2016). Iron chelation drugs bind iron so that it can be excreted. A Canadian drug review describes three: deferoxamine, given by slow subcutaneous infusion, usually overnight on most nights of the week, and deferasirox and deferiprone, taken by mouth (CADTH, 2016). Deferiprone can cause a severe drop in neutrophils, so blood counts are monitored and patients

report fever or sore throat at once (CADTH, 2016). Thalassemia major can also cause functional asplenia, so the same vaccine recommendations apply (PHAC, 2026).

CANADIAN CONTEXT

Sickle Cell Disease in Canada

- **How many people:** about 6,500 people in Canada live with sickle cell disease, about 3,500 of them in Ontario, and numbers are expected to grow (Ontario Health, 2023).
- **Who is affected:** the disease is most common in people whose families come from parts of Africa, India, the Middle East and the Mediterranean (Ontario Health, 2023). In Canada it mostly affects racialized people, especially Black people. Sickle cell trait occurs in all racial and ethnic groups, so ancestry alone should never be used to rule it in or out.
- **Newborn screening:** programs vary by province and territory. Ontario and British Columbia screen all newborns, and Alberta added sickle cell disease to its newborn panel in 2019 (Alberta Health Services, 2019; Canadian Institute of Child Health, n.d.).
- **Access to care:** Ontario's quality standard calls for a yearly assessment by an interprofessional team at a dedicated sickle cell centre, with a care plan shared with the patient's circle of care (Ontario Health, 2023). People in smaller or remote communities may live far from such centres.
- **Racism:** the first statement of Ontario's standard is care free from racism, anti-Black racism, discrimination and stigma (Ontario Health, 2023).
- **Advocacy:** patient organizations such as the Sickle Cell Awareness Group of Ontario (SCAGO) support patients and families and advocate for better care.

CLINICAL JUDGMENT

A Vaso-occlusive Crisis in the Emergency Department

Names and details are fictional; this is a composite story.

Daniel Boateng, 24, has sickle cell disease (hemoglobin SS). He arrives at 0140 with severe pain in his lower back and both thighs, rated 9 out of 10, that began 5 hours ago. His home medications have not helped. Heart rate 112 beats/min, blood pressure 128/76 mm Hg, respiratory rate 22 breaths/min, temperature 37.6 °C, SpO2 96% on room air. Hemoglobin is 76 g/L; his baseline in his care plan is 88 g/L.

- **Recognize cues:** severe pain typical of his crises, tachycardia, a hemoglobin 12 g/L below baseline, normal oxygen saturation.
- **Analyze cues:** this fits a vaso-occlusive crisis. Nothing yet suggests acute chest syndrome, but he is at risk.
- **Prioritize hypotheses:** uncontrolled pain is the immediate priority; acute chest syndrome and opioid-related hypoventilation are the main risks.
- **Generate solutions:** analgesia from his individualized plan within 30 minutes of triage; frequent reassessment; oral fluids; incentive spirometry once admitted.
- **Take action:** the nurse gives the first dose 20 minutes after triage and reassesses pain, sedation and breathing often. Six hours later he reports new left-sided chest pain. Temperature is 38.4 °C, respiratory rate 28 breaths/min and SpO2 90%. The nurse applies oxygen, places him upright and calls the physician at once using SBAR, stating a concern for acute chest syndrome.
- **Evaluate outcomes:** a chest X-ray shows a new infiltrate. He is admitted to a monitored bed with hematology involved.

20.4 Bleeding and Clotting Disorders

Hemostasis needs working platelets, clotting factors and a balance between forming and breaking down clots (section 20.1).

Thrombocytopenia

Thrombocytopenia is a platelet count below the laboratory's reference range (section 20.1). Canadian Blood Services explains that it results from decreased production of platelets or from their increased destruction, consumption or sequestration (Lafrance et al., 2025). Low production follows marrow failure, such as aplastic anemia (section 20.2) or leukemia (section 20.5), and chemotherapy (Chapter 9). Consumption occurs in disseminated intravascular coagulation (described below), and in liver disease an enlarged

spleen from portal hypertension can lower the count (Poon et al., 2022). Drugs can also lower the count, including heparin (heparin-induced thrombocytopenia [HIT], Chapter 19).

Immune thrombocytopenia (ITP) is an acquired autoimmune disorder in which the platelet count is low (Neunert et al., 2019). Most people have bruising and petechiae; more severe cases cause nosebleeds, gastrointestinal bleeding or heavy menstrual bleeding (American Society of Hematology [ASH], 2019). Hematology directs treatment. For adults with newly diagnosed ITP and a count below 30×10^9/L, the ASH guideline suggests a short course of corticosteroids (Neunert et al., 2019). Intravenous immunoglobulin (IVIG), a plasma protein product, is also licensed for ITP in Canada (Rutledge Harding et al., 2024). Platelet transfusion is generally reserved for critical bleeding in ITP (Lafrance et al., 2025).

Symptoms often appear only when the count is very low (Canadian Cancer Society, n.d.-b). The nurse looks for:

- **Petechiae:** tiny, flat, red or purple pinpoint spots caused by bleeding under the skin (Figure 20.5).
- **Purpura:** larger patches of bleeding under the skin; **ecchymoses** are bruises.
- **Mucosal bleeding:** bleeding gums, nosebleeds, or oozing that will not stop.
- **Hidden bleeding:** pink, red or brown urine; black or bloody stool; vomit that looks like coffee grounds (Canadian Cancer Society, n.d.-b).

On darker skin, a bruise may look darker than the skin around it rather than blue or purple, and palpation may find tenderness or swelling (Pusey-Reid et al., 2023). Pusey-Reid et al. (2023) advise natural or other indirect light, because fluorescent light casts a bluish tint, and comparing the area with an unaffected site. Petechiae can also be hard to see on darker skin, so the nurse inspects areas with less pigment as well, such as the inside of the mouth, the gums and palate, and the conjunctiva.

Figure 20.5 Petechiae on the lower leg of a person with immune thrombocytopenia and a very low platelet count. On darker skin, petechiae may look darker than the surrounding skin rather than red, and are easier to find in good light. (credit: "Petechia lower leg" by James Heilman, MD/Wikimedia Commons, CC BY-SA 4.0)

Using the Clinical Judgment Measurement Model (CJMM; Chapter 1, section 1.4), the nurse treats a falling count as a cue. Bleeding precautions protect the patient: an extra-soft toothbrush, an electric razor, no rectal thermometers, suppositories or enemas, a check with the prescriber before any intramuscular injection, and no straining at stool (Canadian Cancer Society, n.d.-b). The nurse holds firm pressure on puncture sites, prevents falls (Chapter 8) and checks with the prescriber or pharmacist before giving drugs that weaken platelets, such as acetylsalicylic acid (ASA).

For inpatients with low production caused by therapy, Canadian Blood Services suggests one dose of platelets when the count is below 10×10^9/L, with higher thresholds before procedures and during significant bleeding (Lafrance et al., 2025). Choosing Wisely Canada advises against routine platelet transfusion for chemotherapy-induced thrombocytopenia, noting that a count of 10×10^9/L or more usually allows adequate hemostasis (Canadian Society for Transfusion Medicine [CSTM], 2026). A new headache, blurred vision or a change in level of consciousness can signal bleeding in the brain (Canadian Cancer Society, n.d.-b). The nurse escalates at once (Chapter 6; Chapter 31).

PATIENT EDUCATION

Living With a Low Platelet Count

The nurse teaches the patient and family how to lower the chance of bleeding at home and when to call for help (Canadian Cancer Society, n.d.-b):

- Brush with an extra-soft toothbrush and floss very gently, if at all, as the care team advises.
- Shave with an electric razor, not a blade.

- Do not use rectal thermometers, suppositories or enemas. Ask about a stool softener to avoid straining.
- Check with the pharmacist or prescriber before taking any over-the-counter pain or cold medicine, because some contain ASA or other drugs that weaken platelets.
- Avoid alcohol, contact sports and activities that could cause a fall or injury.
- Use pads rather than tampons during menstruation.
- Ask before any injection into a muscle.
- Call the care team if bleeding cannot be controlled after 10 minutes of pressure or keeps getting worse.
- Call 9-1-1 for a sudden severe headache, blurred vision, confusion or unusual drowsiness, or for vomiting blood or material that looks like coffee grounds.

Hemophilia and Von Willebrand Disease

Hemophilia is an inherited lack of a clotting factor. Hemophilia A is a lack of factor VIII and makes up 80% to 85% of cases; hemophilia B is a lack of factor IX (Poon et al., 2022). Bleeding Disorders Canada, the national patient organization for people with bleeding disorders, estimates that hemophilia A affects about 3,900 people in Canada and hemophilia B about 800 (Bleeding Disorders Canada, 2024).

The gene changes sit on the X chromosome, so hemophilia usually affects males who inherit an affected X chromosome from their mother. Females who have one affected X chromosome are called carriers, and some carriers bleed, for example with heavy or prolonged menstrual periods (Srivastava et al., 2020). Severity follows the factor level: below 1 IU/dL is severe, above 5 IU/dL is mild, and levels in between are moderate (Poon et al., 2022). Severe hemophilia causes bleeding with little or no injury, especially into joints, muscles and soft tissues (Srivastava et al., 2020). A patient may first feel tingling or tightness in a joint; a joint bleed then shows increasing swelling, warmth or pain, or a growing loss of movement. Factor is ideally given as soon as a bleed is suspected (Srivastava et al., 2020). A head injury is treated as a possible bleed in the brain, and bleeding in the throat or neck is an emergency because it can block the airway; treatment is not delayed while waiting for symptoms or a full assessment (Srivastava et al., 2020). Bleeding into deep muscles such as the iliopsoas can also cause large blood loss (Poon et al., 2022; Srivastava et al., 2020).

Treatment replaces the missing factor with factor VIII or factor IX concentrates, including extended half-life products (Poon et al., 2022). Regular prophylaxis is standard care for severe hemophilia. Emicizumab, a non-factor product given to prevent bleeds in hemophilia A, is supplied through Canadian Blood Services and Héma-Québec (Poon et al., 2022). Desmopressin can treat minor bleeds in mild hemophilia A (Poon et al., 2022). Practically all people with hemophilia in Canada are registered with one of 25 hemophilia or bleeding disorder programs, where a team provides comprehensive care (Poon et al., 2022). Patients carry a FactorFirst card that names the diagnosis, the first emergency treatment and the clinic's contact (Poon et al., 2022). The nurse reads the card, believes the patient's report of a bleed and helps start factor without delay.

Von Willebrand disease (VWD) is a lack or defect of von Willebrand factor (VWF), a protein needed to stop bleeding from mucous membranes in the first stage of clotting (Poon et al., 2022). It is the most common inherited bleeding disorder, with a prevalence of about 1 in 1,000 people (Poon et al., 2022). Common signs are frequent nosebleeds, large bruises, heavy menstrual periods, and long bleeding after dental work, surgery, injury or childbirth (Centers for Disease Control and Prevention [CDC], 2024). Treatment depends on the type: desmopressin for people who respond (not type 2B) and concentrates that contain both factor VIII and VWF (Poon et al., 2022). Antifibrinolytic drugs such as tranexamic acid help control mucosal bleeding, and hormonal therapy can help heavy menstrual bleeding (CDC, 2024; Poon et al., 2022). Cryoprecipitate is not recommended for hemophilia A or VWD (Rotin & Mack, 2025).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is uncontrolled activation of clotting throughout the circulation. Clots form in small vessels and use up clotting factors and platelets; at the same time, the body breaks clots down and releases fibrin degradation products. Depending on that balance, the patient may bleed, clot, or both (Poon et al., 2022). Triggers include severe infection and sepsis (Chapter 4), trauma and massive tissue injury, obstetric complications and cancer (Poon et al., 2022; Popescu et al., 2022).

Because platelets and clotting factors are being used up while clots are broken down, results typically show a falling platelet count and fibrinogen, a rising D-dimer (a fibrin-related marker) and a prolonged prothrombin time (PT); the International Society on

Thrombosis and Haemostasis (ISTH) overt DIC score combines these tests (Poon et al., 2022; Popescu et al., 2022). Removing the trigger is the most important treatment (Poon et al., 2022). A bleeding patient may receive plasma, fibrinogen concentrate, cryoprecipitate or platelets (section 20.6), but replacement does not stop the process, and prothrombin complex concentrate (PCC) is contraindicated because it promotes clotting in DIC (Poon et al., 2022).

The nurse watches for new oozing from IV sites, drains, wounds and gums, and for blood in urine or stool. Cool, mottled or dusky fingers and toes, falling urine output and new confusion can signal clotting in small vessels. Bleeding with a falling blood pressure or rising heart rate needs rapid response (Chapter 6).

GOING DEEPER

Reading DIC Labs

Required for RN students; optional for PN students.

DIC laboratory pattern. No single test diagnoses DIC. The ISTH overt DIC score adds points from four widely available tests: platelet count, PT, fibrinogen and a fibrin-related marker such as D-dimer (Popescu et al., 2022). The maximum is 8 points, and a total of at least 5 is consistent with overt DIC (Poon et al., 2022). Because DIC changes quickly, trends over hours matter more than one result: a platelet count that halves, a fibrinogen that keeps falling and a D-dimer that keeps rising all point the same way. Fibrinogen and factor VIII tend to rise in uncomplicated liver disease, so low levels of both in a patient with liver disease suggest that consumption or DIC has been added (Poon et al., 2022).

20.5 Leukemia, Lymphoma and Myeloma

Blood cancers start in the marrow or the lymphatic system. Cancer biology, chemotherapy and immunotherapy are taught in Chapter 9; this section focuses on what is specific to blood cancers and what the nurse sees at the bedside.

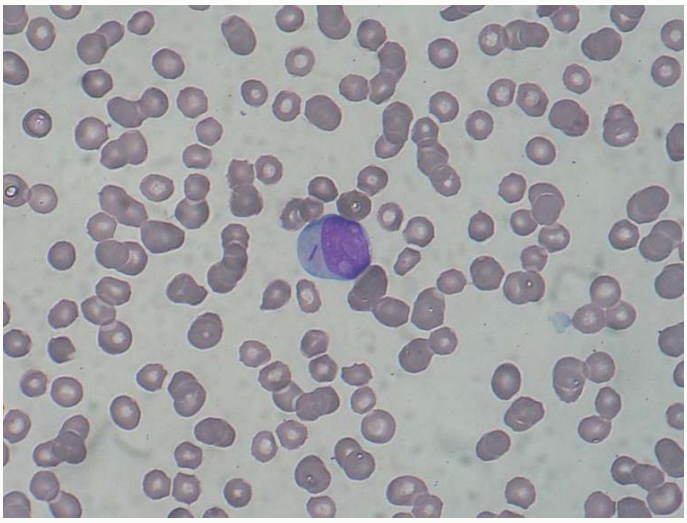

Figure 20.6 A myeloblast with an Auer rod, a thin rod in the cell's cytoplasm. Auer rods are a feature of acute myeloid leukemia, and blasts on a smear are often the first clue to leukemia. (credit: "Myeloblast with Auer Rod smear 2009-11-23" by Paulo Henrique Orlandi Mourao/Wikimedia Commons, CC BY-SA 3.0)

Leukemias

Leukemia is a blood cancer that arises from the blood-forming stem cells of the bone marrow (Canadian Cancer Society, 2022). Immature cells, called blasts, fail to mature and gradually crowd out normal blood cells. Leukemias are grouped in two ways. Acute leukemias start suddenly and develop over days or weeks; chronic leukemias develop over months or years. Myeloid leukemias come from myeloid stem cells, and lymphocytic (lymphoblastic) leukemias from lymphoid stem cells. The four main types are acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), chronic myeloid leukemia (CML) and chronic lymphocytic leukemia (CLL) (Canadian Cancer Society, 2022).

For 2026, the Canadian Cancer Statistics Advisory Committee projected 6,500 new diagnoses of leukemia and 3,200 deaths from it in Canada (Brenner et al., 2026; Canadian Cancer Society, 2026b).

When blasts fill the marrow, the patient shows signs of marrow failure:

- **Anemia:** fatigue, weakness, breathlessness and pallor (section 20.2).
- **Infection:** fever and repeated infections, because the white cells present do not work normally.
- **Bleeding:** petechiae, bruising, nosebleeds and gum bleeding from thrombocytopenia (section 20.4).

Diagnosis begins with a CBC and a blood smear (section 20.1), which may show blasts and low counts (Figure 20.6). A bone marrow aspiration and biopsy (Figure 20.7) removes marrow cells for laboratory testing, which shows whether leukemia cells are present and, if so, the type (Canadian Cancer Society, n.d.-a). After the procedure, the nurse checks the site for bleeding, especially when the platelet count is low. Treatment ranges from monitoring in some chronic leukemias to chemotherapy, targeted drugs and stem cell transplant (Chapter 9). Acute promyelocytic leukemia, a form of AML, carries a high risk of serious bleeding and clotting early in treatment. For these patients, Canadian Blood Services lists a higher platelet transfusion threshold (below 30 to 50 × 10^9/L) and notes that it is the only situation in which fibrinogen is routinely replaced as prevention (Lafrance et al., 2025; Rotin & Mack, 2025).

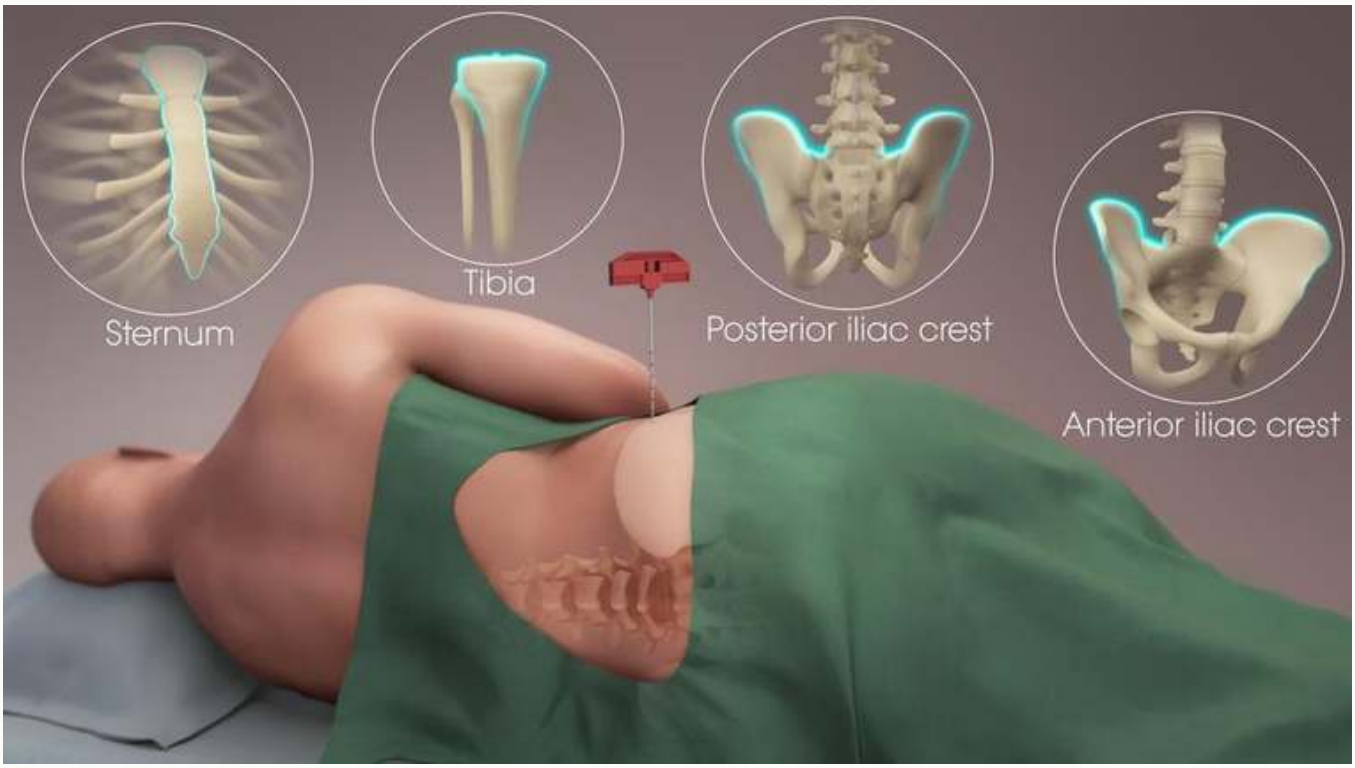

Figure 20.7 Sites that can be used for bone marrow aspiration and biopsy: the sternum, the tibia, and the posterior and anterior iliac crests. (credit: "Site for procedure of Bone Marrow" by Scientific Animations (scientificanimations.com)/Wikimedia Commons, CC BY-SA 4.0)

Lymphomas

Lymphoma is a cancer of lymphocytes that usually grows in lymph nodes or other lymphatic tissue. The two main groups are Hodgkin lymphoma and non-Hodgkin lymphoma; the second is far more common. For 2026, the Canadian Cancer Statistics Advisory Committee projected 12,100 new diagnoses of non-Hodgkin lymphoma and 3,200 deaths from it in Canada, compared with 1,250 new diagnoses of Hodgkin lymphoma and 120 deaths (Brenner et al., 2026; Canadian Cancer Society, 2026a, 2026d).

The most common sign of non-Hodgkin lymphoma is enlarged, usually painless lymph nodes in the neck, groin or armpit (Canadian Cancer Society, n.d.-d). Patients may also have itching, fatigue or **B symptoms**, a set of three general symptoms used in staging and prognosis (North American Association of Central Cancer Registries [NAACCR], 2025):

- unexplained fever above 38 °C;
- drenching night sweats, enough to need a change of bedclothes;
- unexplained loss of more than 10% of usual weight over the 6 months before diagnosis.

Diagnosis needs a biopsy of an affected node. The nurse asks about these symptoms, weighs the patient on the same scale each time and records temperatures and night sweats accurately.

Multiple Myeloma

Multiple myeloma is a cancer of plasma cells, the marrow cells that make antibodies. Abnormal plasma cells multiply in the bone marrow, and the disease can weaken bone, lower blood counts and damage the kidneys (Canadian Cancer Society, n.d.-c). For 2026, the Canadian Cancer Statistics Advisory Committee projected 4,400 new diagnoses of multiple myeloma and 1,800 deaths from it in Canada (Brenner et al., 2026; Canadian Cancer Society, 2026c).

The main features are often remembered as CRAB (Canadian Cancer Society, n.d.-c):

- **High calcium:** thirst, frequent urination, dehydration, constipation, nausea, vomiting, weakness, drowsiness and confusion.
- **Kidney problems:** up to kidney failure (Chapter 27).
- **Anemia:** fatigue and breathlessness.
- **Bone disease:** pain and fractures, often in the back, ribs, hips or skull.

Patients are also prone to infection and may have low platelets, thick blood (hyperviscosity) or nerve problems. New back pain with leg weakness, numbness or trouble passing urine can signal spinal cord compression, a cancer emergency (Canadian Cancer Society, n.d.-c; Chapter 9).

Hypercalcemia is taught in Chapter 3 and hypercalcemia of malignancy in Chapter 9. The nurse recognizes new confusion, drowsiness or constipation in a patient with myeloma as possible cues of a rising calcium, checks the result and reports it promptly. Fragile bones make safe movement central. The nurse assesses pain before activity and treats it (Chapter 5), helps the patient move without twisting or lifting, uses a mobility aid and the bed's lowest position, and puts fall prevention in place (Chapter 8). Gentle activity as tolerated is encouraged, because bed rest weakens bone and muscle further.

Nursing Care Across Blood Cancers

Blood cancers and their treatments often leave patients with low white cells, low platelets and anemia at the same time.

- **Infection prevention:** Neutropenia means a low neutrophil count. The nurse uses careful hand hygiene and infection prevention and control (IPAC) practices (Chapter 4), teaches the patient to report fever and treats fever in neutropenia as an emergency (Chapter 9).
- **Bleeding:** The nurse uses the bleeding precautions in section 20.4 and the transfusion practices in section 20.6.
- **Fatigue:** The nurse plans rest between activities and links fatigue to the hemoglobin trend.
- **Tumour lysis syndrome:** Rapid cell death at the start of treatment can upset electrolytes and harm the kidneys (Chapter 9).

A **stem cell transplant** replaces blood-forming stem cells. Autologous transplants use the patient's own stem cells, and allogeneic transplants use stem cells from a donor; both are used for some leukemias, lymphomas and myeloma (Canadian Cancer Society, n.d.-e). **Graft-versus-host disease**, listed among the possible side effects of transplant (Canadian Cancer Society, n.d.-e), occurs after allogeneic transplant when the donor's immune cells react against the recipient's tissues (Chapter 9).

Diagnosis brings fear, financial strain and decisions about work and family. Treatment can affect fertility, so the nurse makes sure that patients of reproductive age have had the chance to discuss fertility before treatment starts (Chapter 9). Specialized treatment is concentrated in large centres, so many rural, remote and northern patients must stay far from home for weeks. Inuit from remote communities often travel thousands of kilometres to southern cities for cancer care. In one Canadian study, Inuit patients and their medical escorts described feeling directed with little support and lacking explanations of the decisions they faced (Jull et al., 2021). The nurse explains each step, arranges an Inuktitut interpreter when wanted, includes the escort and family, and connects the patient with Indigenous patient navigators and culturally safe supports (Chapter 2).

20.6 Blood Components and Transfusion

Transfusion can save lives, but each unit carries risks and comes from a volunteer donor. In Canada, Canadian Blood Services supplies blood outside Quebec and Héma-Québec supplies Quebec; Health Canada regulates blood under the *Food and Drugs Act*

and the *Blood Regulations*, and the Canadian Standards Association (CSA) blood standard covers facilities that collect, process, test, store and use blood components for transfusion (Gabarin & Yan, 2024).

Components and Plasma Products

A **blood component** is a part of donated blood, separated after collection (Table 20.3):

- **Red blood cell concentrate:** red cells with most plasma and white cells removed. In a non-bleeding adult weighing about 70 kg, one unit usually raises hemoglobin by about 10 g/L (Rotin & Mack, 2025).
- **Platelets:** pooled from several donors or collected from one donor by apheresis, and stored at room temperature (20 °C to 24 °C) with gentle agitation (Rotin & Mack, 2025).
- **Frozen plasma:** plasma that contains all the clotting factors.
- **Cryoprecipitate:** a small volume made from frozen plasma that is rich in fibrinogen. Fibrinogen concentrate is increasingly preferred in Canada (Rotin & Mack, 2025).

Plasma protein products are drugs made by pharmaceutical companies from pooled donor plasma, or made by recombinant technology, and distributed to hospitals by the blood operators (Gabarin & Yan, 2024). They include albumin, IVIG, PCC, fibrinogen concentrate and factor concentrates (CSTM, 2026; Poon et al., 2022; Rutledge Harding et al., 2024).

Compatibility starts with the ABO and RhD groups. In an emergency, before the patient's group is known, uncrossmatched group O red cells are given. Group O RhD-negative red cells are reserved for females of child-bearing age, children and patients known or suspected to have anti-D antibodies; in discussing emergency supply, Canadian Blood Services refers to females 45 years and younger (Trudeau et al., 2021). Outside emergencies, RhD-negative girls, and RhD-negative women who could become pregnant, are not routinely given RhD-positive components, because antibodies to RhD could harm a future fetus (Duncan, 2020). Group O RhD-negative red cells and group AB plasma are in short supply; Choosing Wisely Canada advises keeping O-negative red cells for O-negative patients, noting that O-positive red cells are acceptable for males and for females who cannot become pregnant, and keeping AB plasma for group AB patients and emergencies in which the group is unknown (CSTM, 2026). Some patients need specially processed components, such as irradiated or washed products; the prescriber and the transfusion service decide.

Table 20.3 Blood components and plasma products: what each is, why it is given, and nursing points (Rotin & Mack, 2025; Gabarin & Yan, 2024; Rutledge Harding et al., 2024; CSTM, 2026; original wording)

Product	What it contains	Main uses	Nursing points
Red blood cell concentrate	Red cells in a preserving solution; leukoreduced	Symptomatic anemia; acute blood loss	Give one unit, then reassess in stable patients; not for volume replacement; refrigerated until issued
Platelets	Pooled or single-donor platelets, often pathogen-reduced	Bleeding with low or poorly working platelets; prevention when the count is very low	Stored at room temperature, never refrigerated; generally avoided in ITP, HIT and thrombotic thrombocytopenic purpura (TTP)
Frozen plasma	Plasma with all clotting factors	Bleeding with clotting factor deficiency when no specific product exists; massive hemorrhage; plasma exchange	Must be ABO compatible; thawed before use; not for volume or a mildly raised INR
Cryoprecipitate	Concentrated fibrinogen and other factors from plasma	Bleeding with low fibrinogen	Thawed before use; not used to treat hemophilia A or VWD
Albumin	Protein from pooled plasma	Selected uses such as therapeutic plasma exchange	A plasma protein product; routine 5% albumin is not recommended outside plasma exchange
IVIG	Antibodies from many donors	Immune deficiency, ITP and some neurologic disorders	Start slowly and raise the rate as tolerated; watch for headache and chills, and for thrombosis during or up to 8 days after the infusion

Product	What it contains	Main uses	Nursing points
PCC and fibrinogen concentrate	Concentrated clotting factors or fibrinogen	Urgent warfarin reversal (PCC); low fibrinogen with bleeding	Dosed like drugs; PCC is contraindicated in DIC

Before a Transfusion

Red cells are given for symptomatic anemia or bleeding, not because of one number. Canadian Blood Services describes the restrictive thresholds generally considered: hemoglobin below 70 g/L for most hospitalized patients, including those in intensive care and oncology, below 75 g/L after cardiac surgery, and below 80 g/L for patients with cardiac ischemia or undergoing orthopedic surgery. The decision is individualized (Rotin & Mack, 2025). Choosing Wisely Canada advises against transfusion when another therapy, such as iron for stable iron deficiency, would work as well, and advises that stable, non-bleeding patients receive a single red cell unit, with the patient and hemoglobin reassessed before any further unit (CSTM, 2026). Standard thresholds such as 70 g/L do not apply in sickle cell disease, and hematology or transfusion medicine specialists should be involved in those decisions (CSTM, 2026; section 20.3).

Informed consent is required before transfusion. Facility policy sets out what is discussed: the product, its benefits and risks, including serious ones, and the alternatives; the discussion is documented (O'Reilly, 2020). Consent and capacity are taught in Chapter 1, section 1.5. A capable patient may refuse blood or some blood products. Before a refusal is accepted, the team explains what could happen without the transfusion and records that conversation (O'Reilly, 2020). The nurse does not assume the reason. The nurse asks which products and procedures the patient will and will not accept, checks for an advance directive or wishes expressed while capable, and makes sure the team has discussed alternatives, such as early treatment of iron deficiency. The nurse respects the decision and continues care without pressure.

Before blood is issued, the laboratory does a **group and screen** (also called type and screen): ABO and RhD typing and a screen for antibodies against red cells (Duncan, 2020). A **crossmatch**, done serologically or electronically, confirms that donor red cells are compatible with the patient's plasma. The nurse labels the sample at the bedside, in the patient's presence, at the time it is drawn. If the patient has been transfused or pregnant in the past 3 months, the sample must be drawn within 96 hours before the transfusion (Duncan, 2020).

The patient needs a dedicated IV line; medications are not infused with blood components (a separate lumen of a multi-lumen central line may be used). Canadian Blood Services suggests a 20- to 22-gauge catheter for routine adult transfusion and 16 to 18 gauge for rapid transfusion, with a standard blood set that has a 170- to 260-micron filter (O'Reilly, 2020). The line is primed with the component or a compatible solution, such as sterile 0.9% sodium chloride, and flushed afterwards with 0.9% sodium chloride (O'Reilly, 2020). The nurse collects the component from the transfusion service only when the patient, line and paperwork are ready (Figure 20.8).

Giving Blood Safely

Canadian Blood Services calls for positive identification at every step, from labelling the sample at the bedside with at least two unique identifiers to giving the component, using the patient's identification band. Whenever possible, the patient confirms the band by spelling their name and stating their date of birth (O'Reilly, 2020). At the bedside, in the patient's presence, the component label is checked against the band and the order. Facility policy sets whether a second person performs an independent double check.

Canadian Blood Services describes the following monitoring (O'Reilly, 2020); hospital policy governs local practice:

- An assessment and baseline vital signs, documented no more than 30 minutes before the transfusion starts.
- A slow start: the guide gives 50 mL/h as the adult starting rate for red cells, platelets, plasma and cryoprecipitate.
- The nurse stays with the patient, or close enough to observe closely, for the first 5 to 15 minutes of each unit.
- After 15 minutes, the nurse reassesses the patient and repeats vital signs, then increases the rate if there is no reaction; further checks follow policy.
- Each component is transfused within 4 hours of issue. An interrupted transfusion is stopped once 4 hours have passed, even if it is not finished.

Blood warmers are used during rapid transfusion to prevent hypothermia, and pressure devices must not exceed 300 mm Hg (O'Reilly, 2020). The nurse documents the product and unit number, start and finish times, volume, vital signs, staff involved and any reaction. Any change in the patient's condition within 6 hours after a transfusion is treated as a possible reaction and reported to the transfusion service. Outpatients go home with written information on signs to report (O'Reilly, 2020).

Figure 20.8 A unit of red blood cell concentrate connected to a blood administration set with an in-line filter. The nurse checks the unit tag against the patient and the order at the bedside before starting. CLINICAL SAFETY

The Bedside Transfusion Check

The final check happens in the patient's presence, using the identification band, immediately before the component is given. Canadian Blood Services calls it the last opportunity to prevent an identification error (O'Reilly, 2020).

- Ask the patient to say and spell their full name and give their date of birth, and match both to the identification band. If the patient cannot answer, use the band and the facility's process for patients who cannot confirm their identity.
- Match the band to the component's tag or label and to the transfusion order: name, identification number, ABO and RhD group, unit number and product type.
- Confirm that consent is documented and that any special requirement, such as irradiated product, has been met.
- Check the bag's expiry, appearance and integrity; do not use a bag that is leaking, clumped or discoloured.
- Use only 0.9% sodium chloride or another solution the facility lists as compatible, and no medications, in the line.
- Perform an independent double check when policy requires it.
- If anything does not match, do not start. Return the unit to the transfusion service and call it.

SCOPE IN PRACTICE

Who Checks and Gives Blood

Whether a nurse may check, hang or monitor a transfusion depends on authority, competence and context (Chapter 1, section 1.3). Authority comes from legislation and a valid order. Competence includes knowing the components, the bedside check and the signs of a reaction, often confirmed by an employer's education and skills check. Context includes the patient's condition and the supports nearby.

Employer policy decides who may perform each step. Some hospitals limit which nurses may hang blood or act as the second checker, or assign transfusion to registered nurses (RNs). These limits are employer practices, not College of Nurses of Ontario

(CNO) rules, and policies differ between employers and between provinces and territories. A practical nurse (PN), called a licensed practical nurse (LPN) in some provinces and a registered practical nurse (RPN) in Ontario, follows their own employer's policy.

Some duties never depend on role. Every nurse who notices signs of a possible reaction stops the transfusion, stays with the patient, keeps the line open with 0.9% sodium chloride and calls for help, including a rapid response if the patient is unstable (Chapter 6). As the patient's needs change, the RPN consults the RN and the team.

Transfusion Reactions

A **transfusion reaction** is any harmful response to a blood component or product. Canadian national surveillance for 2018 to 2019 reported a risk of about 1 reaction for every 2,600 units of blood components transfused (Laureano et al., 2022). Manitoba's provincial guidance notes that most reactions begin between 1 and 30 minutes after the transfusion starts (Shared Health, 2024). Table 20.4 summarizes the main types (Laureano et al., 2022):

- **Acute hemolytic transfusion reaction:** rapid destruction of transfused red cells, most often from ABO incompatibility caused by an identification error. It is rare but can be fatal.
- **Febrile non-hemolytic transfusion reaction:** fever and chills without hemolysis, more common with platelets.
- **Allergic and anaphylactic reactions:** from hives and itching to a rare, life-threatening anaphylaxis.
- **Transfusion-associated circulatory overload (TACO):** fluid overload that causes breathlessness and pulmonary edema.
- **Transfusion-related acute lung injury (TRALI):** sudden lung injury that floods the lungs with fluid, not from heart failure, and can cause respiratory failure.
- **Septic reaction:** from a component contaminated with bacteria, more often platelets.
- **Delayed hemolytic transfusion reaction:** hemolysis more than 24 hours later, often 1 to 2 weeks after transfusion.

Because signs overlap at first, the first actions are the same for any suspected reaction, as provincial guidance describes (Shared Health, 2024; Laureano et al., 2022):

- **Stop** the transfusion. Disconnect the component but do not discard it.
- **Keep the vein open** with 0.9% sodium chloride through new IV tubing.
- **Stay** with the patient and check vital signs at least every 15 minutes until the patient is stable.
- **Check** the patient's identity and the component label again, ideally with a second person.
- **Notify** the prescriber and the transfusion service. The prescriber decides whether the transfusion may continue.
- **Send** the samples policy requires and return the bag with the tubing attached, clamped and capped.
- **Document** the event and complete the facility's reaction report.

Severe signs, such as low blood pressure, breathing difficulty, chest or back pain or dark urine, need immediate rapid response (Chapter 6). Anaphylaxis is treated with epinephrine and airway support (Laureano et al., 2022; Chapter 21). For a minor reaction such as hives alone, the prescriber may allow the transfusion to restart, but only within 4 hours of the original start, with close observation for the next 15 minutes (Shared Health, 2024).

Hemovigilance is the surveillance of transfusions and their outcomes. The hospital transfusion service reports reactions to the provincial office, which forwards reports to the Public Health Agency of Canada, and reports some events to Health Canada and Canadian Blood Services (Yan, 2020). When in doubt, the guidance is to report.

Table 20.4 Transfusion reactions: timing, signs and first actions (Laureano et al., 2022; Shared Health, 2024; original wording)

Reaction	Usual timing	Key signs	First actions
Acute hemolytic	During the transfusion, often early	Fever, chills, pain (such as back or flank pain), breathlessness, low blood pressure, dark urine, low urine output, oozing	Stop; keep line open with new saline tubing; rapid response; recheck identity and label; notify transfusion service
Febrile non-hemolytic	During or up to 4 hours after	Temperature rise of more than 1 °C and/or above 38 °C; chills or rigors	Stop; assess for more serious causes; notify; treat fever as ordered

Reaction	Usual timing	Key signs	First actions
Allergic (minor)	During transfusion	Hives, itching, flushing	Stop; notify; antihistamine as ordered; restart only if the prescriber allows
Anaphylactic	During the transfusion, often early	Wheeze, throat swelling, low blood pressure	Stop; call for help; epinephrine and airway support
TACO	During or up to 12 hours after	Breathlessness, signs of volume overload such as crackles and edema; blood pressure may rise	Stop; sit upright; oxygen; notify; diuretic as ordered
TRALI	During or within 6 hours after	Breathlessness and low oxygen from non-cardiogenic pulmonary edema; blood pressure may fall; fever possible	Stop; oxygen and respiratory support; rapid response; notify
Septic	During or after	Fever, fast heart rate, low blood pressure	Stop; rapid response; blood cultures from patient and bag; notify
Delayed hemolytic	More than 24 hours, often 1 to 2 weeks	Falling hemoglobin, jaundice, low-grade fever	Report to the prescriber and transfusion service

GOING DEEPER

Telling TACO From TRALI

Required for RN students; optional for PN students.

Both cause sudden breathlessness and low oxygen saturation during or after a transfusion. Canadian Blood Services lists features that help tell them apart (Laureano et al., 2022):

- **Timing:** TACO appears up to 12 hours after transfusion; TRALI appears within 6 hours of the transfusion ending.
- **Blood pressure:** may be raised in TACO; may be low in TRALI.
- **Fever:** usually absent in TACO, though it can occur; may be present in TRALI.
- **Fluid overload and diuretics:** TACO shows volume overload and improves with diuretics; in TRALI, both are inconsistent.
- **Brain natriuretic peptide (BNP):** raised in TACO; inconsistent in TRALI.

Suspected TRALI is also reported to Canadian Blood Services, with its TRALI patient data form, in addition to any provincial form (Yan, 2020).

Massive Hemorrhage in Brief

Older definitions of massive hemorrhage, such as 10 or more red cell units in 24 hours, can only be applied looking back. A more practical marker at the bedside is the critical administration threshold: needing 3 or more red cell units within 1 hour (Trudeau et al., 2021). A **massive hemorrhage protocol** is a hospital plan that, once activated, speeds the delivery of components to the bedside and coordinates the team while the bleeding is controlled. Protocols supply red cells, plasma and platelets in ratios that approximate whole blood, and replace fibrinogen early (Trudeau et al., 2021). Uncrossmatched group O red cells are used until the patient's group is confirmed. For trauma, most protocols include early tranexamic acid, an antifibrinolytic; in the large trial behind this practice, the benefit was seen when it was given within 3 hours of injury (Trudeau et al., 2021).

The nurse keeps components flowing and the patient warm and monitored. Transfused blood is run through an approved blood warmer; temperature is checked continuously or at least hourly, because a temperature below 35 °C impairs clotting. The citrate in blood products lowers ionized calcium, so calcium is monitored and replaced (Trudeau et al., 2021). Blood work, including ionized calcium, is repeated at least every hour (Trudeau et al., 2021). Shock is taught in Chapter 6 and surgical blood management in Chapter 7.

PRACTICE STORY

One Unit at a Time

Names and details are fictional; this is a composite story.

Nurse: Mariam Haddad, RN. Years in practice: 7. Setting: medical unit, Ontario.

Mr. Lucien Thibodeau was 86, with heart failure and anemia from a slow gastrointestinal bleed that had since stopped. His hemoglobin that morning was 64 g/L, and two units of red cells were ordered. The first unit went in over 3 hours without a problem. He said he felt "a bit less wobbly."

I started the second unit just after supper. His blood pressure was 138/74 mm Hg, his heart rate 82 and his oxygen saturation 95% on room air. About an hour in, he pressed his call bell. He was sitting forward, breathing fast and coughing. His blood pressure had climbed to 172/90 mm Hg, his heart rate was 108 and his saturation had dropped to 88%. I heard crackles at both lung bases that had not been there at noon.

I stopped the transfusion and kept the line open with saline on new tubing. I sat him upright with his legs down, started oxygen under our protocol and called for help. My charge nurse came in, and I called the physician on duty with an SBAR (Situation, Background, Assessment, Recommendation) report, saying I suspected circulatory overload. He ordered a diuretic and a chest X-ray. I stayed with Mr. Thibodeau, checked his vital signs every 15 minutes and watched his urine output. Within an hour his breathing had eased and his saturation was back to 93%. I returned the bag and tubing to the transfusion service and completed the reaction report.

Later I looked at his chart again. After the first unit, nobody had checked his hemoglobin or asked whether he still needed a second. For a frail man with a weak heart, the volume of two units in one day was too much. Now, when I see an order for more than one unit in a stable patient, I ask whether we can give one, reassess, and then decide.

Reflect: What cues suggested circulatory overload rather than an allergic reaction? If an RPN had been caring for Mr. Thibodeau and noticed his breathlessness, what should the RPN have done first, and when should the RPN have involved the RN?

Chapter 20 Summary

Introduction

- Blood disorders and transfusion affect patients on every unit, and nurses read results, follow trends and act on changes.
- The chapter covers blood tests, anemias, inherited hemoglobin disorders, bleeding and clotting disorders, blood cancers and transfusion.

20.1 Blood and Its Tests

- Blood cells are made in the bone marrow from stem cells; erythropoietin from the kidneys drives red cell production, which needs iron, vitamin B12 and folate.
- The CBC reports hemoglobin (g/L), hematocrit (L/L), red cell indices, white cells with a differential and platelets ($\times 10^9$/L); ranges vary by laboratory.
- Laboratories prefer serum ferritin to screen for iron deficiency, but inflammation can raise it.
- Critical values are phoned to the team; the nurse assesses the patient, notifies the prescriber and documents.
- INR, aPTT, fibrinogen and D-dimer each answer a different clotting question; reagent and laboratory affect their ranges.

20.2 Anemias

- Anemia results from blood loss, low production or early destruction of red cells, and is always a sign with a cause.
- Pallor is assessed in the conjunctiva, mouth, nail beds and palms on every skin tone, and confirmed with a hemoglobin level.
- Iron deficiency anemia needs a search for the source of loss, including gastrointestinal investigation in men and postmenopausal women.
- Oral iron is first-line; IV iron needs monitoring for hypersensitivity, which can occur with any product.
- Vitamin B12 deficiency causes large red cells and nerve damage that can become permanent; potassium is monitored early in treatment.
- In older adults, anemia is linked with poorer outcomes and should be investigated, not accepted as aging.

20.3 Sickle Cell Disease and Thalassemia

- Hemoglobin S causes sickling, hemolysis and blocked blood vessels; sickle cell trait is a carrier state.
- Acute chest syndrome, fever with functional asplenia, stroke, splenic sequestration and priapism are emergencies.

- Ontario's quality standard expects treatment of a pain crisis to start within 30 minutes of triage or within 60 minutes of arrival, with frequent reassessment and an individualized plan.
- Stigma and anti-Black racism affect sickle cell care in Canada; nurses believe the patient's report of pain and challenge biased labels.
- Hydroxyurea, transfusion and iron chelation are the mainstays of long-term care; transfusion-dependent thalassemia leads to iron overload.

20.4 Bleeding and Clotting Disorders

- Thrombocytopenia comes from low production or from increased destruction, consumption or sequestration of platelets; ITP is immune, and platelet transfusion is reserved for critical bleeding.
- On darker skin, bruises may look darker than the surrounding skin and petechiae can be hard to see, so the nurse uses natural or indirect light, compares with an unaffected site and checks the mouth and conjunctiva.
- Bleeding precautions include an extra-soft toothbrush, an electric razor, no rectal routes and a check before intramuscular injections; neurologic change is escalated at once.
- Hemophilia A (factor VIII) and B (factor IX) are X-linked; joint and muscle bleeds need prompt factor replacement guided by the FactorFirst card and a bleeding disorder program.
- VWD is the most common inherited bleeding disorder and often causes heavy menstrual bleeding; desmopressin, factor VIII/VWF concentrates and tranexamic acid are used.
- DIC consumes platelets and factors, causing bleeding and clotting; treating the cause comes first, and new oozing with hypotension needs rapid response.

20.5 Leukemia, Lymphoma and Myeloma

- Leukemias are acute or chronic and myeloid or lymphocytic; blasts crowd out normal cells and cause anemia, infection and bleeding.
- Lymphoma most often shows painless swollen lymph nodes and may cause B symptoms: fever, drenching night sweats and weight loss.
- Multiple myeloma causes high calcium, kidney problems, anemia and bone disease; new confusion or constipation may signal hypercalcemia, and fall prevention protects fragile bones.
- Nursing care across blood cancers covers infection prevention in neutropenia, bleeding, fatigue and tumour lysis, with stem cell transplant as autologous or allogeneic.
- Patients from rural, remote and northern communities, including Inuit, often travel far for care and need clear explanations, interpreters and culturally safe support.

20.6 Blood Components and Transfusion

- Components include red cells, platelets, frozen plasma and cryoprecipitate; plasma protein products such as albumin, IVIG, PCC and fibrinogen concentrate are distributed by Canadian Blood Services and Héma-Québec.
- Restrictive thresholds guide red cell transfusion (generally below 70 g/L in most hospitalized patients, individualized), and stable, non-bleeding patients receive one unit at a time, then reassessment.
- Consent covers benefits, risks and alternatives; a capable patient may refuse, and the nurse explores what the patient will accept without assumptions.
- Safe administration requires positive identification in the patient's presence, a dedicated line with no medications, baseline and 15-minute vital signs, a slow start with close observation and completion within 4 hours of issue.
- For any suspected reaction, the nurse stops the transfusion, keeps the vein open with saline through new tubing, stays, rechecks identity and label, notifies and escalates; reactions are reported through hemovigilance systems.
- Massive hemorrhage protocols deliver components quickly in balanced ratios, with early tranexamic acid in trauma, blood warming and calcium monitoring.

Key Terms (53)

acute chest syndrome: a new lung infiltrate with fever or respiratory symptoms in a person with sickle cell disease; an emergency

acute hemolytic transfusion reaction: rapid destruction of transfused red cells, most often from ABO incompatibility, causing fever, pain, hypotension and dark urine.

anemia: a hemoglobin below the reference range for the person's age and sex; a sign with an underlying cause

anemia of inflammation: anemia caused by inflammatory signals that block iron absorption and trap iron in storage cells

aplastic anemia: failure of the bone marrow to produce enough red cells, white cells and platelets

B symptoms: unexplained fever above 38 °C, drenching night sweats and unexplained loss of more than 10% of body weight in the 6 months before diagnosis.

blood component: a part of donated blood separated after collection, such as red cells, platelets, plasma or cryoprecipitate.

complete blood count (CBC): a blood test that reports hemoglobin, hematocrit, red cell count and indices, white cell count and differential, and platelet count

critical value: a laboratory result far enough outside the reference range that the laboratory reports it to the care team at once

crossmatch: a test, serologic or electronic, that confirms donor red cells are compatible with the patient's plasma.

cryoprecipitate: a small-volume plasma component rich in fibrinogen.

disseminated intravascular coagulation (DIC): uncontrolled activation of clotting throughout the circulation that consumes platelets and clotting factors and can cause both bleeding and clotting.

ecchymosis: a bruise; bleeding under the skin that may look darker than the surrounding skin on darker skin tones.

febrile non-hemolytic transfusion reaction: fever and chills during or up to 4 hours after a transfusion without destruction of red cells.

ferritin: the storage form of iron; serum ferritin is the screening test laboratories prefer when iron deficiency is suspected

frozen plasma: plasma that contains all the clotting factors, frozen after collection and thawed before use.

functional asplenia: loss of the spleen's ability to filter bacteria even though the spleen is present, as in sickle cell disease

graft-versus-host disease: a complication of allogeneic transplant in which the donor's immune cells react against the recipient's tissues.

group and screen: laboratory ABO and RhD typing with a screen for antibodies against red cells; also called type and screen.

hematocrit: the fraction of blood volume made up of red blood cells; reported in L/L

hematopoiesis: the production of blood cells, which in adults takes place in the bone marrow

hemoglobin: the iron-containing protein in red blood cells that carries oxygen; reported in g/L

hemolysis: destruction of red blood cells before the end of their normal lifespan

hemophilia: an inherited lack of clotting factor VIII (hemophilia A) or factor IX (hemophilia B), usually affecting males.

hemovigilance: the surveillance of transfusions and their outcomes to improve safety.

hydroxyurea: an oral drug that raises fetal hemoglobin and reduces sickling; handled as a hazardous drug

immune thrombocytopenia (ITP): an acquired autoimmune disorder with a low platelet count, causing bruising, petechiae and sometimes mucosal bleeding.

iron chelation: drug treatment that binds excess iron so that it can be excreted

iron deficiency anemia: anemia caused by too little iron for hemoglobin production, with small, pale red cells and low ferritin

iron overload: excess body iron, usually from repeated transfusion, that damages the heart, liver and endocrine glands

jaundice: yellow colour of the sclera, mucous membranes and skin caused by raised bilirubin

leukemia: a cancer that starts in the blood-forming stem cells of the bone marrow, in which immature cells crowd out normal blood cells.

lymphoma: a cancer of lymphocytes that usually grows in lymph nodes or other lymphatic tissue; the two main groups are Hodgkin and non-Hodgkin lymphoma.

macrocytic anemia: anemia with large red cells, typically from vitamin B12 or folate deficiency

massive hemorrhage protocol: a hospital plan that speeds delivery of blood components and coordinates the team during life-threatening bleeding.

mean corpuscular volume (MCV): the average size of red blood cells, in femtolitres, used to sort anemias into small-cell, normal-cell and large-cell patterns

multiple myeloma: a cancer of plasma cells in the bone marrow that can cause high calcium, kidney problems, anemia and bone disease.

pernicious anemia: an autoimmune disease in which loss of intrinsic factor prevents absorption of vitamin B12

petechiae: tiny, flat, red or purple pinpoint spots caused by bleeding under the skin.

plasma protein product: a drug made from pooled donor plasma or by recombinant technology, such as albumin, IVIG, PCC or a factor concentrate.

purpura: patches of bleeding under the skin that are larger than petechiae.

red blood cell concentrate: a unit of donated red cells with most plasma and white cells removed.

reticulocyte: a young red blood cell recently released from the marrow; the count shows whether the marrow is responding to anemia

sickle cell disease: inherited disorders in which hemoglobin S makes red cells rigid and sickle-shaped, causing hemolysis and blocked blood vessels

sickle cell trait: carrying one hemoglobin S gene; carriers generally do not have the disease but can pass the gene on

stem cell transplant: replacement of blood-forming stem cells with the patient's own (autologous) or a donor's (allogeneic) stem cells.

thalassemia: inherited disorders in which too little of one hemoglobin protein chain is made

thrombocytopenia: a platelet count below the laboratory's reference range, from decreased production or from increased destruction, consumption or sequestration of platelets.

transfusion reaction: any harmful response to a blood component or product.

transfusion-associated circulatory overload (TACO): fluid overload from transfusion, during or up to 12 hours after it, that causes breathlessness and signs of volume overload such as pulmonary edema.

transfusion-related acute lung injury (TRALI): sudden lung injury, with fluid in the lungs that is not caused by heart failure, during a transfusion or within 6 hours after it.

vaso-occlusive crisis: an episode of acute pain caused by sickled cells blocking blood flow

von Willebrand disease (VWD): the most common inherited bleeding disorder, caused by a lack or defect of von Willebrand factor; it often causes nosebleeds, bruising and heavy menstrual bleeding.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Ms. Abena Owusu (Questions 1–4): Ms. Abena Owusu, 27, has sickle cell disease (hemoglobin SS) and arrives at a community hospital emergency department at 0215. She reports pain in her lower back and both thighs, 9 out of 10, that began 6 hours ago and did not improve with her home medication. Heart rate 108 beats/min, blood pressure 124/78 mm Hg, respiratory rate 20 breaths/min, temperature 37.3 °C, SpO2 97% on room air. She carries a written care plan from her sickle cell clinic. As the nurse takes her to a stretcher, a staff member says, "She's in here every month looking for opioids."

1. [CORE] Which action by the nurse is most important in the first 30 minutes after triage?

a. Obtaining a urine drug screen before giving any analgesic medication

b. Starting analgesia as directed by her individualized care plan

c. Applying oxygen by nasal prongs to reduce sickling

d. Starting IV fluids at a high rate to reverse the crisis

Answer: b — Ontario's quality standard expects treatment of a vaso-occlusive crisis to start within 30 minutes of triage or within 60 minutes of arrival, and the individualized plan names what works for her (b) (section 20.3). A drug screen (a) delays care and reflects bias rather than a clinical need. Oxygen (c) has no proven benefit in an uncomplicated crisis when saturation is normal. Overhydration (d) is avoided because it can cause pulmonary edema.

2. [CORE] How should the nurse respond to the staff member's comment?

a. Agree, and ask the physician to choose non-opioid analgesics only

b. Say nothing, to avoid conflict in front of the patient

c. Document the comment in Ms. Owusu's health record as a behavioural concern about opioid use

d. Say that her frequent visits reflect her disease, and treat her pain promptly

Answer: d — Labels such as "drug-seeking" are not assessments, and Ontario's standard calls for care free from racism and stigma; challenging the comment respectfully protects the patient (d) (section 20.3). Agreeing (a) lets bias change her treatment. Silence (b) allows stigma to continue. Recording the comment as a behavioural concern (c) carries the bias into her record.

3. [CORE] Four hours after admission to the medical unit, which finding requires the nurse to notify the physician immediately?

a. New chest pain, temperature 38.5 °C and SpO2 falling to 91%

b. Pain decreasing from 9 to 5 out of 10 after the latest dose

c. Urine output of 40 mL/h

d. Mild nausea after drinking juice

Answer: a — New chest pain with fever and falling saturation suggests acute chest syndrome, an emergency that can progress to respiratory failure (a) (section 20.3). Falling pain scores (b) show a response to treatment. A urine output of 40 mL/h (c) is adequate. Mild nausea (d) needs attention but is not urgent.

4. [CORE] The nurse teaches Ms. Owusu to use an incentive spirometer. Which statement shows she understands its purpose?

a. "It will lower my pain without more medication."

b. "It tells me when my oxygen level is low."

c. "Deep breaths with it keep my lungs open and help prevent a chest problem."

d. "I only need to use it if I start coughing up sputum or feel short of breath."

Answer: c — Deep breathing with an incentive spirometer helps prevent acute chest syndrome in admitted patients, particularly those with chest or back pain (c) (section 20.3). It does not treat pain (a) or measure oxygen (b). It is used to prevent complications, not only once cough or breathlessness appears (d).

5. [CORE] A 46-year-old woman's results are hemoglobin 94 g/L, MCV 71 fL, RDW 18.5% and ferritin 6 µg/L. Which interpretation fits these results best?

a. Vitamin B12 deficiency
b. Anemia of inflammation
c. Iron deficiency anemia
d. Hemolytic anemia

Answer: c — Low hemoglobin with small cells, mixed cell sizes and very low ferritin is the pattern of iron deficiency anemia (c) (section 20.1, Table 20.1). B12 deficiency (a) causes large cells. Anemia of inflammation (b) has a normal or high ferritin. Hemolysis (d) usually gives normal or large cells with a high reticulocyte count, not a low ferritin.

6. [CORE] The nurse is assessing a patient with dark brown skin for anemia. Which approach is most appropriate?

a. Inspect the inner lower eyelids, mouth, nail beds and palms
b. Compare the colour of the patient's face with that of the nurse's own face
c. Rely on the pulse oximeter, because a normal saturation rules out anemia
d. Assume pallor cannot be assessed and skip this part of the examination

Answer: a — Pallor is easier to see where pigment does not hide colour, such as the conjunctiva, mouth, nail beds and palms (a) (section 20.2). Comparing with another person's face (b) is unreliable. Oxygen saturation (c) can be normal in severe anemia. Pallor can still be assessed (d), although no sign replaces a hemoglobin level.

7. [CORE] Which statement by a patient starting oral iron shows that teaching was effective?

a. "I'll take my iron with my morning coffee so I don't forget it."
b. "I'll take an extra tablet on days when I feel more tired than usual."
c. "I'll take my iron together with my calcium tablet."
d. "I'll take it with orange juice and wait before having tea."

Answer: d — Vitamin C helps iron absorption, and tea and coffee reduce it, so waiting 1 to 2 hours is advised (d) (section 20.2, Patient Education box). Coffee (a) and calcium (c) reduce absorption. Iron is taken exactly as prescribed; extra doses (b) add side effects and risk without faster benefit.

8. [CORE] A 72-year-old man with pernicious anemia has not received treatment for several months. Which findings does the nurse expect?

a. Spoon-shaped nails and a craving for ice
b. Numbness and tingling in the feet and an unsteady gait
c. Dark urine and yellow sclera
d. Bleeding gums and bruising

Answer: b — Vitamin B12 deficiency damages nerves, causing peripheral neuropathy and ataxia (b) (section 20.2). The findings in (a) are linked with iron deficiency, not B12 deficiency. Dark urine and jaundice (c) suggest hemolysis. Bleeding and bruising (d) suggest low platelets or a clotting problem.

9. [CORE] At 0300 the laboratory phones a hemoglobin of 66 g/L for a patient whose value was 92 g/L yesterday. The patient reports feeling light-headed. What should the nurse do first?

a. Assess the patient, including vital signs, and notify the prescriber at once
b. Record the value and report it at morning rounds
c. Ask the laboratory to repeat the test before telling anyone
d. Encourage oral fluids, document the value and recheck the hemoglobin in 6 hours

Answer: a — This is a critical value with a sharp fall and new symptoms, so the nurse assesses for bleeding and instability and notifies the prescriber promptly (a) (sections 20.1 and 20.2). Waiting for rounds (b), delaying for a repeat test (c) or waiting 6 hours (d) could allow ongoing bleeding to cause shock.

10. [CORE] An RPN is caring for a patient on a medical unit who has iron deficiency anemia and has been stable. The patient now has a heart rate of 124 beats/min, new chest discomfort and a black, sticky stool. Which action is most appropriate for the RPN?

a. Continue the care plan and document the findings for the next shift
b. Give the next scheduled dose of oral iron and recheck in an hour
c. Stay with the patient, check vital signs and consult the RN at once
d. Transfer care of the patient to an RN before doing any assessment

Answer: c — Every nurse who notices deterioration acts and escalates; the RPN consults the RN as the patient's needs change, under the authority, competence and context framework and employer policy (c) (Chapter 1, section 1.3; section 20.2). Documenting only (a) and giving iron (b) ignore signs of bleeding and cardiac strain. Handing off before assessing (d) delays care.

11. [CORE] A 68-year-old woman is newly diagnosed with iron deficiency anemia. She has no obvious source of bleeding. Which next step does the nurse expect the team to plan?

a. Oral iron only, with no further testing
b. A blood transfusion to bring her hemoglobin back into the normal range
c. A diet higher in red meat as the main treatment
d. Upper endoscopy and colonoscopy

Answer: d — In postmenopausal women and men, iron deficiency anemia calls for a search for gastrointestinal bleeding, including cancer (d) (section 20.2). Treating with iron alone (a) or diet (c) could let a cancer progress. A stable patient does not need transfusion to normal levels (b) (section 20.6).

12. [CORE] During an IV iron infusion, a patient develops facial flushing and chest tightness. Blood pressure is 128/80 mm Hg and SpO2 97%. What is the nurse's first action?

a. Increase the rate to finish the infusion quickly
b. Stop the infusion, stay with the patient, monitor closely and call the prescriber
c. Reassure the patient that this is expected and continue
d. Give an oral antihistamine and continue at the same rate

Answer: b — Any reaction during IV iron is treated as possible hypersensitivity; the nurse stops the infusion, monitors for progression to anaphylaxis and calls the prescriber (b) (section 20.2). Speeding up (a) or continuing (c) increases exposure. Giving a drug and continuing (d) needs a prescriber's order and ignores possible progression.

13. [CORE] Which factors increase a person's risk of vitamin B12 deficiency? Select all that apply.

a. Long-term metformin therapy
b. Heavy menstrual bleeding
c. Previous gastric surgery
d. A diet that includes red meat several times a week
e. Long-term use of a proton pump inhibitor
f. Regular use of an anti-inflammatory drug

Answer: a, c, e — Metformin (a), gastric surgery (c) and proton pump inhibitors (e) are linked with B12 deficiency (section 20.2). Heavy menstrual bleeding (b) and anti-inflammatory drugs (f), through gastrointestinal bleeding, cause iron loss. Red meat (d) is a source of B12.

14. [CORE] A patient with sickle cell disease is admitted with a pain crisis. Which finding most strongly suggests acute chest syndrome?

a. New cough and fever with an infiltrate on chest X-ray
b. Pain in both thighs rated 8 out of 10
c. Yellow sclera that the patient says are usual for him
d. Hemoglobin of 84 g/L, the same as his baseline

Answer: a — Acute chest syndrome is defined by a new infiltrate on chest X-ray with symptoms such as fever, cough or chest pain (a) (section 20.3). Limb pain (b) is typical of a vaso-occlusive crisis. Chronic jaundice (c) reflects ongoing hemolysis. A hemoglobin at baseline (d) is not a sign of acute chest syndrome.

15. [CORE] An adult with sickle cell disease calls the clinic to say he has a temperature of 38.7 °C. What should the nurse advise?

a. Take an antipyretic and call back if the fever lasts 3 days
b. Increase fluids and rest at home
c. Book the next available routine clinic appointment
d. Go to the emergency department now, because fever can mean a serious infection

Answer: d — Functional asplenia puts people with sickle cell disease at risk of overwhelming bloodstream infection; fever needs urgent assessment and antibiotics within 30 minutes of arrival (d) (section 20.3). Waiting (a, b, c) risks sepsis.

16. [CORE] A new parent asks what it means that their baby's newborn screen shows sickle cell trait. Which response is accurate?

a. "Your baby has a mild form of sickle cell disease and will need hydroxyurea."
b. "The trait will turn into the disease during adolescence."
c. "Your baby carries one sickle gene, generally does not have the disease and could pass the gene on later in life."
d. "Sickle cell trait occurs only in families of African ancestry."

Answer: c — Sickle cell trait means one hemoglobin S gene; carriers generally do not have the disease but can pass the gene on (c) (section 20.3). The trait is not a mild disease (a) and does not progress to disease (b). The trait occurs in all racial and ethnic groups (d).

17. [CORE] A patient with sickle cell disease is starting hydroxyurea. Which teaching point is correct?

a. Blood tests are needed only if symptoms of infection appear
b. Use reliable contraception; anyone handling the capsules wears gloves
c. Open the capsules and sprinkle the powder on food to make them easier to take
d. Stop the drug during each pain crisis

Answer: b — Hydroxyurea can harm a fetus and is handled as a hazardous drug (b) (section 20.2, Medications box). It suppresses the marrow, so regular blood counts are needed (a). Opening capsules (c) exposes people to the powder. Stopping during crises (d) is not advised; changes are made by the prescriber.

18. [RN] A patient has hemoglobin 98 g/L, MCV 114 fL and a low reticulocyte count. Which cause is most consistent with these findings?

a. Acute gastrointestinal bleeding
b. Iron deficiency
c. Hemolysis
d. Vitamin B12 or folate deficiency

Answer: d — Large cells with a low reticulocyte count point to impaired production from B12 or folate deficiency (d) (Going Deeper box). Acute bleeding (a) is normocytic with a reticulocyte rise once the marrow responds. Iron deficiency (b) causes small cells. Hemolysis (c) causes a high reticulocyte count.

19. [RN] A 30-year-old man has hemoglobin 122 g/L, MCV 64 fL, red blood cell count 6.1 × 10^{12}/L and ferritin 110 µg/L. What is the most appropriate interpretation?

a. Thalassemia trait is likely; iron is not indicated without proven deficiency
b. The pattern confirms iron deficiency, and the nurse expects oral iron to be ordered
c. The pattern suggests vitamin B12 deficiency
d. The pattern is normal, and no follow-up is needed

Answer: a — Very small cells with a high red cell count and normal ferritin suggest thalassemia trait (a) (Going Deeper box; section 20.3). The normal ferritin argues against iron deficiency (b), and giving iron without deficiency adds to iron load. B12 deficiency (c) causes large cells. An MCV of 64 fL is well below the reference range (d).

20. [RN] A patient with severe pernicious anemia starts cyanocobalamin injections. Which change in laboratory results does the nurse expect, and monitor for, in the first week?

a. A fall in the reticulocyte count and a rise in serum potassium
b. A rise in ferritin to above the reference range
c. A rise in the reticulocyte count within about 5 to 7 days, with a risk of low potassium
d. An immediate return of the MCV to normal

Answer: c — As red cell production restarts, reticulocytes rise within days and potassium can fall sharply, so it is monitored closely in the first 48 hours (c) (section 20.2; Going Deeper box). Reticulocytes rise rather than fall, and potassium falls rather than rises (a). B12 does not raise ferritin (b). The MCV normalizes gradually as new cells replace old ones (d).

Case: Diane Martel (Questions 21–26): Diane Martel, 62, is on a medical oncology unit with acute myeloid leukemia. Her hemoglobin is 66 g/L, and one unit of red cells is ordered. Ten minutes after the unit is started, she has chills and says, "My lower back really hurts." Her temperature has risen from 37.1 °C to 38.8 °C, her heart rate from 88 to 122, and her blood pressure has fallen from 128/76 to 92/54 mm Hg.

21. [CORE] Which findings are the most important cues that Diane may be having a serious transfusion reaction?

a. Her hemoglobin of 66 g/L, which was measured before the transfusion began

b. Her diagnosis of acute myeloid leukemia

c. Back pain with a falling blood pressure and rising heart rate

d. The order for a single unit of red cells rather than two units

Answer: c — New back pain, hypotension and tachycardia soon after a red cell unit starts point to a serious reaction, such as acute hemolysis or sepsis (section 20.6). The low hemoglobin was the reason for transfusion, not a reaction cue. Leukemia explains her anemia but not the sudden change. Ordering one unit is good practice and is not a cue.

22. [CORE] The nurse analyzes the cues. Which reaction best fits the combination of fever, back pain and hypotension within minutes of starting red cells?

a. Acute hemolytic transfusion reaction

b. Minor allergic reaction

c. Delayed hemolytic transfusion reaction

d. Febrile non-hemolytic reaction

Answer: a — Fever, chills, pain and hypotension early in a red cell transfusion fit an acute hemolytic reaction, usually from ABO incompatibility (section 20.6, Table 20.4). A minor allergic reaction causes hives and itching without hypotension. Delayed hemolysis occurs days to weeks later. A febrile non-hemolytic reaction causes fever and chills but not hypotension or back pain, so it cannot be assumed when serious signs are present.

23. [CORE] Which concern does the nurse place first?

a. Diane may become anxious about receiving any transfusions in the future.

b. Diane may have a life-threatening reaction that is affecting her circulation.

c. Diane's hemoglobin will not reach the target the prescriber set for today.

d. Diane's back pain may come from lying in bed.

Answer: b — Hypotension and tachycardia show that circulation is threatened, which comes first (section 20.6; Chapter 6). Anxiety matters but is not the priority. Reaching a hemoglobin target is less urgent than her safety. Back pain from positioning would not explain fever and hypotension.

24. [CORE] The nurse plans care. Which plan best addresses Diane's situation?

a. Slow the transfusion, give acetaminophen as ordered and recheck her vital signs in 1 hour

b. Finish the unit quickly so that the bag can be returned to the transfusion service with all of its tubing

c. Stop the transfusion, keep the vein open with 0.9% sodium chloride on new tubing and call for urgent help

d. Flush the existing line with dextrose 5% in water and then restart the same unit at a slower rate

Answer: c — Any suspected serious reaction requires stopping the transfusion, keeping IV access with saline through new tubing and calling for urgent help; the transfusion service is then notified (section 20.6). Slowing the unit continues the exposure. Finishing the unit gives more of a possibly incompatible product. Dextrose is never used with blood, and the unit must not be restarted.

25. [CORE] After stopping the transfusion and calling for help, what should the nurse do next?

a. Discard the bag and tubing in a biohazard container so that no one else is exposed to them.

b. Recheck Diane's band against the unit label, and keep the bag and tubing for the transfusion service.

c. Remove the IV catheter so that no more of the component can enter the vein.

d. Wait for the physician to arrive before taking another set of vital signs.

Answer: b — A clerical check of the patient and label can find an identification error, and the bag and tubing are returned for investigation (section 20.6). Discarding the bag destroys evidence. IV access must be kept for treatment. Vital signs are checked at least every 15 minutes without waiting.

26. [CORE] An hour later, Diane's first urine since the reaction is dark red-brown. How should the nurse interpret this finding?

a. It suggests ongoing hemolysis and must be reported now.

b. It shows that the reaction has resolved.

c. It is an expected finding after any red cell transfusion.

d. It means she needs more oral fluid only.

Answer: a — Dark urine after a suspected hemolytic reaction suggests hemoglobin in the urine and possible kidney injury, so it is reported at once (section 20.6, Table 20.4). It does not show resolution. It is not an expected finding after transfusion. Fluids may be part of treatment, but the finding needs urgent reporting, not only fluids.

27. [CORE] A patient has a platelet count of 18 × 10^9/L after chemotherapy. Which actions should the nurse include in the plan of care? Select all that apply.

a. Provide an extra-soft toothbrush.

b. Take the temperature rectally for accuracy.

c. Offer an electric razor for shaving.

d. Check with the prescriber before giving an intramuscular injection.

e. Encourage the patient to avoid straining at stool.

f. Give acetylsalicylic acid for a headache.

Answer: a, c, d, e — An extra-soft toothbrush, an electric razor, checking before intramuscular injections and avoiding straining all reduce bleeding (section 20.4). Rectal thermometers can injure the mucosa and are avoided. ASA weakens platelets, and a new headache in a patient with a low platelet count should be assessed and reported, not just treated.

28. [CORE] The nurse is assessing a patient with dark skin and a low platelet count for petechiae. Which approach is best?

a. Look for blue or purple bruising on the abdomen under the room's fluorescent light.

b. Rely on the trend in the platelet count instead of a full skin assessment.

c. Ask the patient whether the skin looks redder than usual.

d. Inspect the oral mucosa and conjunctiva in natural or indirect light.

Answer: d — Petechiae can be easier to see where there is less pigment, such as the mouth and conjunctiva, and natural or indirect light is preferred to fluorescent light (section 20.4). Bruises on darker skin may look darker rather than blue, and fluorescent light adds a bluish tint. The count does not show where the patient is bleeding. Redness can be hard to see on darker skin, and asking alone is not an assessment.

29. [CORE] A man with severe hemophilia A arrives with a warm, swollen, painful knee and a FactorFirst card. What is the nurse's priority?

a. Apply a heating pad to the knee to ease the pain and stiffness before anything else is done.

b. Help the patient move the knee through its full range several times to prevent stiffness.

c. Follow the card and notify the prescriber so factor VIII replacement starts without delay.

d. Give an intramuscular injection of an analgesic.

Answer: c — A joint bleed needs factor replacement as soon as it is suspected, and the FactorFirst card states the first emergency treatment (section 20.4). Heat is not part of first care for a joint bleed, which pairs prompt factor with rest, short periods of ice, compression and elevation. Moving a bleeding joint through its full range can worsen the bleed. An intramuscular injection risks a bleed into the muscle and does not treat the joint bleed.

30. [CORE] A patient with multiple myeloma has new confusion, constipation and extreme thirst. What should the nurse do first?

a. Encourage more dietary calcium to protect the bones.

b. Check the latest calcium result and report the findings promptly.

c. Reorient the patient and recheck in the morning.

d. Give a laxative for the constipation now and reassess the patient in 24 hours.

Answer: b — Confusion, constipation and thirst in myeloma are cues of hypercalcemia, which needs prompt reporting (section 20.5; Chapter 3). Extra calcium would worsen it. Reorienting alone delays care. A laxative treats only one symptom and misses the cause.

31. [CORE] A patient receiving treatment for leukemia has a low neutrophil count. Which action best protects the patient?

a. Teach the patient to report a fever right away and practise careful hand hygiene.

b. Encourage visits from family members who have colds, for emotional support.

c. Take the temperature only once a day to avoid disturbing rest.

d. Wait for a second high temperature before reporting the fever to the prescriber or team.

Answer: a — In neutropenia, infection can progress quickly, so fever is reported at once and hand hygiene is essential (section 20.5; Chapter 9). Visitors with colds expose the patient to infection. Once-daily temperatures may miss a fever. Waiting for a second fever delays emergency treatment.

32. [CORE] During the bedside check before a red cell transfusion, which action is correct?

a. Confirm the patient's identity using the room number, the bed number and the chart.

b. Complete the check with a second nurse at the nursing station to save time.

c. Read the patient's name aloud and accept a nod as confirmation.

d. Have the patient spell their name and give their birth date, and match these to the band and label.

Answer: d — Identifiers given by the patient where possible and matched to the band and label in the patient's presence prevent wrong-patient transfusion (section 20.6). Room and bed numbers are not identifiers. A check away from the bedside misses errors. A nod to a name read aloud can confirm the wrong person.

33. [CORE] Which solution may be infused through the same line as red blood cells?

a. Dextrose 5% in water

b. 0.9% sodium chloride

c. Ringer's lactate

d. An IV antibiotic

Answer: b — Sterile 0.9% sodium chloride is the compatible solution used to prime and flush a blood line (section 20.6). Dextrose 5% in water and Ringer's lactate are not used with red cells. Medications are not infused with blood components.

34. [CORE] A capable adult declines a red cell transfusion recommended for a hemoglobin of 68 g/L. Which response by the nurse is best?

a. "Can you tell me what you will and will not accept, so the team can talk with you about other options?"

b. "If you were family, you would want the blood."

c. "Your religion must be the reason, so I'll call your faith leader."

d. "You do not have a choice about this when your hemoglobin is this low."

Answer: a — A capable patient may refuse blood; the nurse explores what the patient will accept and supports a discussion of risks and alternatives, which is documented (section 20.6; Chapter 1, section 1.5). Option b pressures the patient. Option c assumes a reason. Option d is false and disrespects the patient's right to refuse.

35. [CORE] An RPN is caring for a patient whose red cell transfusion was started by an RN 20 minutes ago. The patient now has hives and is wheezing, and the throat feels tight. What should the RPN do first?

a. Slow the transfusion and wait for the RN to return from break.

b. Document the hives and recheck in 15 minutes.

c. Stop the transfusion, stay with the patient and call for urgent help.

d. Give the next medication due and then report.

Answer: c — Wheeze and throat tightness suggest anaphylaxis. Every nurse who notices a possible reaction stops the transfusion, stays with the patient and escalates, whoever started the unit (section 20.6, Scope in Practice box; Chapter 6). Slowing the unit and waiting delays care. Documenting alone ignores airway risk. Other tasks can wait.

36. [CORE] A patient with sepsis has new oozing from all IV sites, a falling platelet count and a blood pressure of 86/50 mm Hg. Which action should the nurse take first?

a. Apply pressure dressings to the IV sites and reassess at the end of the shift.

b. Ask the patient to stay in bed and avoid brushing the teeth.

c. Remove all IV catheters to stop the oozing and apply pressure to each site.

d. Activate the rapid response team, giving an SBAR report.

Answer: d — Bleeding from several sites with hypotension in sepsis suggests DIC and shock, which need urgent escalation (section 20.4; Chapter 6). Waiting until the end of the shift is unsafe. Bleeding precautions help but do not address shock. Removing IV access would prevent treatment.

37. [CORE] A stable, non-bleeding patient has a hemoglobin of 66 g/L, and two units of red cells are ordered. Which action reflects Canadian guidance?

a. Give both units back to back so the patient has fewer interruptions overnight.

b. Hold both units until the hemoglobin falls below 60 g/L on a repeat test.

c. Ask the prescriber whether one unit can be given and the patient reassessed before the second.

d. Give the second unit only if the first causes a reaction.

Answer: c — Choosing Wisely Canada advises a single red cell unit for stable, non-bleeding patients, with the patient and hemoglobin reassessed before any further unit (section 20.6). Giving both without reassessment increases the risk of overload. There is no rule to wait for 60 g/L; thresholds are individualized. A reaction is a reason to stop, not to give more.

38. [RN] A patient with septic shock has these results over 6 hours: platelets 140 × 10⁹/L, then 62 × 10⁹/L; fibrinogen 2.8 g/L, then 1.1 g/L; D-dimer rising; PT prolonged. How should the nurse interpret this pattern?

a. It suggests heparin-induced thrombocytopenia.

b. It suggests consumption of platelets and clotting factors consistent with DIC.

c. It is expected with fluid resuscitation alone.

d. It suggests immune thrombocytopenia.

Answer: b — Falling platelets and fibrinogen with a rising D-dimer and prolonged PT show consumption and fibrinolysis, the pattern of DIC (Going Deeper box, section 20.6). HIT lowers platelets after heparin exposure but does not consume fibrinogen. Dilution does not explain a rising D-dimer. ITP lowers platelets without this clotting pattern.

39. [RN] Which statement about the ISTH overt DIC score is accurate?

a. It is based on one test, the D-dimer, measured at a single point in time.

b. It replaces the need to find and treat the cause of DIC.

c. It is used to choose the dose of prothrombin complex concentrate for a bleeding patient.

d. It combines four common tests, and a total of 5 or more is consistent with overt DIC.

Answer: d — The score adds points for the platelet count, PT, fibrinogen and a fibrin-related marker, and a total of at least 5 is consistent with overt DIC (Going Deeper box, section 20.6). No single test diagnoses DIC. Treating the cause remains the most important step. PCC is contraindicated in DIC.

40. [RN] Two hours into a transfusion, a patient becomes short of breath with crackles. Which finding most supports TACO rather than TRALI?

a. Blood pressure 178/96 mm Hg and an elevated BNP

b. Temperature 38.6 °C and low blood pressure

c. No improvement after a diuretic

d. A normal BNP with a blood pressure of 84/50 mm Hg

Answer: a — A raised blood pressure and a raised BNP favour TACO (Going Deeper box, section 20.6). In TRALI, fever may be present, blood pressure may fall, and the response to diuretics and the BNP are inconsistent, so fever with hypotension (b), no improvement after a diuretic (c), and hypotension with a normal BNP (d) all point more toward TRALI.

21 Immunity, Allergy and HIV

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain innate and adaptive immunity, and interpret immune-related tests (white cell differential, CD4 count, HIV viral load).
2. Distinguish the four types of hypersensitivity, and take and document an accurate allergy history, including penicillin allergy labels.
3. Recognize severe drug and allergic reactions on a range of skin tones, and escalate them.
4. Care for immunocompromised adults, including atypical signs of infection and cautions with live vaccines.
5. Explain HIV transmission, testing, PrEP, PEP and U=U, and offer testing in a non-stigmatizing way.
6. Support people living with HIV through antiretroviral therapy, adherence, monitoring and prevention of opportunistic infections, with a distinctions-based, strengths-based lens.
7. Describe autoimmunity, and give adult vaccines safely under the Canadian Immunization Guide: screening, consent, hesitancy conversations and reporting adverse events following immunization.
8. Distinguish RN and RPN roles in immunization and HIV care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 6	Clinician; Scholar	Foundations of Practice
5, 6, 7	Educator; Advocate	Foundations of Practice; Ethical Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Every adult unit cares for people whose immune systems shape the plan of care. An allergy entry sits at the top of almost every medication record. A wrong or vague entry can do as much harm as a missing one: it can steer a patient away from the best antibiotic or fail to warn the next prescriber about a reaction that must never recur. Many patients also take drugs that weaken immunity, such as corticosteroids, transplant medicines, biologic therapies and chemotherapy. In these patients, infection can start quietly and progress quickly, so the nurse watches for small changes. People living with human immunodeficiency virus (HIV) who take effective antiretroviral therapy (ART) come to hospital for the same reasons as anyone else, and they deserve care that is skilled and free of stigma (section 21.5). Adults also need vaccines throughout life, and screening for, giving and documenting them is nursing work.

This chapter begins with a focused review of the immune system, the immune tests nurses see most often and the way immunity changes with age (section 21.1). Section 21.2 explains the four types of hypersensitivity and the everyday skills that prevent allergic harm: taking and documenting an allergy history, understanding penicillin allergy labels, caring for people with latex allergy, recognizing angioedema and severe skin reactions, and preventing anaphylaxis. Section 21.3 covers immunodeficiency and the care of adults whose defences are weakened. The rest of the chapter turns to HIV, from testing and prevention to living well on treatment (sections 21.4 and 21.5), and then to autoimmunity and adult immunization (section 21.6).

The chapter builds on earlier ones. Inflammation, infection prevention and control (IPAC) and sepsis are taught in Chapter 4. The recognition and emergency treatment of anaphylaxis, including the epinephrine dose, are taught in Chapter 6, section 6.5. Cancer treatment and neutropenia are covered in Chapter 9, respiratory vaccines in Chapter 13, and blood products and immune globulin in Chapter 20.

21.1 The Immune System: A Focused Review

Innate and Adaptive Immunity

The **immune system** protects the body from microbes, toxins and abnormal cells. It works in two connected layers that share information.

Innate immunity is the defence a person is born with. It acts within minutes to hours and responds in the same way every time it meets a threat, because it has no memory (Marshall et al., 2018). Its parts include:

- **Barriers:** intact skin and mucous membranes, along with body temperature, acidity and chemical substances that make tissues hostile to microbes.
- **Phagocytes:** cells that engulf and destroy microbes. Neutrophils arrive first and live only briefly. Macrophages can persist in tissues for months or years and show fragments of what they have eaten to T cells.
- **Complement:** a chain of blood proteins that coats microbes so phagocytes can take them up, and that can kill some microbes and infected cells directly (Marshall et al., 2018).

Inflammation, the innate response to injury and infection, is taught in Chapter 4, section 4.1.

Adaptive immunity is slower to start but precise. It responds to an **antigen**, any molecule the immune system can recognize as a target, and each response is aimed at one antigen. It needs time to reach full strength the first time, and it remembers what it has met. Its main cells are two kinds of lymphocyte: B cells and T cells (Marshall et al., 2018; Figure 21.1).

When a B cell is activated, it matures into a plasma cell that secretes **antibodies** (immunoglobulins), proteins that bind one antigen. There are five classes (Marshall et al., 2018):

- **IgG:** the main antibody when the body meets an antigen for the second time; the only class that crosses the placenta; it neutralizes toxins and viruses and helps phagocytes and complement.
- **IgM:** the first antibody produced when the body meets a new antigen.
- **IgA:** the guard of mucous membranes, such as those of the airway and gut, where it blocks microbes and toxins.
- **IgE:** the antibody of allergic reactions, which also takes part in defence against parasites.
- **IgD:** an antibody whose role is still not well understood.

T cells do not make antibodies. **CD4 T cells**, also called helper T cells, direct the immune response by releasing signalling proteins called cytokines that switch on other cells, including B cells and macrophages. **CD8 T cells**, or cytotoxic T cells, kill cells infected with viruses and some tumour cells (Marshall et al., 2018). HIV infects and depletes CD4 T cells, which is why their number is followed closely in people living with HIV (section 21.5).

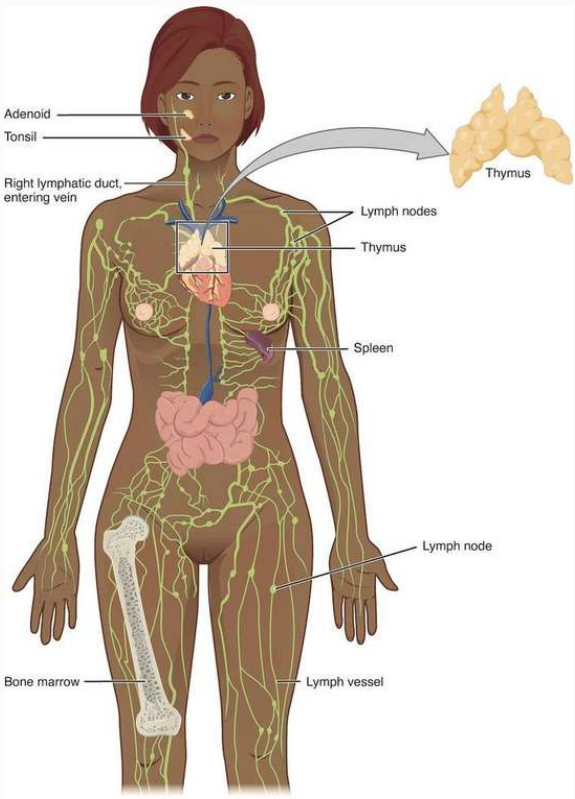

Figure 21.1 The lymphatic system. Lymphocytes are made in the bone marrow, T cells mature in the thymus, and both gather in the lymph nodes, spleen and tonsils, where they meet antigens carried in lymph and blood. (credit: Figure 21.2, "Anatomy of the Lymphatic System," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The defining feature of adaptive immunity is memory. After an infection clears, most of the responding cells die, but a small number of memory B and T cells remain. If the same antigen returns, these cells produce a faster and more effective response (Marshall et al., 2018). Vaccines use this principle: they create memory without the illness.

A person can gain immunity in two ways:

- **Active immunity:** the body makes its own antibodies and memory cells. It is natural after an infection and artificial after a vaccine. It takes time to develop but can last.
- **Passive immunity:** ready-made antibodies come from someone else. It is natural when a pregnant person's IgG crosses the placenta and artificial when immune globulin is injected or infused, as with intravenous immune globulin (IVIG) (Chapter 20). It works at once, which helps when there is no time to wait for a vaccine response, but it is temporary because no memory cells are made (Marshall et al., 2018).

Immune Tests the Nurse Sees

Several tests reflect immune function. Reference ranges vary by laboratory, so the nurse reads each result against the range on the patient's own report.

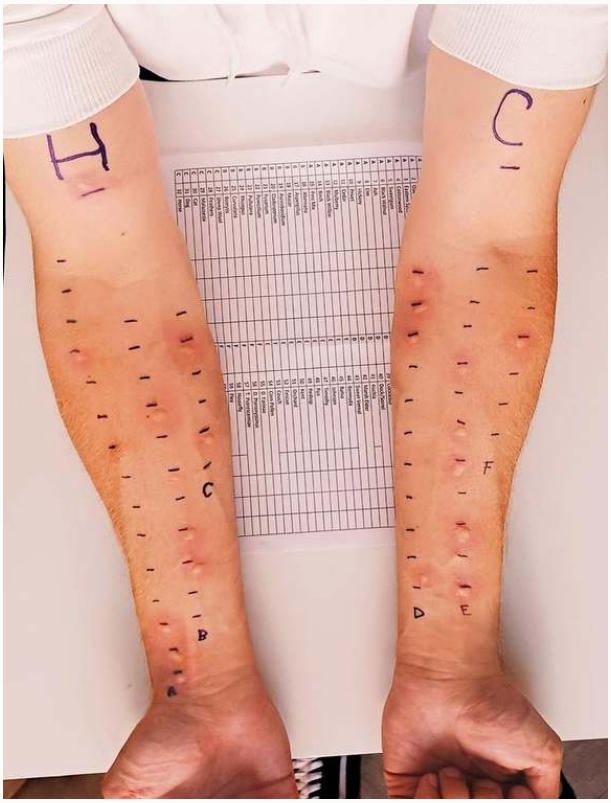

Figure 21.2 Skin prick testing on the forearms. Each pen mark labels one allergen, and a raised, red wheal at a site suggests sensitization to that allergen; redness is harder to judge on darker skin. A positive test is interpreted with the history.

- **White blood cell count and differential:** the first look at immune cells. Ranges and the meaning of high and low counts are taught in section 20.1. The differential includes the absolute lymphocyte count, which the nurse reads alongside the patient's diagnosis, medications and trend.
- **Serum immunoglobulin levels:** IgG, IgA and IgM are measured when an antibody deficiency is suspected, for example in an adult with repeated sinus infections and pneumonias (McCusker et al., 2018).
- **CD4 count:** the number of CD4 T cells in the blood, the key measure of immune health in HIV (section 21.5). Treatment guidelines and this chapter give it in cells per microlitre (cells/µL). Some laboratories print the SI equivalent in × 10^9/L instead; the two express the same quantity, so 200 cells/µL equals 0.2 × 10^9/L.
- **HIV viral load:** the amount of HIV genetic material in the blood, reported in copies per millilitre (copies/mL) (section 21.5).
- **Allergy tests:** allergists confirm an allergy suspected from the history with skin prick testing (Figure 21.2), in which a tiny amount of allergen is introduced through a light prick and the skin is watched for a raised wheal, or with a blood test for allergen-specific IgE. Skin testing needs a skilled tester, carries some risk, and can be affected by factors that include skin colour. The blood test is a safe alternative that can screen many allergens at once (Ellis et al., 2024). A positive test shows only that IgE is present, so results are always read together with the history.

The Aging Immune System

Immunosenescence is the natural, gradual decline in immune function that comes with age (National Advisory Committee on Immunization [NACI], 2018). It has three practical effects for nurses.

First, older adults are more likely to develop some infections. Shingles is the clearest example. After chickenpox, the varicella-zoster virus (VZV) stays in the body in an inactive state. As cell-mediated immunity weakens with age or immune suppression, the virus can reactivate as **herpes zoster** (shingles) (NACI, 2018; Figure 21.3). Shingles is more common in older adults and in people who are immunocompromised, and its estimated lifetime risk in the general Canadian population reaches up to 30% (Krishnan et al., 2026).

Second, infection may not look the way students expect. Fever can be low or absent, and the first sign may be new confusion, a fall or a loss of appetite. This atypical presentation is taught in Chapter 4, and its link with delirium in Chapter 8.

Third, some vaccines work less well as people age, which is why certain vaccines are designed with older adults in mind. NACI found that the effectiveness of the older live zoster vaccine falls with age and is significantly lower in adults over 70 than in those aged 50 to 59. The non-live **recombinant zoster vaccine (RZV)** stays more effective across all age groups (NACI, 2018). NACI recommends RZV for adults aged 50 and older without contraindications (NACI, 2018) and two doses for adults aged 18 and older who are, or will be, immunocompromised (Krishnan et al., 2026). Some influenza vaccines are also designed for older adults (Chapter 13).

GOING DEEPER

Inside a Type I Reaction

Required for RN students; optional for PN students.

A type I (immediate) reaction needs two meetings with the allergen. At the first, called **sensitization**, helper T cells of a type that favours allergy steer B cells to make IgE against the allergen. The IgE attaches to receptors on mast cells in tissues and on basophils in the blood. The person has no symptoms, but these cells are now primed (Marshall et al., 2018).

At the next exposure, the allergen binds neighbouring IgE molecules on the cell surface and links them (cross-linking). Within minutes the cell releases histamine, leukotrienes and prostaglandins (Marshall et al., 2018), which widen blood vessels, make capillaries leak, tighten airway muscle and cause itch. Symptoms can also return after the first episode has fully settled. When they come back within 48 hours, the reaction is called biphasic anaphylaxis; in a meta-analysis of 2,890 adults, a median of 6.5% had it (Golden et al., 2024).

Mast cells also release the enzyme **tryptase**. A 2023 practice parameter suggests drawing an acute serum tryptase as early as possible, ideally within 2 hours after symptoms begin, and a later baseline level for comparison. A rise of at least 20% plus 2 µg/L (2 ng/mL) above baseline supports systemic mast cell activation (Golden et al., 2024), but a normal result does not rule out anaphylaxis (Warrington et al., 2018). The nurse records when symptoms began and when the sample was drawn.

21.2 Hypersensitivity and Allergy

Hypersensitivity is an excessive or misdirected immune response that damages the body's own tissues. An **allergy** is hypersensitivity to a substance harmless to most people, such as a food, pollen or drug. Drug allergy is unpredictable and occurs at ordinary doses (Warrington et al., 2018).

Four Types of Hypersensitivity

Hypersensitivity reactions are grouped into four types by mechanism (Table 21.1) (Marshall et al., 2018):

- **Type I (immediate):** IgE on mast cells and basophils triggers a reaction within minutes, as in hives, allergic rhinitis and anaphylaxis.
- **Type II:** IgG or IgM binds the person's own cells, and complement destroys them, as in a hemolytic transfusion reaction (section 20.6).
- **Type III:** antibody–antigen clumps called immune complexes settle in tissues and inflame them over days to weeks, as in serum sickness and lupus (Chapter 34).
- **Type IV (delayed):** T cells and macrophages, not antibodies, cause inflammation 2 or more days after exposure, as in contact dermatitis and the tuberculin skin test reaction (Chapter 13). Many delayed drug rashes, including the severe reactions later in this section, are T cell-mediated (Warrington et al., 2018).

Table 21.1 The four types of hypersensitivity reaction (Marshall et al., 2018; Warrington et al., 2018)

Type	What happens	Usual timing	Examples	Nursing focus
Type I: immediate, IgE-mediated	IgE on mast cells and basophils binds the allergen; the cells release histamine and other mediators	Minutes, sometimes up to a few hours	Anaphylaxis, hives, allergic rhinitis, food, insect sting and some drug allergies	Check allergies before every drug and food; recognize anaphylaxis early and act (Chapter 6)
Type II: antibody against cells	IgG or IgM binds the person's own cells; complement destroys them	Hours	Hemolytic transfusion reaction, autoimmune hemolytic anemia, immune thrombocytopenia	Follow transfusion checks; stop the transfusion and report a reaction (section 20.6); watch blood counts
Type III: immune complex	Antibody-antigen clumps deposit in tissues and trigger inflammation	Days to weeks	Serum sickness, systemic lupus erythematosus	Assess joints, skin and kidney function; report new rash, fever or joint pain
Type IV: delayed, T cell-mediated	T cells and macrophages cause inflammation without antibodies	2 days or more; severe drug reactions can take weeks	Contact dermatitis, tuberculin skin test reaction, delayed drug rashes, including the severe reactions described later in this section	Ask about recent new drugs; inspect skin and mucous membranes; report promptly

Taking and Documenting an Allergy History

An accurate allergy history starts with three distinctions:

- **Allergy:** an immune-mediated reaction, such as hives, swelling, wheeze or anaphylaxis.
- **Drug intolerance:** an unwanted drug effect at a low, sometimes below-therapeutic, dose that is not immune-mediated (Warrington et al., 2018).
- **Side effect:** a known effect of a drug at usual doses. Nausea, diarrhea, stomach pain and headache with an antibiotic are common side effects, not allergic reactions (Ontario Medical Association [OMA] Section on Allergy, 2025).

The nurse asks open questions and records the substance by generic name (and brand, if known) without abbreviations; what happened, in detail; its timing in relation to the dose; its severity and treatment; and when it occurred and whether the drug has been taken since (Institute for Safe Medication Practices Canada [ISMP Canada], 2016; Warrington et al., 2018).

ISMP Canada counts death or serious harm from giving a drug to which a patient's allergy was already known, or from failing to ask about allergies, as a "never event." In the incidents it reviewed, the earlier reaction was already on file but was not flagged or was lost between paper and electronic records. It recommends confirming the allergy record whenever a history is taken and at every transition in care (ISMP Canada, 2016). The nurse also checks allergy status before any new drug, applies an allergy band where employer policy requires one and documents according to the Documentation standard (Chapter 1).

CLINICAL SAFETY

The Allergy Label

An allergy label can harm a patient in two directions. A missing or vague entry, such as "antibiotics" or "sulfa?", leaves the next nurse unable to protect the patient. An entry that records a side effect as an allergy can deny the patient the safest and most effective drug for years (Saravanabavan et al., 2023).

A useful entry names the exact drug, describes the reaction, states when it happened and how long after the dose, records its severity and treatment, and notes any later doses that were tolerated (ISMP Canada, 2016; Warrington et al., 2018). For example: "Amoxicillin, 2019: itchy raised rash on trunk 2 hours after first dose, treated with an oral antihistamine; no breathing problems." That entry tells the team far more than "penicillin allergy."

The nurse checks the allergy record at every handover, at every transfer between units or facilities, and before every first dose of a drug. If a patient's story does not match the record, the nurse reports the difference to the prescriber or pharmacist. The nurse never removes or changes a label alone, but follows the employer's process, so that the reason for the change stays visible to every clinician (ISMP Canada, 2016).

Penicillin Allergy Labels

Penicillin is the most frequently reported drug allergy, affecting about 10% of patients, yet more than 80% of people who report it have a negative skin test, and about 90% of adult inpatients tolerate penicillin after evaluation (Warrington et al., 2018). In five Vancouver hospitals, delabelling programs removed the label from 697 of 711 patients (98.0%) (Saravanabavan et al., 2023).

A false label has real costs: less effective antibiotic choices, surgical site infections and infections with resistant organisms (Saravanabavan et al., 2023). In a large UK primary care cohort, adults with a documented penicillin allergy had a 69% higher risk of methicillin-resistant *Staphylococcus aureus* (MRSA) and a 26% higher risk of *Clostridioides difficile* infection than matched adults, partly because they received more alternative antibiotics (Blumenthal et al., 2018; see Chapter 4 on stewardship).

Delabelling is the removal of an inaccurate allergy label after the history is reviewed and, when needed, testing is done. A short scoring tool, PEN-FAST, sorts histories by risk; a score below 3 means low risk (Trubiano et al., 2020). Some histories, such as common side effects alone, need no testing. Some patients go directly to an oral challenge (a test dose given while a clinician observes), while others need skin testing first, and people with severe past reactions see an allergist (OMA Section on Allergy, 2025).

Testing and challenge are prescriber or allergist decisions. The nurse takes the precise history that makes delabelling possible, monitors the patient during a challenge as ordered, documents the outcome and teaches the patient that the label is gone and why.

Latex Allergy

Latex allergy is an allergic reaction to natural rubber latex, found in some gloves and other products. People at higher risk include health care and laboratory workers, people who have had many surgeries (such as 10 or more), and people allergic to certain foods, including banana, avocado, kiwi, passion fruit and chestnut (Canadian Centre for Occupational Health and Safety [CCOHS], 2023). Reactions range from dry, itchy, irritated skin, which is not an allergy, to a delayed contact rash (type IV) and immediate hives, wheeze, swelling or anaphylaxis (type I) (CCOHS, 2023; Marshall et al., 2018). The nurse asks about latex on admission and before every procedure, uses non-latex products, informs the perioperative team (Chapter 7) and follows the employer's latex-safe care policy.

Angioedema

Angioedema is swelling of the deeper layers of the skin or the lining of the mouth, throat or gut. It has two main mechanisms (Kanani et al., 2018):

- **Histamine-mediated angioedema** is often allergic and often comes with hives (urticaria): itchy, raised wheals with pale centres, each of which usually fades within about 24 hours (Figure 6.2).
- **Bradykinin-mediated angioedema** is driven by the peptide bradykinin, and hives are typically absent. It may be acquired, caused by a drug or inherited: **hereditary angioedema** is a rare inherited deficiency or dysfunction of the C1 inhibitor protein.

ACE inhibitor angioedema occurs in about 0.1% to 6% of people taking angiotensin-converting enzyme (ACE) inhibitors (Chapters 18 and 19). Most cases appear in the first week, but up to one-third appear months to years after the drug was started. The

drug is stopped in anyone who develops angioedema, and swelling can recur for about a month afterward (Kanani et al., 2018). Histamine is not directly involved in hereditary and acquired angioedema, so those forms do not respond to antihistamines or corticosteroids (Kanani et al., 2018). ACE inhibitor angioedema is also bradykinin-driven, and it is suspected in anyone taking an ACE inhibitor who develops angioedema without hives (Kanani et al., 2018). An emergency medicine practice statement found that epinephrine, antihistamines and corticosteroids have not been shown to help in ACE inhibitor angioedema, although they may be tried (Rosenbaum et al., 2020), so the nurse cannot count on the usual allergy drugs to reverse it.

Swelling of the larynx can quickly cause fatal asphyxiation (Kanani et al., 2018). A swollen tongue or lips, a changed voice, trouble swallowing, drooling or noisy breathing is an emergency: the nurse stays with the patient, calls the rapid response team at once (Chapter 6) and later documents the reaction.

On darker skin, the redness of hives can be hard to see because melanin masks it (Akinbisehin et al., 2026). The nurse looks for raised wheals in good light, feels for warmth, asks about itch and asks whether the face or lips look different from usual.

Severe Cutaneous Adverse Reactions

Severe cutaneous adverse reactions (SCARs) are rare but deadly delayed drug reactions.

Stevens-Johnson syndrome (SJS) and **toxic epidermal necrolysis (TEN)** are one disease at different extents: the epidermis dies and separates from the layer beneath. Detachment of less than 10% of the body surface is SJS, more than 30% is TEN, and the range between is an overlap. The reaction usually begins within 4 weeks of starting the drug (Akinbisehin et al., 2026). Fever, sore throat, fatigue and sore, red eyes come early; a rash then spreads and may blister, and the mouth, eyes and other mucous membranes ulcerate (Warrington et al., 2018). The eyes are involved in up to 75% of patients; mortality reaches 30%. High-risk drugs include allopurinol, carbamazepine, lamotrigine, nevirapine and sulfonamide antibiotics (Akinbisehin et al., 2026).

Drug reaction with eosinophilia and systemic symptoms (DRESS) usually develops 2 to 6 weeks after a drug is started. It brings a widespread rash, fever, swollen lymph nodes, facial and ear swelling, a high eosinophil count and involvement of organs such as the liver, kidneys and lungs; mortality reaches 10% (Akinbisehin et al., 2026). Anticonvulsants, sulfonamides and allopurinol are common causes, and symptoms can persist for weeks after the drug is stopped (Warrington et al., 2018).

On darker skin, early SJS/TEN lesions may look darker and less distinct rather than red, and mouth or eye involvement may be the first clear sign. A DRESS rash may look violet or darker than the surrounding skin (Akinbisehin et al., 2026). The nurse inspects the mouth, eyes and skin in good light and does not wait for redness.

Stopping the culprit drug is the most effective treatment (Warrington et al., 2018), but that decision belongs to the prescriber. The nurse reports a new rash with fever or mucosal sores at once, holds the next dose under employer policy until the prescriber assesses the patient, and escalates if the prescriber cannot be reached. A UK national guideline advises that adults who have lost epidermis over more than 10% of the body surface be moved promptly to a burn centre or an intensive care unit (ICU) experienced in caring for SJS/TEN (Creamer et al., 2016). The reaction is documented in detail as an allergy, and the patient is referred to an allergist (Warrington et al., 2018).

CLINICAL JUDGMENT

A New Rash on Day 9

Names and details are fictional; this is a composite story.

Mr. Daniel Osei, 61, is on a medical unit after a stroke. Carbamazepine was started 9 days ago for new seizures. At 0700 he tells the registered practical nurse (RPN) his mouth is too sore to eat and his eyes feel "full of sand." He has dark brown skin.

- **Recognize cues:** Temperature 38.7 °C, heart rate 112 beats/min, blood pressure 116/70 mm Hg, respiratory rate 20 breaths/min, oxygen saturation (SpO2) 96% on room air. Crusted lips, ulcers inside both cheeks, watery red eyes. Dusky, grey-purple patches on his chest and back, two with thin blisters. He says the skin "burns."
- **Analyze cues:** A new drug started 9 days ago, fever, mucosal ulcers, eye involvement and blistering skin fit a severe cutaneous adverse reaction. Blisters mean the epidermis is separating.
- **Prioritize hypotheses:** SJS/TEN is the most urgent possibility; infection and sepsis must also be considered. Skin loss threatens fluid balance, infection and his eyes.

- **Generate solutions:** Hold the 0800 carbamazepine dose under hospital policy and report immediately; protect the skin; keep him drinking if he can; prepare for urgent assessment and possible transfer.
- **Take action:** The RPN notifies the registered nurse (RN); they assess him together, and the RN calls the physician using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6). The physician stops carbamazepine, orders bloodwork and consults dermatology and ophthalmology. The RPN documents findings, times and the held dose, and adds a detailed allergy entry.
- **Evaluate outcomes:** The nurses reassess skin, mouth, eyes, vital signs, intake and output at least hourly, measure any spread of blisters and report changes at once. By evening he is transferred to a specialized unit.

Preventing Anaphylaxis

The recognition and emergency treatment of anaphylaxis, including the adult epinephrine dose, are taught in Chapter 6, section 6.5; this section covers prevention.

The most frequent triggers are drugs, foods and insect venom; others seen in hospital include antiseptics, latex and contrast media (Cardona et al., 2020). The nurse checks the allergy record before every drug, blood product, contrast study and meal tray, asks the patient again when anything is new, and follows employer policy on observation after first doses and after vaccines (section 21.6).

Only about half of people who have had anaphylaxis are referred to an allergist, although referral identifies the cause and teaches self-management (Cardona et al., 2020), so the nurse advocates for it. The Canadian EpiPen monograph states that patients are prescribed two autoinjectors (Figure 6.3 shows how to hold one), should carry them at all times and should wear medical identification (Mylan Specialty, 2024). A written anaphylaxis emergency plan lists symptoms, the steps to take and where the device is kept (Association des allergologues et immunologues du Québec [AAIQ], 2020). As of October 2026, EpiPen autoinjectors and an epinephrine nasal spray (neffy) are marketed in Canada; Allerject and Emerade are no longer marketed (Health Canada, n.d.-b).

PATIENT EDUCATION

Carrying and Using an Epinephrine Autoinjector

The nurse teaches the patient, and family if the patient wishes, with a trainer device and the instructions for the patient's own product:

- **Know the signs.** Hives or swelling of the face, lips or tongue; a cough, wheeze, hoarse voice, throat tightness or trouble breathing or swallowing; vomiting or cramps; or feeling faint, dizzy or a sense that something terrible is happening (AAIQ, 2020).
- **Use it first.** Give the epinephrine as soon as a known or suspected reaction begins, then call 9-1-1 and say it is a life-threatening allergic reaction (AAIQ, 2020).
- **Where.** Inject into the outer thigh, through clothing if needed. For EpiPen, hold it firmly in place for 3 seconds. Never inject into the buttock (Mylan Specialty, 2024).
- **Second dose.** If symptoms do not improve, a second dose may be given once 5 to 15 minutes have passed (Mylan Specialty, 2024).
- **Go to hospital,** ideally by ambulance, even if you feel better, because symptoms can return (AAIQ, 2020).
- **Storage.** Keep it at room temperature, protected from light; do not refrigerate or freeze it. Check that the liquid is clear and replace the device before its expiry date (Mylan Specialty, 2024).
- **Carry it always.** Carry both devices everywhere and wear medical identification (Mylan Specialty, 2024).

The adult dose is taught in Chapter 6.

21.3 Immunodeficiency and the Immunocompromised Patient

Primary and Secondary Immunodeficiency

Immunodeficiency is a state in which the immune system cannot defend the body adequately. A person who is **immunocompromised** has defences weakened by a disease or its treatment.

Primary immunodeficiencies are built into the immune system, usually because of inherited changes. They are rare, and many are found in childhood, but more than half of people with antibody deficiencies are diagnosed as adults. **Common variable immunodeficiency (CVID)**, the most important example in adults, usually begins after age 10. It causes repeated sinus and lung infections and is linked with autoimmune disease, digestive problems and a higher risk of cancer. It is treated with immunoglobulin replacement (Chapter 20), which many patients need for life (McCusker et al., 2018). Warning signs in adults include two or more new sinus infections in a year without allergy, a pneumonia every year for more than one year, repeated need for intravenous antibiotics, persistent thrush and chronic diarrhea with weight loss (McCusker et al., 2018). In the most severe primary immunodeficiencies, live vaccines can cause severe, spreading and even fatal infection, while non-live vaccines are safe but may protect less well (McCusker et al., 2018).

Secondary immunodeficiency is acquired. It results from another disease, from malnutrition or from treatment with drugs that suppress immunity (McCusker et al., 2018). Common causes in adult care are:

- **Drugs:** corticosteroids; transplant drugs, such as calcineurin inhibitors and antimetabolites; biologic therapies, such as tumour necrosis factor (TNF) inhibitors (for example, adalimumab); and chemotherapy (Chapter 9).
- **Infections:** HIV above all (section 21.4).
- **Chronic diseases:** diabetes (Chapter 22), advanced chronic kidney disease (Chapter 27) and cancers of the blood cells (Chapter 20).
- **Other causes:** malnutrition, removal or loss of function of the spleen (Chapter 20) and aging (section 21.1).

Table 21.2 summarizes what these causes mean for nursing care. The Canadian Tuberculosis Standards illustrate the effect: people living with HIV have a very high risk that tuberculosis (TB) infection will progress to disease; transplant recipients, people with stage 4 or 5 kidney disease and people taking TNF inhibitors or corticosteroids have a high risk; and people with diabetes have a moderate risk (Campbell et al., 2022).

Table 21.2 Common causes of secondary immunodeficiency and what they mean for nursing care (AbbVie Corporation, 2022; Campbell et al., 2022; McCusker et al., 2018; NACI, 2018; Public Health Agency of Canada, 2026e)

Cause	Effect on immunity	Nursing points
Corticosteroids	Suppress inflammation and immune responses; raise the risk that TB infection progresses to disease	Signs of infection, including fever, may be muted; do not stop long-term therapy without an order (Chapter 23); check vaccine plans with the prescriber
Transplant immunosuppressants	Suppress the immune response to prevent rejection; raise the risk of TB disease	Give on time, every time; report signs of infection early; avoid live vaccines; strict hand hygiene
Biologics, such as TNF inhibitors	Block specific immune signals; raise the risk of serious infection, TB and hepatitis B reactivation	Confirm TB and hepatitis B screening was done before the first dose; assess for infection before each dose and report it; no live vaccines during therapy
Chemotherapy	Suppresses the bone marrow, which can cause neutropenia (Chapter 9)	Treat fever as an emergency (Chapter 9); check the neutrophil count before procedures
HIV	Depletes CD4 T cells; very high risk that TB infection progresses to disease; opportunistic infections (section 21.5)	Support ART adherence; follow CD4 count and viral load (section 21.5); non-stigmatizing care
Diabetes and chronic kidney disease	Raise the risk of infection, including progression of TB infection (moderate risk with diabetes, high with stage 4 or 5 kidney disease)	Inspect feet, skin and wounds; keep glucose in target (Chapter 22); report infection early
Older age	Immunosenescence weakens T cell responses and vaccine responses	Expect atypical signs such as confusion or falls (Chapter 8); keep vaccines up to date

Recognizing Infection When Immunity Is Low

When immunity is weak, the body may not mount the fever, redness, swelling or pus that usually signal infection. An immunocompromised adult may have a serious infection with a normal or only slightly raised temperature. The nurse therefore

watches trends and subtle changes: new confusion or fatigue, a rising respiratory or heart rate, a falling blood pressure, reduced urine output or a vague report of "not feeling right." These early warning signs and the escalation steps for sepsis are taught in Chapters 4 and 6. Fever in a patient with neutropenia is a medical emergency, covered in Chapter 9. Because TB infection is more likely to progress to disease in many of these patients (Campbell et al., 2022), the nurse also reports symptoms that could suggest TB (Chapter 13).

Screening before treatment is part of prevention. The Canadian product monograph for adalimumab, a TNF inhibitor, directs that patients be checked for both active and inactive TB before starting, that TB infection be treated before therapy begins, and that people at risk be checked for previous hepatitis B infection. It also states that therapy should not be started during an active infection and should be stopped if a serious infection or sepsis develops (AbbVie Corporation, 2022). Before giving a dose of a biologic, the nurse confirms that screening results are on the record, asks about fever and new symptoms, and reports any sign of infection to the prescriber before proceeding.

Nursing Care and Teaching

Care for an immunocompromised adult combines protection, early detection and teaching:

- **Infection prevention:** routine practices and hand hygiene by everyone who enters the room, visitors included (Chapter 4).
- **Devices:** avoid unnecessary invasive devices, such as urinary catheters and intravenous lines, and ask daily whether each one is still needed (Chapter 4).
- **Food safety:** reinforce safe food handling, because foodborne infections can be more serious when immunity is weak, and follow any food advice from the care team.
- **Vaccines:** The Canadian Immunization Guide (CIG) advises immunizing before planned immunosuppression whenever possible and vaccinating family members and other close contacts, with annual influenza vaccine encouraged. People who are severely immunocompromised should not receive a **live vaccine**, one that contains a weakened living microbe. Non-live vaccines are given at least 2 weeks before immunosuppressive therapy begins in people with blood cancers, and live vaccines at least 4 weeks before an organ transplant. Vaccine responses are often weaker and shorter in immunocompromised people, and live vaccines wait at least 6 months after treatment with an antibody that targets B cells (Public Health Agency of Canada [PHAC], 2026e). People taking adalimumab may receive other vaccines but not live ones (AbbVie Corporation, 2022). NACI recommends two doses of the non-live recombinant zoster vaccine for adults aged 18 and older who are or will be immunocompromised; before immunosuppressive therapy, the second dose can be given as early as 4 weeks after the first (Krishnan et al., 2026). Immunization is covered in section 21.6.
- **When to call:** teach the patient to report a fever, chills, a new cough, burning on urination, a red or draining wound, or simply feeling unwell, the same day.
- **Medication safety:** teach patients never to stop or skip a transplant drug or biologic without talking to the prescriber, and to tell every health care provider which immunosuppressing drugs they take.

All nurses monitor these patients and act on change. An RPN who notices subtle signs of infection reports them at once and consults the RN as the patient's needs change, as described in Chapter 1, section 1.3.

LIFESPAN CONSIDERATIONS

Immunosenescence, Vaccines and HIV After 50

- **Older adults first.** Immunosenescence means infection may appear as confusion, a fall or loss of appetite rather than fever (Chapters 4 and 8). The nurse compares today's behaviour and function with the person's usual baseline, asking family when the patient cannot say.
- **Vaccine priorities.** NACI recommends the recombinant zoster vaccine for adults aged 50 and older without contraindications, because shingles becomes more common with age and the older live vaccine works less well in older adults (NACI, 2018). Influenza and pneumococcal vaccines, also priorities for older adults, are covered in Chapter 13. The nurse checks immunization status on admission and at discharge.

- **HIV after 50.** With effective ART, people living with HIV are growing older (section 21.5), and some will meet age-related conditions, such as heart and kidney disease, alongside HIV. Older adults also have sexual health needs. Age alone is never a reason to skip a sexual health history or the offer of an HIV test (section 21.4).

21.4 HIV: Infection, Testing and Prevention

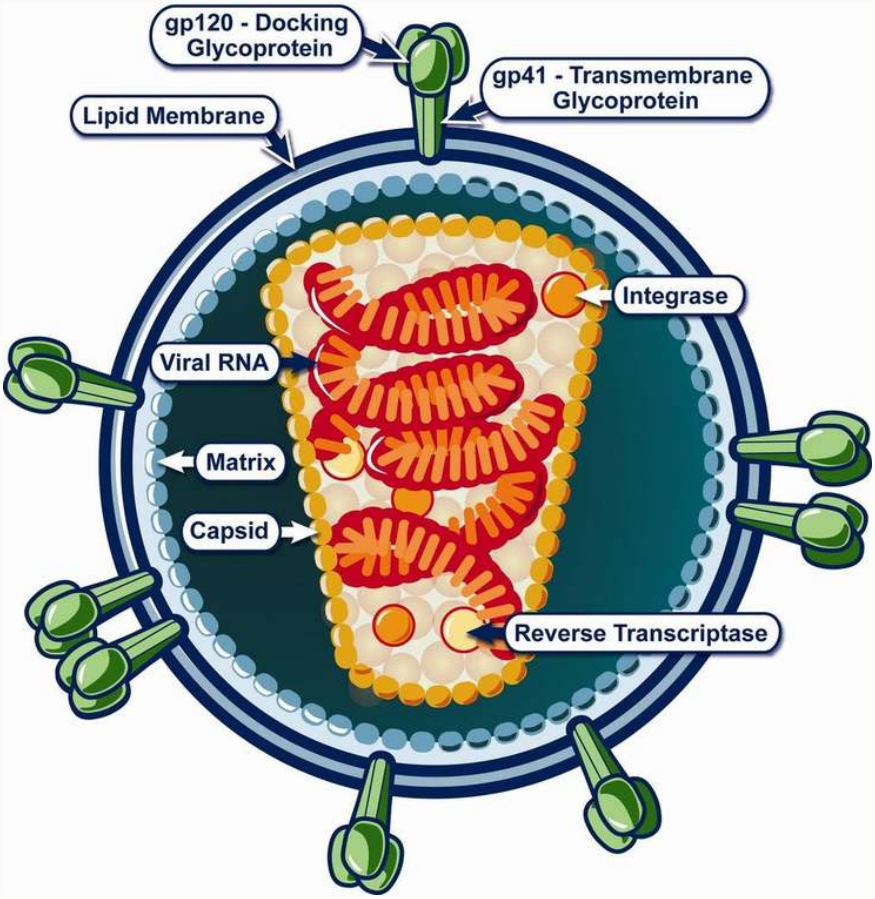

Figure 21.4 The structure of HIV: an outer envelope with docking proteins that attach to the CD4 receptor on a host cell, and a capsid holding the viral RNA and the enzymes reverse transcriptase and integrase. (credit: National Institute of Allergy and Infectious Diseases, public domain)

Human immunodeficiency virus (HIV) can now be prevented, found early and treated well. Nurses help close the remaining gaps: people never offered a test, people unaware of prevention medicines, and people who avoid care for fear of how they will be treated. Section 21.5 covers treatment.

How HIV Causes Disease

HIV is a retrovirus (Figure 21.4). Its genes are carried as RNA, and it brings its own enzymes into the cells it infects: reverse transcriptase copies the viral RNA into DNA, integrase splices that DNA into the host cell's chromosomes, and protease cuts new viral proteins into working parts. Each enzyme is a target of antiretroviral drugs (section 21.5; Figure 21.5). Because viral DNA stays in infected cells for their lifetime, treatment controls HIV but does not cure it.

HIV mainly infects CD4 T helper cells, which coordinate both antibody and cell-mediated responses (section 21.1). Untreated, the virus destroys them faster than the body replaces them, and over years the falling CD4 count leaves the person open to infections and cancers a healthy immune system controls.

HIV passes from person to person through a small set of body fluids: blood, semen and pre-seminal fluid, vaginal fluid, rectal fluid and human milk. The main routes are anal or vaginal sex without a condom or other prevention, sharing needles or other drug-use equipment, and transmission during pregnancy, birth or breastfeeding or chestfeeding (Chapter 29). HIV is not passed on through healthy, unbroken skin or through casual contact such as kissing, hugging, shaking hands, sharing food or toilet seats, and mosquitoes do not spread it (Public Health Agency of Canada [PHAC], 2025b). A person whose viral load stays suppressed on treatment does not transmit HIV through sex (PHAC, 2023b).

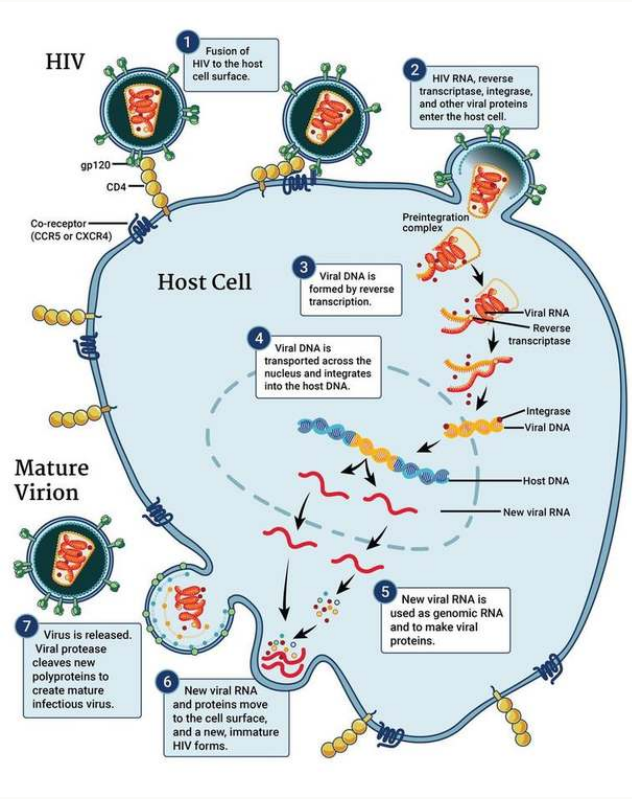

Figure 21.5 The HIV replication cycle. Antiretroviral drug classes act at different steps: entry, reverse transcription, integration and maturation by protease (section 21.5). (credit: "HI-Virus Replication Cycle" by NIAID/Wikimedia Commons, CC BY 2.0)

Untreated HIV moves through three broad stages:

- **Acute HIV infection:** the first weeks after the virus enters the body. The virus multiplies quickly, the viral load is very high and the person is highly infectious. At least half of people have a mild flu-like illness 2 to 4 weeks after infection, with fever, sore throat, rash or swollen lymph nodes, among other symptoms; others notice nothing (PHAC, 2025c). Antibody tests may still be negative (see the window period, below).
- **Chronic HIV infection:** the immune system partly controls the virus, and the person may feel well for years while CD4 cells are slowly lost.
- **Advanced HIV disease:** in the United States surveillance case definition, **acquired immunodeficiency syndrome (AIDS)**, or stage 3 HIV, is a CD4 count below 200 cells/µL (0.2×10^9/L), a CD4 percentage below 14%, or the diagnosis of an AIDS-defining opportunistic illness (Selik et al., 2014). With treatment, most people never reach this stage, but people diagnosed late may arrive in hospital with an opportunistic infection as the first sign of HIV.

HIV in Canada

PHAC (2024a) estimated that 65,270 people were living with HIV in Canada at the end of 2022. About 1 in 10 of them did not know they had HIV. Canada committed to the global **95-95-95 targets** for 2025: 95% of people living with HIV diagnosed, 95% of those diagnosed on treatment, and 95% of those on treatment with a suppressed viral load. In 2022, the estimates were 89%, 85% and 95%, so only the third target was met. PHAC estimated 1,848 new infections in 2022, about 15% more than its 2020 estimate, and noted that the COVID-19 pandemic disrupted services (PHAC, 2024a).

Surveillance counts first-time diagnoses, not new infections. In 2024, 2,288 people received a first HIV diagnosis in Canada (5.5 per 100,000 population), fewer than in 2023 but more than before the pandemic (PHAC, 2026c). Manitoba (19.5 per 100,000) and Saskatchewan (18.6 per 100,000) had the highest rates in 2024, and the Atlantic region had the lowest (1.7 per 100,000). Among males diagnosed in 2024, male-to-male sexual contact was the most common exposure category (49.9%); among females, heterosexual contact was the most common (58.1%); and injection drug use accounted for 16.9% of all first-time diagnoses (PHAC, 2026c).

Race and ethnicity were reported for only 38.1% of 2024 diagnoses, so PHAC (2026c) cautions that the figures may not represent everyone diagnosed. Among the 871 diagnoses with these data, 31.6% were among Black people, 25.4% among white people and 7.1% among Indigenous people (6.1% First Nations, 0.3% Inuit and 0.7% Métis). Data about First Nations communities are

governed by the First Nations principles of OCAP® (ownership, control, access and possession), so the nurse uses published aggregate figures and respects community control over local data.

These patterns reflect structures, not personal failings. The federal STBBI (sexually transmitted and blood-borne infections) action plan names gay, bisexual and other men who have sex with men, people who inject drugs, Indigenous Peoples, Black communities, people who experience incarceration, and trans and non-binary people as key populations. It points to stigma, including in health care, anti-Black racism, anti-Indigenous racism rooted in colonial policies, the criminalization of HIV non-disclosure, and unequal access to income, housing, food and mental health support (PHAC, 2024b). Chapter 2 teaches cultural safety and anti-racist care.

CANADIAN CONTEXT

HIV in Canada

- **Two figures to know:** an estimated 65,270 people were living with HIV in Canada at the end of 2022, and about 1 in 10 of them had not been diagnosed (PHAC, 2024a).
- **Where diagnoses are highest:** in 2024, Manitoba and Saskatchewan had first-diagnosis rates more than three times the national rate of 5.5 per 100,000 (PHAC, 2026c).
- **Communities leading the response:** community organizations, including Indigenous-led and Black-led organizations, offer testing, harm reduction, peer support and help finding care. The federal action plan commits to funding community-led projects and to peer-based approaches such as peer navigation, in which a person with lived experience helps someone move through testing and care (PHAC, 2024b).
- **Finding local testing:** in Ontario, Sexual Health Infoline Ontario (1-800-668-2437) helps people find sexual health services, and the province lists anonymous testing sites (Government of Ontario, 2025). Local public health units and community health centres offer testing across Canada.
- **For the nurse:** the most useful thing a nurse can do is offer HIV testing routinely, in a matter-of-fact way, to every adult in their care who has not been tested recently.

Testing

PHAC's HIV screening guidance asks clinicians to make HIV testing a routine part of care and to offer it whether or not the person asks (PHAC, 2013, 2020). Testing should be offered to anyone who asks; anyone with signs of HIV or of immune-related illness; sexually active people who have never been tested; people who are pregnant or planning a pregnancy; people who have shared drug-use equipment or had condomless sex with a partner whose HIV status is positive or unknown; and survivors of sexual assault. People with ongoing risk should be tested at least yearly, and some more often (PHAC, 2013). That guide is under review, so the nurse watches for updates; PHAC's current STBBI guidance also supports offering screening during routine care (PHAC, 2025d).

HIV testing is voluntary; verbal consent is enough, and the person may decline (PHAC, 2020). Before the test, the nurse explains the window period, how results are kept private and the limits of that privacy (positive results are reported to public health), and the right to refuse (PHAC, 2013). A negative result opens a talk about prevention. A positive result is given in person, with time for questions, a rapid link to HIV care and support for partner notification (PHAC, 2013, 2020). Consent is taught in Chapter 1, section 1.5.

Three kinds of tests are used (PHAC, 2020):

- **Laboratory screening test:** a fourth-generation test on a blood sample detects both HIV antibodies and the p24 antigen, a viral protein that appears before antibodies. It can be reactive 15 to 20 days after exposure. A reactive screen is followed by confirmatory testing in the laboratory.
- **Point-of-care (rapid) test:** a finger-prick test that gives a result within minutes. It detects antibodies only, so it becomes reactive later, about 20 to 30 days after exposure. A reactive rapid result is preliminary and must be confirmed with a standard laboratory test.
- **Self-test:** Health Canada approved the first home-based HIV self-test in Canada in 2020 (Health Canada, n.d.-a). As of September 2026, two self-test kits are approved: one uses a finger prick and the other an oral swab (PHAC, 2026a). A reactive self-test must be confirmed with a standard laboratory test (PHAC, 2020).

The **window period** is the time between infection and the point when a test can reliably detect it; a person can test negative but be highly infectious during it. PHAC (2020) states that it can last up to 12 weeks, so after a negative test within 12 weeks of a possible exposure, the nurse offers repeat testing.

In Ontario, people can choose standard (name-based) testing or anonymous testing, in which results are given using a code known only to the person and no name or Ontario Health Insurance Plan (OHIP) number is needed (Government of Ontario, 2025). Every province and territory requires positive HIV results, AIDS diagnoses or both to be reported to public health (PHAC, 2013). In Ontario, the laboratory reports a positive name-based test with the person's name and contact information, and a confirmed positive anonymous test without them. Public health units require that sexual and drug-use partners be told of a possible exposure, by the person, their health care provider or public health (Community Legal Education Ontario [CLEO], 2022). The nurse explains these rules before testing so that consent is informed.

Prevention Options

The nurse helps each person choose the options that fit their life (Table 21.3).

Condoms, external or internal, prevent HIV and also protect against other sexually transmitted infections and pregnancy, which antiretroviral prevention does not (PHAC, 2023b).

Pre-exposure prophylaxis (PrEP) is the use of antiretroviral medication by an HIV-negative person to prevent HIV. The 2025 Canadian guideline states that PrEP is appropriate for adults and adolescents who ask for it, and that clinicians should ask about HIV risk at routine visits and actively offer PrEP when they identify risk, even if the person has not raised it (Tan et al., 2025). Daily oral tenofovir disoproxil fumarate/emtricitabine is recommended for every HIV-negative person for whom PrEP is suitable and is available in Canada as generic products. For cisgender men and transgender women whose risk comes from sex with cisgender men, the same drug can also be taken "on demand", before and after sex; on-demand dosing is not recommended for cisgender women or people who inject drugs. For cisgender men and transgender women whose risk comes from sex, the guideline also lists daily oral emtricitabine/tenofovir alafenamide (an option that may be considered) and long-acting injectable cabotegravir, which Health Canada approved for PrEP in 2024 (Tan et al., 2025). Follow-up includes (Tan et al., 2025):

- HIV testing before the first dose and again at 30 days, then on a schedule that depends on the form of PrEP: every 3 months for daily tablets and every 2 months for the injection;
- kidney function (serum creatinine) at baseline and then every 3 to 12 months, depending on the drug and the person's kidney risk;
- screening for gonorrhea, chlamydia and syphilis at baseline and every 3 to 4 months;
- hepatitis B and hepatitis C testing at baseline, repeated yearly for people who remain susceptible, and pregnancy testing as appropriate.

Post-exposure prophylaxis (PEP) is a 28-day course of antiretroviral drugs taken after a possible exposure. It is an emergency: the Canadian guideline says to start it as soon as possible and no later than 72 hours after the exposure (Tan et al., 2025). The preferred regimens are bictegravir/emtricitabine/tenofovir alafenamide, or dolutegravir with tenofovir disoproxil fumarate/emtricitabine. Follow-up HIV testing is done 4 to 6 weeks after the exposure, with a final test at 12 weeks (Tan et al., 2025). PEP is not started after sex with a partner who has an undetectable viral load, because that exposure carries no risk of sexual transmission (Tan et al., 2025). After a work exposure, such as a needlestick, the nurse gives first aid, reports it at once under employer policy and is assessed urgently for PEP (Chapter 4).

Undetectable = untransmittable (U=U) describes the scientific consensus that HIV cannot be passed on through sex when someone living with HIV takes ART as prescribed and keeps a viral load below 200 copies/mL, measured every 4 to 6 months (PHAC, 2023b). PHAC (2023b) notes limits: U=U does not prevent other sexually transmitted infections or pregnancy; the evidence behind it comes from sexual transmission, so it does not apply to shared drug-use equipment or to transmission during pregnancy, breastfeeding or chestfeeding; it depends on continuing treatment and regular viral load tests; and suppression is not a cure. Talking about U=U helps reduce fear and shame.

Harm reduction prevents HIV among people who use drugs: new sterile needles, syringes and other equipment for every use, supervised consumption services and treatment for opioid use disorder (Chapter 11).

Table 21.3 HIV prevention options at a glance (Tan et al., 2025; PHAC, 2023b)

Option	Who it is for	Timing	Nursing points
Condoms (external or internal)	Anyone who has anal or vaginal sex	Every time, from start to finish of sex	Also protect against other sexually transmitted infections and pregnancy; teach correct use and offer free supplies
Pre-exposure prophylaxis (PrEP)	HIV-negative people who ask for it or are at increased risk through sex or drug use	Daily oral, on demand (selected groups only) or long-acting injection	Rule out HIV first; HIV test 30 days after starting, then every 2 to 3 months; check kidney function and screen for sexually transmitted infections
Post-exposure prophylaxis (PEP), non-occupational	A person with a possible exposure, such as condomless sex or a shared needle	Start as soon as possible, no later than 72 hours after exposure; take for 28 days	Treat as an emergency; refer to the emergency department or a sexual health clinic; HIV tests at 4 to 6 weeks and 12 weeks
Occupational exposure	A health care worker with a needlestick or a splash of blood or other body fluid	First aid and reporting at once; PEP assessment urgently	Follow employer policy and Chapter 4; occupational health arranges follow-up testing
Treatment as prevention (U=U)	People living with HIV and their partners	Viral load below 200 copies/mL, checked every 4 to 6 months	Prevents sexual transmission only; support adherence; condoms still protect against other infections
Harm reduction supplies	People who use drugs	New sterile equipment for every use	Offer supplies without judgment; link to supervised consumption and treatment (Chapter 11)

21.5 Living With HIV: Treatment and Nursing Care

A person who starts treatment early and keeps taking it can expect to stay well and will not pass HIV on through sex. In hospital, the main threats to that outcome are missed doses, drug interactions and stigma.

Antiretroviral Therapy

Antiretroviral therapy (ART) is a combination of drugs from different classes that stops HIV from multiplying. The adult antiretroviral guidelines of the United States Department of Health and Human Services (DHHS) recommend ART for everyone with HIV, to prevent illness and death and to prevent transmission, and advise starting it right away, or as soon as possible after diagnosis, on the day of diagnosis when possible (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2025). The goal is a viral load that stays below the level the laboratory test can detect.

Most regimens combine two or three drugs from these classes:

- **Nucleoside reverse transcriptase inhibitors (NRTIs):** the "backbone" of most regimens (for example, emtricitabine, lamivudine, tenofovir alafenamide and abacavir).
- **Non-nucleoside reverse transcriptase inhibitors (NNRTIs):** for example, rilpivirine.
- **Integrase strand transfer inhibitors (INSTIs):** the anchor of most first regimens (for example, bictegravir, dolutegravir and cabotegravir).
- **Protease inhibitors:** for example, darunavir, given with a "booster" (cobicistat or ritonavir) that slows the drug's breakdown.

Many people take a single tablet once a day. Examples marketed in Canada include bictegravir/emtricitabine/tenofovir alafenamide (Gilead Sciences Canada, 2025), dolutegravir/lamivudine (ViiV Healthcare ULC, 2025a) and dolutegravir/abacavir/lamivudine (ViiV Healthcare ULC, 2023). For people whose virus is already suppressed, long-acting cabotegravir and rilpivirine can replace daily pills with injections into the gluteal muscle, given by a health care professional monthly or every 2 months (ViiV Healthcare ULC, 2025b).

Adherence, Interactions and Resistance

HIV copies itself with many errors. When missed doses let drug levels fall, the virus multiplies again and copies that resist the drugs are selected, which can make a regimen fail and narrow future choices. Poor adherence, side effects and drug interactions that lower antiretroviral levels are leading causes of treatment failure (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2025). The nurse asks about missed doses without judgment and helps remove barriers: pill organizers, reminders, a regular pharmacist, peer navigators, and help with cost, housing, mental health or substance use.

Every new drug, supplement and over-the-counter product is checked with the pharmacist. Key interactions from Canadian product monographs:

- **Integrase inhibitors and polyvalent cations:** antacids and laxatives containing aluminum or magnesium, and calcium or iron supplements, reduce absorption. Bictegravir/emtricitabine/tenofovir alafenamide is taken at least 2 hours before or after these products, or together with food, but not at the same time on an empty stomach (Gilead Sciences Canada, 2025). Dolutegravir products are taken 2 hours before or 6 hours after cation-containing medicines; calcium or iron supplements may be taken at the same time only with food (ViiV Healthcare ULC, 2023, 2025a).
- **Boosted regimens:** cobicistat strongly inhibits CYP3A, the liver enzyme that clears many drugs, so regimens boosted with cobicistat must not be given with drugs that depend heavily on CYP3A for clearance (Janssen Inc., 2023b).
- **Rilpivirine and acid suppression:** proton pump inhibitors are contraindicated; H2-receptor antagonists must be given at least 12 hours before or 4 hours after rilpivirine, and antacids at least 2 hours before or 4 hours after; rilpivirine is taken with a meal (Janssen Inc., 2023a).
- **Rifampin:** this tuberculosis drug is contraindicated with bictegravir because it lowers bictegravir levels (Gilead Sciences Canada, 2025); Chapter 13 covers tuberculosis.

In hospital, the nurse never stops or interrupts ART without a prescriber's order and gives each dose on time. If a patient cannot take anything by mouth, the nurse contacts the prescriber and pharmacist before a dose is missed. Stopping a regimen that contains emtricitabine, lamivudine or tenofovir can cause a severe flare of hepatitis B in a person who also has hepatitis B (Gilead Sciences Canada, 2025).

Monitoring

The **viral load** (HIV RNA) is the amount of virus in the blood, and it shows whether treatment is working. The **CD4 count** shows the state of the immune system (section 21.1). After ART starts, the viral load is checked every 4 to 8 weeks until it is undetectable, then every 3 to 4 months, and in some stable, adherent people every 6 months. CD4 counts are repeated every 3 to 4 months in the first 1 to 2 years if the count is below 300 cells/µL; once the count is 300 cells/µL or more with a suppressed viral load, CD4 monitoring becomes optional unless there is a clinical reason (Panel on Antiretroviral Guidelines for Adults and Adolescents, n.d.). Kidney and liver function, lipids and glucose are also checked periodically.

GOING DEEPER

Viral Load, CD4 Count and Resistance Testing

Required for RN students; optional for PN students.

- **Undetectable:** a viral load below the lower limit of detection of the assay used, which varies by test. For example, the Canadian monograph for long-acting cabotegravir/rilpivirine describes suppression as HIV RNA below 50 copies/mL (ViiV Healthcare ULC, 2025b). For U=U, PHAC (2023b) uses a threshold of under 200 copies/mL, checked every 4 to 6 months.
- **Blip versus failure:** a viral blip is a single, isolated detectable result after suppression that returns to undetectable on the next test. Virologic failure is the inability to reach or keep a viral load below 200 copies/mL; virologic rebound is a confirmed result of 200 copies/mL or more after suppression (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2025).
- **Resistance testing:** a genotypic resistance test reads the virus's genes for mutations that reduce drug activity. Blood for this test is drawn at diagnosis, without delaying ART, and again at treatment failure, ideally while the person is still taking the failing regimen (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2025).
- **CD4 recovery lags:** viral suppression usually comes within weeks, but CD4 counts rise slowly, often about 50 to 150 cells/µL in the first year (Panel on Antiretroviral Guidelines for Adults and Adolescents, n.d.). Until the count recovers, prophylaxis against opportunistic infections may still be needed.

- **For the nurse:** a rising viral load is a cue to explore adherence, new interacting drugs and vomiting or diarrhea before assuming resistance.

MEDICATIONS

Antiretroviral Classes

- **NRTIs (nucleoside reverse transcriptase inhibitors):** block reverse transcriptase so viral RNA cannot be copied into DNA. Examples: emtricitabine, lamivudine, tenofovir alafenamide, tenofovir disoproxil fumarate, abacavir. Abacavir: the HLA-B*5701 gene is tested before starting; a hypersensitivity reaction (fever, rash, gastrointestinal or respiratory symptoms) means abacavir is never restarted (ViiV Healthcare ULC, 2023). Stopping emtricitabine, lamivudine or tenofovir can trigger a hepatitis B flare.
- **NNRTIs (non-nucleoside reverse transcriptase inhibitors):** bind reverse transcriptase directly. Example: rilpivirine. Taken with a meal; proton pump inhibitors are contraindicated (Janssen Inc., 2023a).
- **INSTIs (integrase strand transfer inhibitors):** stop viral DNA from entering the cell's DNA. Examples: bictegravir, dolutegravir, cabotegravir. Separate from antacids, laxatives, and calcium or iron products exactly as the monograph states (Gilead Sciences Canada, 2025; ViiV Healthcare ULC, 2025a).
- **Protease inhibitors with boosters:** stop viral proteins from being cut into working parts. Example: darunavir with cobicistat. The booster inhibits CYP3A, so many drug combinations are contraindicated (Janssen Inc., 2023b).
- **Long-acting injectables:** cabotegravir with rilpivirine, injected into the gluteal muscle by a health care professional monthly or every 2 months; observe the person for about 10 minutes afterward and keep every appointment (ViiV Healthcare ULC, 2025b).
- **Single-tablet regimens:** bictegravir/emtricitabine/tenofovir alafenamide; dolutegravir/lamivudine; dolutegravir/abacavir/lamivudine.

Opportunistic Infections

An **opportunistic infection** takes advantage of a weakened immune system. Most occur when the CD4 count is below 200 cells/µL, and ART is the best protection.

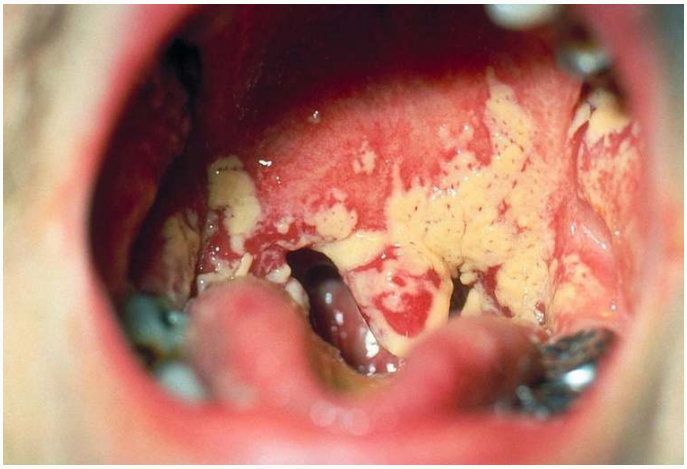

Figure 21.6 Oral candidiasis (thrush): creamy white patches on red, inflamed mucosa. Unlike food debris, the patches do not rinse away. (credit: Centers for Disease Control and Prevention, Public Health Image Library, public domain)

- **Pneumocystis pneumonia (PJP):** caused by the fungus *Pneumocystis jirovecii*. It begins gradually over days to weeks with worsening breathlessness, fever, a dry (non-productive) cough and chest discomfort. With exertion the person breathes fast and the heart rate climbs, and low blood oxygen is the most typical laboratory finding. Oxygen saturation often falls with exercise, although this finding is not specific to PJP. Diagnosis needs induced sputum or bronchoscopy; ordinary coughed-up sputum has low sensitivity and is not used (Panel on Opportunistic Infections in Adults and Adolescents With HIV, 2026).
- **Candidiasis:** a fungal infection. Oral thrush appears as white patches on the tongue, palate or inside the cheeks (Figure 21.6), and pain on swallowing may mean the infection has reached the esophagus; the nurse reports both.
- **Toxoplasmosis:** a parasite that can reactivate in the brain, mainly when the CD4 count is below 50 cells/µL, causing headache, new focal weakness, sometimes fever, and seizures; these are urgent neurologic cues (Panel on Opportunistic Infections in Adults and Adolescents With HIV, 2025b; Chapter 30).
- **Tuberculosis:** more likely and more serious in people living with HIV; Chapter 13 covers screening, airborne precautions and treatment.
- **Cytomegalovirus (CMV):** can infect the retina, typically when the CD4 count is below 50 cells/µL; new floaters, blind spots or changes in vision need urgent referral to an eye specialist (Panel on Opportunistic Infections in Adults and Adolescents With

HIV, 2025a).

- **Kaposi sarcoma:** a cancer linked to human herpesvirus 8 that causes flat or raised patches or nodules on the skin or in the mouth (Figure 21.7). The lesions are classically violet, but their colour varies with skin tone and they can be harder to see on darker skin, so the nurse inspects the whole skin and the mouth in good light.

Figure 21.7 Kaposi sarcoma on the skin of a person with advanced HIV: raised, red-purple patches and nodules. On darker skin the lesions may look brown or black. (credit: unknown author/Wikimedia Commons, public domain)

Prophylaxis prevents PJP. The DHHS opportunistic infection guideline (updated May 27, 2026) recommends trimethoprim-sulfamethoxazole for adults with a CD4 count below 200 cells/µL who are not on ART or are starting it. For people already on ART, prophylaxis is started if the CD4 count falls below 100 cells/µL, whatever the viral load, or falls to 100 to 200 cells/µL while the viral load keeps rising. Prophylaxis can be stopped once ART has raised the CD4 count to 200 cells/µL or more for at least 3 months (Panel on Opportunistic Infections in Adults and Adolescents With HIV, 2026). **Immune reconstitution inflammatory syndrome (IRIS)** is an inflammatory worsening of an infection's signs, usually in the first weeks to months after ART starts, as the recovering immune system reacts to organisms already present; CMV eye disease is one example (Panel on Opportunistic Infections in Adults and Adolescents With HIV, 2025a). The nurse reports any new fever or worsening symptoms after ART begins.

Care in Hospital and Aging With HIV

HIV calls for routine practices only (Chapter 4). No extra gloves, signs, separate dishes or private rooms are needed because of HIV; additional precautions are used only when another condition, such as suspected tuberculosis, calls for them. HIV status is personal health information, shared only with team members who need it and never in hallways or on whiteboards (Chapter 1). Language matters: the nurse says "person living with HIV" rather than "HIV-infected" or "AIDS victim", and documents facts, not judgments.

Because treatment works, many people living with HIV are now older adults. A Quebec study of 3,905 people on ART found that cardiovascular, bone and kidney conditions were more common in people living with HIV than in matched controls and appeared at younger ages, and that polypharmacy was more frequent (Baribeau et al., 2022). The nurse watches for fracture risk, falls and kidney changes, asks about memory and mood, and asks the pharmacist to review every new drug against the antiretroviral regimen. Chapter 8 covers care of older adults.

Stigma, Disclosure and the Law

People living with HIV still meet stigma in health care. A Quebec research team summarized studies from Western countries in which 45% to 83% of people living with HIV reported stigma from health care professionals, including inappropriate questions, unnecessary infection control measures, breaches of confidentiality and refused care; nurses were described as showing more stigmatizing behaviour than other professionals (Pelletier et al., 2022). Stigma leads people to avoid care, take medicines less consistently and test less often (Pelletier et al., 2022). The nurse examines their own assumptions, uses routine practices for everyone and speaks up when colleagues treat a patient differently.

Disclosure of HIV status is the person's own decision. The nurse does not tell family members, visitors or other patients without the person's consent. Notifying sexual or drug-use partners is handled through the public health process described in section 21.4.

Nurses give information about the criminal law, never legal advice. In *R v Mabior* (2012), the Supreme Court of Canada held that a person living with HIV must disclose their status before sex when there is a "realistic possibility of transmission"; the Court found that a low viral load combined with condom use negates that possibility (Department of Justice Canada, 2022). A federal directive

that took effect on December 8, 2018, tells federal prosecutors, who handle these cases in the three territories, not to prosecute when the person has maintained a suppressed viral load (below 200 copies/mL), and generally not to prosecute when condoms were used, only oral sex took place or the person was taking treatment as prescribed (Department of Justice Canada, 2018). Provinces prosecute within their own borders, and Ontario, British Columbia and Quebec have issued their own prosecutorial guidance (Department of Justice Canada, 2022). The federal government consulted on possible reform in 2022, so nurses check current sources before giving patients information about the law.

21.6 Autoimmunity and Adult Immunization

The immune system must attack invaders while leaving the body's own tissues alone. This section introduces what happens when that balance fails and then turns to immunization, one of the most effective ways nurses protect adults.

Autoimmunity

Autoimmunity is an immune response directed against the body's own tissues. Normally, T and B cells that react strongly to self are removed or silenced as they mature, and regulatory T cells hold back those that escape. This is called self-tolerance. In autoimmune disease, tolerance breaks down, and autoantibodies or self-reactive T cells damage tissue. Most autoimmune diseases appear to arise from inherited susceptibility combined with triggers such as infections, certain drugs or other environmental exposures.

Autoimmune disease is common, and it is more common in women. In a United Kingdom study of about 22 million people, 19 common autoimmune disorders together affected 10.2% of people at some point during the study: 13.1% of women and 7.4% of men (Conrad et al., 2023). The same study found that having one autoimmune disease made having another more likely. Examples covered elsewhere in this book include:

- type 1 diabetes (Chapter 22);
- Hashimoto thyroiditis and Graves disease (Chapter 23);
- celiac disease and inflammatory bowel disease (Chapter 25);
- multiple sclerosis (Chapter 32);
- rheumatoid arthritis and systemic lupus erythematosus (Chapter 34);
- immune thrombocytopenia (section 20.4).

Treatment often relies on drugs that suppress the immune system, such as corticosteroids, disease-modifying drugs and biologic agents. A person taking them is immunocompromised, so the care in section 21.3 applies: atypical signs of infection, early reporting of fever, and caution with live vaccines. Vaccines are ideally brought up to date before immunosuppression starts (section 21.3).

Adult Vaccines

Immunization is not only for children. The CIG asks clinicians to counsel every adult about their immunization status and to review immunization records during routine encounters (PHAC, 2026d). Its main recommendations for adults, other than respiratory vaccines (Chapter 13), are summarized here and in Table 21.4 (PHAC, 2026d):

- **Tetanus and diphtheria:** a booster every 10 years, plus one dose of tetanus-diphtheria-acellular pertussis vaccine (Tdap) for adults who have not had Tdap as adults. Tdap is given in every pregnancy, ideally at 27 to 32 weeks (Chapter 29).
- **Measles, mumps and rubella (MMR):** for adults born in 1970 or later who are susceptible. Adults born before 1970 are generally presumed immune, but some, such as health care workers, students, travellers and military personnel, may still need vaccine.
- **Varicella:** for susceptible adults aged 18 to 49 years.
- **Herpes zoster (shingles):** two doses of recombinant zoster vaccine for adults aged 50 years and older, and for adults aged 18 and older who are or will be immunocompromised.
- **Human papillomavirus (HPV):** for people up to and including age 26; older adults at ongoing risk may receive it after shared decision-making.

- **Hepatitis B:** for adults at increased risk, including people with chronic liver or kidney disease, people who inject drugs, men who have sex with men, people with more than one sexual partner in the past 6 months, people living with HIV, and workers exposed to blood (PHAC, 2026b).
- **Hepatitis A:** an inactivated vaccine for adults at increased risk, such as travellers to countries where hepatitis A is common, people with chronic liver disease, people who use drugs in a problematic way and men who have sex with men (PHAC, 2023a).

Vaccines are either live or non-live. A **live attenuated vaccine** contains a weakened virus or bacterium that can still replicate, such as MMR and varicella vaccines; these are generally avoided in pregnancy and in people with significant immunosuppression (section 21.3). An **inactivated vaccine** cannot replicate. Non-live products include toxoid, subunit and recombinant vaccines such as Td, Tdap, HPV, hepatitis A and B vaccines and recombinant zoster vaccine (Krishnan et al., 2026; PHAC, 2023a, 2026b).

Ontario is the worked example. Its schedule funds Tdap once in adulthood and in every pregnancy, Td every 10 years, and a 2-dose shingles series between ages 65 and 70 (Government of Ontario, 2026), completed before the 71st birthday; HPV vaccine for males up to age 26 who have sex with men; and hepatitis A and B vaccines for listed high-risk groups (North Bay Parry Sound District Health Unit, 2025; Ontario Ministry of Health, 2022). Eligibility changes often, so the nurse checks the current provincial schedule.

Table 21.4 Adult vaccines at a glance; Ontario funding is shown as of each source's date (2022 to 2026), and eligibility changes often, so check the current Canadian Immunization Guide and provincial schedule (PHAC, 2023a, 2026b, 2026d; Government of Ontario, 2026; Ontario Ministry of Health, 2022; North Bay Parry Sound District Health Unit, 2025)

Vaccine	Live or inactivated	Adults who should receive it (summary)	Ontario publicly funded? (as of the source date)
Td and Tdap	Inactivated (toxoid)	All adults: Td every 10 years; one adult Tdap dose; Tdap in every pregnancy	Yes: one adult Tdap, Td every 10 years, Tdap in every pregnancy (2026)
MMR	Live	Susceptible adults born in 1970 or later; higher-risk groups such as health care workers and travellers	Yes: eligible from age 1 year; a second adult dose for groups such as health care workers, post-secondary students and travellers (2022)
Varicella	Live	Susceptible adults aged 18 to 49	Limited: adults born before 2000 only through high-risk criteria (2022)
Recombinant zoster	Non-live (recombinant)	Adults 50 and older; adults 18 and older who are or will be immunocompromised	Yes, ages 65 to 70 (2026)
HPV	Non-live (recombinant)	People up to and including 26; older adults at ongoing risk after shared decision-making	Adults only for high-risk males up to age 26 who have sex with men (2025)
Hepatitis B	Non-live (recombinant)	Adults with a higher risk of exposure or of complications	Yes, for listed high-risk groups (2022)
Hepatitis A	Inactivated	Adults at increased risk, such as people with chronic liver disease	Yes, for listed high-risk groups (2022)

Giving Vaccines Safely

Before every vaccine, the nurse screens for contraindications and precautions. The CIG checklist asks whether the vaccine is due, whether the person has had a serious reaction to a vaccine or is allergic to any component (including latex), and whether they are or may be pregnant. For live vaccines it also asks about immunosuppression, other live vaccines in the past 4 weeks and blood products in the past year (PHAC, 2026g). Informed consent follows Chapter 1, section 1.5.

Vaccines must stay within the **cold chain**, the system that keeps them at the right temperature from manufacturer to patient. Refrigerated vaccines are stored between +2 °C and +8 °C in their original packaging. If the temperature goes out of range, the nurse labels the vaccines "do not use", keeps them refrigerated and calls public health or the supplier for advice (PHAC, 2026f).

For most adults, the deltoid is the preferred intramuscular site. The CIG bases needle length on body weight and sex, with 2.5 cm (1 inch) suitable for many adults, 1.6 to 2.5 cm (5/8 to 1 inch) for those under 60 kg and 3.8 cm (1.5 inch) for larger adults. The needle enters at 90 degrees, and aspiration is not recommended (PHAC, 2026g). The person stays under observation for at least 15 minutes,

or 30 minutes when there is a specific concern about a reaction (PHAC, 2026g). The nurse is ready to manage anaphylaxis (Chapter 6, section 6.5). Each vaccine is recorded in the patient's record and, where one exists, the provincial registry.

An **adverse event following immunization (AEFI)** is any unwanted or unexpected health effect that follows a vaccine, whether or not the vaccine caused it. In Ontario, health professionals must report AEFIs to the local public health unit, using the provincial AEFI reporting form (Public Health Ontario, 2026). People who have a reaction can contact their health care provider or public health unit.

Talking About Vaccines

Vaccine hesitancy is a delay in or refusal of vaccination because of concerns about vaccines (PHAC, 2025a). The CIG advises providers to find out where a person's concern comes from and to listen in a calm, non-judgmental way. The nurse asks why the person holds a particular belief and answers in plain words, without jargon. Some people want data and others want stories from experience, so the nurse adapts. Motivational interviewing, a guiding style that helps people find their own reasons for change, can help. The person stays part of the decision, and patience and openness build trust; some people will still decline, and the conversation can continue at the next visit (PHAC, 2025a). Mistrust may be rooted in past harms in health care, especially for Indigenous and Black communities, so the nurse practises cultural safety (Chapter 2).

SCOPE IN PRACTICE

Who Gives Vaccines, and on Whose Authority

CNO's Scope of Practice standard asks every nurse to have the **authority**, the **competence** and a supportive **context** for each activity (Chapter 1, section 1.3).

- **Authority:** in Ontario, giving a vaccine by injection is the controlled act of administering a substance by injection. RNs and RPNs may carry it out when an authorized health care professional has given an order (College of Nurses of Ontario [CNO], 2025, n.d.-a). The order may be a direct order or a directive: an order from a physician or nurse practitioner that a nurse may carry out for a number of patients when specific conditions are met, with employer policy naming who may implement it (CNO, 2025). RNs who are authorized to prescribe may prescribe "any vaccines for prevention of bacterial and viral disease," which is one category on CNO's RN prescribing list (CNO, n.d.-b). RN prescribing is not an entry-level competency, requires additional education, and does not apply in public hospitals.
- **Competence:** the nurse needs current knowledge of the vaccine, screening, technique, cold chain handling, and recognition and emergency treatment of anaphylaxis (Chapter 6). CNO asks whether the nurse has the knowledge, skill and judgment to carry out the activity and manage any adverse outcome (CNO, n.d.-a).
- **Context:** employer policy may limit which nurses immunize and in which settings. An anaphylaxis kit with epinephrine must be at hand, and someone must be available to help in an emergency.
- **Working together:** an RPN who finds a contraindication, an unclear history or a reaction consults the RN or the prescriber before going ahead.
- **Elsewhere in Canada:** rules for nurse-led immunization vary by province and territory, so nurses check their own regulator's standards and employer policy.

PRACTICE STORY

The Sign on the Door

Names and details are fictional; this is a composite story.

Nurse: Amira Mansour, RPN. Years in practice: 4. Setting: medical unit, Ontario.

I came on shift and saw a sheet of paper taped to the door of room 12. Someone had written "Blood and body fluid precautions – HIV" in marker. Inside was Mr. Gauthier, a 58-year-old retired bus driver admitted with pneumonia. His chart showed he had lived with HIV for 20 years and his viral load was undetectable.

Ten minutes later I watched my colleague Kevin put on two pairs of gloves to carry in a breakfast tray. He set it down at the end of the bed and left quickly. Mr. Gauthier looked at the tray, then at the door, and said nothing.

I went to our charge nurse, Lisa, an RN, and told her what I had seen. She came with me, and we took the sign down together. She checked the chart: there was no order for additional precautions, and his chest x-ray and history did not suggest tuberculosis. Routine practices were all he needed, the same as every other patient on the unit. Lisa said she would find out who had posted the sign and remind the whole team at huddle that a diagnosis never goes on a door.

> Later I asked Kevin if we could talk in the medication room. I didn't want to embarrass him. He told me he had heard that "you can't be too careful" with HIV. I explained that gloves are for contact with blood or body fluids, not for meal trays, and that a person with an undetectable viral load does not transmit HIV through sex. He was quiet, then said he hadn't thought about how it looked from the bed.
>
> When I brought Mr. Gauthier his pills, I apologized for the sign. He said, "That's the third hospital that's done that." I thought about how many people stay home rather than face that, and about how a piece of paper had told every visitor and cleaner something that belonged only to him.
>
> Reflect: How did the sign breach Mr. Gauthier's privacy, and what would you document? If the sign reappeared or a colleague refused care, when would you involve the RN, the charge nurse or the manager, and why?

Chapter 21 Summary

Introduction

- Allergy labels, immunocompromised patients, people living with HIV and adult vaccines are part of everyday nursing on adult units.
- An allergy entry that is wrong or vague can harm a patient as much as one that is missing.

21.1 The Immune System: A Focused Review

- Innate immunity (barriers, phagocytes, complement) acts fast and has no memory; adaptive immunity (B cells, antibodies, CD4 and CD8 T cells) is specific and builds memory.
- The five antibody classes have different roles; IgE drives type I allergy and IgG crosses the placenta.
- Vaccines give active immunity with memory; immune globulin gives passive, temporary protection.
- Common immune tests include the white cell differential, immunoglobulin levels, CD4 count, HIV viral load and allergy tests; read results against the patient's own laboratory ranges.
- Immunosenescence raises the risk of infections such as shingles, blunts fever and weakens some vaccine responses; NACI recommends recombinant zoster vaccine from age 50.

21.2 Hypersensitivity and Allergy

- Hypersensitivity has four types: I (IgE, immediate), II (antibody against cells), III (immune complexes) and IV (delayed, T cell-mediated).
- An accurate allergy history separates allergy from intolerance and side effects and records the drug, reaction, timing, severity, treatment and date.
- Most penicillin labels are inaccurate, and false labels are linked to resistant infections and C. difficile; delabelling is a prescriber or allergist decision supported by the nurse's history and teaching.
- ACE inhibitor angioedema can appear after years on the drug, usually without hives, and airway swelling is an emergency.
- SJS/TEN and DRESS are delayed, life-threatening drug reactions; on darker skin they may look dusky, violet or darker rather than red; the nurse reports at once and holds the next dose per policy.
- Anaphylaxis prevention includes checking allergies before every drug and meal, allergist referral, two autoinjectors, medical identification and an action plan.

21.3 Immunodeficiency and the Immunocompromised Patient

- Primary immunodeficiencies are rare and inherited, though many antibody deficiencies, such as CVID, are diagnosed in adults; secondary causes include drugs, HIV, chronic disease, malnutrition and aging.
- Infection may cause little or no fever in immunocompromised adults; subtle changes are escalated early.
- TB and hepatitis B screening precede TNF inhibitor therapy, and doses are not given during active infection without the prescriber's review.

- The Canadian Immunization Guide advises vaccinating before immunosuppression, avoiding live vaccines in severe immunosuppression and vaccinating close contacts.

21.4 HIV: Infection, Testing and Prevention

- HIV is a retrovirus that destroys CD4 T helper cells; untreated, it moves from acute infection through chronic infection to advanced HIV disease (AIDS).
- HIV spreads through blood, semen, vaginal and rectal fluids and human milk, not through casual contact.
- In 2022, about 65,270 people in Canada were living with HIV and about 1 in 10 were undiagnosed; first-diagnosis rates in 2024 were highest in Manitoba and Saskatchewan, and the patterns reflect stigma, racism, colonialism, criminalization and unequal access to care.
- Nurses offer HIV testing routinely with verbal consent, explain the window period (up to 12 weeks) and, in Ontario, the options of nominal or anonymous testing and public health reporting.
- Prevention combines condoms, PrEP, PEP (started within 72 hours and taken for 28 days), U=U and harm reduction.

21.5 Living With HIV: Treatment and Nursing Care

- ART is recommended for everyone with HIV, started as soon as possible after diagnosis, with the goal of an undetectable viral load.
- Missed doses and drug interactions lead to resistance; in hospital, ART is never interrupted without a prescriber's order, and every new drug is checked with the pharmacist.
- Viral load shows whether treatment works; the CD4 count shows immune status and recovers slowly.
- Pneumocystis pneumonia, candidiasis, toxoplasmosis, tuberculosis, cytomegalovirus and Kaposi sarcoma are key opportunistic illnesses; trimethoprim-sulfamethoxazole prophylaxis starts below a CD4 count of 200 cells/µL in people not yet on ART or starting it.
- HIV needs routine practices only; nurses protect privacy, counter stigma, leave disclosure to the person, and know the criminal law only in outline.

21.6 Autoimmunity and Adult Immunization

- Autoimmunity results from a breakdown of self-tolerance; it is common and more common in women, and its treatment often makes people immunocompromised.
- The Canadian Immunization Guide recommends adult Td boosters, one adult Tdap dose, MMR and varicella for susceptible adults, recombinant zoster vaccine from age 50, HPV and hepatitis vaccines for eligible adults; Ontario funds some of these.
- Safe immunization includes screening, consent, cold chain storage at +2 °C to +8 °C, correct technique, at least 15 minutes of observation, documentation and AEFI reporting to the local public health unit in Ontario.
- Nurses address vaccine hesitancy by listening, clarifying concerns and respecting the person's decision.

Key Terms (40)

acquired immunodeficiency syndrome (AIDS) / advanced HIV disease: the most advanced stage of HIV infection, defined for surveillance as a CD4 count below 200 cells/µL, a CD4 percentage below 14%, or an AIDS-defining opportunistic illness.

acute HIV infection: the first weeks after HIV enters the body, when the viral load is very high, the person is highly infectious and a flu-like illness may occur.

adaptive immunity: the slower, antigen-specific part of the immune system, carried out by B cells and T cells, that develops memory after exposure.

adverse event following immunization (AEFI): any unwanted or unexpected health effect that follows a vaccine, whether or not the vaccine caused it.

allergy: a hypersensitivity reaction to a substance that is harmless to most people, such as a food, pollen or drug.

anaphylaxis: a severe, potentially life-threatening allergic reaction involving more than one body system; its recognition and emergency treatment are taught in Chapter 6.

angioedema: swelling of the deeper layers of the skin or of the lining of the mouth, throat or gut, caused by histamine or by bradykinin.

antibody: a protein (immunoglobulin) made by plasma cells that binds one specific antigen.

antigen: any molecule that the immune system can recognize as a target and respond to.

antiretroviral therapy (ART): a combination of drugs from different classes that stops HIV from multiplying.

autoimmunity: an immune response against the body's own tissues that results from a breakdown of self-tolerance.

CD4 T cell: a helper T cell that directs the immune response by releasing cytokines; the cell HIV infects and depletes.

cold chain: the system that keeps vaccines at the correct temperature, usually +2 °C to +8 °C, from manufacturer to patient.

delabelling: removing an inaccurate allergy label after the history is reviewed and, when needed, testing or a supervised challenge is done.

DRESS: drug reaction with eosinophilia and systemic symptoms; a delayed, severe drug reaction with rash, fever, swollen lymph nodes, facial swelling, eosinophilia and organ involvement, usually 2 to 6 weeks after a drug is started.

drug intolerance: an unwanted, non-immune effect of a drug that occurs at a low or below-therapeutic dose.

HIV non-disclosure: not telling a sexual partner about one's HIV status; a criminal matter in Canada only when there is a realistic possibility of transmission.

human immunodeficiency virus (HIV): a retrovirus that infects CD4 T helper cells and, without treatment, gradually destroys the immune system.

hypersensitivity: an excessive or misdirected immune response that damages the body's own tissues; grouped into types I to IV.

IgE: the antibody class that binds mast cells and basophils and drives type I allergic reactions.

immune reconstitution inflammatory syndrome (IRIS): an inflammatory worsening of an infection's signs, usually in the first weeks to months after ART starts, caused by the recovering immune system reacting to organisms already present.

immunocompromised: having immune defences weakened by a disease or its treatment.

immunodeficiency: a state in which the immune system cannot defend the body adequately; primary when built into the immune system, secondary when acquired.

immunosenescence: the natural, gradual decline in immune function that comes with age.

inactivated vaccine: a vaccine containing an organism or its parts that cannot replicate; non-live vaccines also include toxoid, subunit and recombinant vaccines.

innate immunity: the inborn, rapid first line of defence, including barriers, phagocytes and complement, which responds the same way each time and has no memory.

Kaposi sarcoma: a cancer linked to human herpesvirus 8 that causes patches or nodules on the skin or in the mouth; classically violet, with colour that varies by skin tone.

latex allergy: an allergic reaction to natural rubber latex, either delayed (type IV contact dermatitis) or immediate (type I, including anaphylaxis).

live attenuated vaccine: a vaccine containing a weakened organism that can still replicate, such as MMR or varicella vaccine.

live vaccine: a vaccine containing a weakened form of a living microbe; generally avoided in people who are severely immunocompromised.

opportunistic infection: an infection that takes advantage of a weakened immune system.

Pneumocystis pneumonia (PJP): a fungal lung infection that causes gradually worsening breathlessness, fever, dry cough and hypoxemia in people with low CD4 counts.

post-exposure prophylaxis (PEP): a 28-day course of antiretroviral drugs started as soon as possible, and within 72 hours, after a possible exposure to HIV.

pre-exposure prophylaxis (PrEP): antiretroviral medication taken by an HIV-negative person before possible exposure to prevent HIV.

Stevens-Johnson syndrome: a severe, usually drug-induced reaction in which the epidermis dies and separates over less than 10% of the body surface, with mucosal ulcers.

toxic epidermal necrolysis: the most extensive form of the same reaction as Stevens-Johnson syndrome, with detachment of more than 30% of the body surface.

undetectable = untransmittable (U=U): the scientific consensus that a person living with HIV who takes treatment and keeps a viral load below 200 copies/mL does not transmit HIV through sex.

vaccine hesitancy: a delay in or refusal of vaccination because of concerns about vaccines.

viral load: the amount of HIV RNA in the blood, used to judge whether antiretroviral therapy is working.

window period: the time between HIV infection and the point when a test can reliably detect it; up to 12 weeks.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Thomas Leblanc (Questions 1–4): Mr. Thomas Leblanc, 58, is admitted to a medical unit with pneumonia. His electronic record lists "penicillin allergy." When the nurse asks about it, he says that at age 16 he had loose stools for two days while taking amoxicillin for an ear infection, and that he has "avoided penicillin ever since." He is treated with a non-penicillin antibiotic and improves. On day 4, he mentions that his family physician started him on a new anticonvulsant 4 weeks ago for nerve pain in his face. That evening his temperature is 38.9 °C, his face and ears are swollen, a widespread rash covers his trunk and arms, and the nurse feels enlarged lymph nodes in his neck. Results from the afternoon show an eosinophil count of 1.6 × 10^9/L and a rise in his liver enzymes.

1. [CORE] Based on Mr. Leblanc's description of what happened when he took amoxicillin, how should the nurse interpret his penicillin label?

a. The reaction suggests a type I allergy, because diarrhea is a common early feature of IgE-mediated drug reactions in teenagers and young adults

b. The reaction he describes is a common side effect, and the label may be inaccurate and worth reviewing with the prescriber

c. The label must be confirmed as a true allergy because any reaction to an antibiotic is recorded as an allergy for life

d. The reaction proves he has a delayed type IV allergy to all beta-lactam antibiotics, including cephalosporins

Answer: b — Diarrhea and other stomach upset with an antibiotic are common side effects, not allergic reactions, so the label may be wrong and can be reviewed for delabelling (b) (section 21.2, Taking and Documenting an Allergy History; Penicillin Allergy Labels). Diarrhea alone is not a feature of a type I reaction (a). Not every reaction is an allergy; recording side effects as allergies causes harm (c). Nothing in his history suggests a type IV reaction, and the history does not justify avoiding a whole drug group (d).

2. [CORE] Which entry should the nurse make in Mr. Leblanc's record about his amoxicillin history?

a. "Penicillin allergy, patient avoids all penicillins; reaction unknown; do not give any antibiotic in this family"

b. "PCN intolerance; mild; please clarify with family physician at discharge and update record when possible"

c. "No known drug allergies; patient's reported penicillin reaction was diarrhea and is therefore not significant"

d. "Amoxicillin, age 16: loose stools for 2 days; no rash, swelling or breathing problems; no treatment"

Answer: d — A useful entry names the drug, describes the reaction, gives its timing and severity, and states what treatment was needed, without abbreviations (d) (section 21.2, Clinical Safety box). Entry (a) keeps a vague label and adds an instruction the history does not support. Entry (b) uses an abbreviation and gives no detail. Entry (c) removes the label on the nurse's own authority; any change to an allergy entry follows the employer's process with the prescriber and patient.

3. [CORE] Which finding in Mr. Leblanc's evening assessment most strongly suggests a severe drug reaction rather than a simple rash?

a. Fever, facial swelling, enlarged lymph nodes, a high eosinophil count and rising liver enzymes 4 weeks after a new drug

b. A rash on the trunk and arms that appeared in the evening, after he had been in bed for most of the afternoon

c. A history of loose stools with amoxicillin as a teenager, which suggests that he reacts to many types of medication

d. Improvement of his pneumonia on a non-penicillin antibiotic, which suggests that his immune system is overactive

Answer: a — A widespread rash with fever, facial swelling, swollen lymph nodes, eosinophilia and liver involvement 2 to 6 weeks after starting a drug fits drug reaction with eosinophilia and systemic symptoms (DRESS), and anticonvulsants are common causes (a) (section 21.2, Severe Cutaneous Adverse Reactions). The timing of the rash in the day (b) is not a warning sign. His amoxicillin history was a side effect and does not predict other reactions (c). Recovery from pneumonia (d) is expected and is not a sign of hypersensitivity.

4. [CORE] What is the nurse's priority action for Mr. Leblanc this evening?

a. Give an oral antihistamine from the as-needed orders and reassess the rash at the next scheduled vital signs

b. Apply a cool compress to the face, document the rash, and report it to the day team at morning handover

c. Report to the prescriber now, hold the next anticonvulsant dose per policy, and escalate if needed

d. Remove the anticonvulsant from his medication list and tell him he must never take it again

Answer: c — A suspected severe drug reaction is reported immediately, the next dose is held according to employer policy pending the prescriber's assessment, and the nurse escalates if the prescriber cannot be reached (c) (section 21.2, Severe Cutaneous Adverse Reactions). An antihistamine (a) does not treat DRESS and delays assessment. Waiting until morning (b) risks organ damage. Stopping a drug permanently and changing the medication list is a prescriber's decision (d); the nurse documents the reaction and reports it.

5. [CORE] A patient asks why a vaccine protects for years but an injection of immune globulin protects only for a while. Which response by the nurse is accurate?

a. "Immune globulin contains live microbes that the body slowly clears, so its effect fades once they are gone."

b. "A vaccine gives you antibodies that were made by other people, and these last much longer than the antibodies your own body makes."

c. "A vaccine trains your own immune system to form memory cells; immune globulin gives borrowed antibodies that wear off."

d. "Immune globulin works only on the innate immune system, which has no memory, so it must be repeated often."

Answer: c — Vaccines create active immunity: the person's own B and T cells respond and leave memory cells. Immune globulin gives passive immunity: ready-made antibodies that act at once but are temporary because no memory cells form (c) (section 21.1). Immune globulin contains antibodies, not microbes (a). Option (b) describes passive immunity, not vaccination. Antibodies are part of adaptive immunity, and the reason for repeat doses is the lack of memory cells, not an effect on innate immunity (d).

6. [CORE] Which antibody class is responsible for type I allergic reactions?

a. IgE

b. IgA

c. IgM

d. IgG

Answer: a — IgE binds to mast cells and basophils and drives type I reactions (a) (section 21.1). IgA protects mucous membranes (b). IgM is the first antibody made in a new response (c). IgG is the main antibody in a repeat response and the only class that crosses the placenta (d).

7. [CORE] An 82-year-old resident of a long-term care home is admitted with new confusion. Her temperature is 37.4 °C. Her daughter says, "She can't have an infection; she doesn't have a fever." Which response by the nurse is best?

a. "You are right that infection is unlikely without a fever, so the team will look first for a medication, stroke or other cause."

b. "A temperature of 37.4 °C is a fever in anyone over 80, so she clearly has an infection."

c. "Confusion in older adults is part of normal aging and does not usually need investigation."

d. "Older adults often have a weaker fever response, so infection can show up first as confusion; we will look for it."

Answer: d — Immunosenescence can blunt fever, and infection in older adults often presents atypically, for example as new confusion, so infection must still be considered (d) (section 21.1, The Aging Immune System). Ruling out infection because of a normal temperature (a) is unsafe. The nurse should not label a single temperature as proof of infection (b). New confusion is never normal aging and needs assessment (c) (Chapter 8).

8. [CORE] Which statement about penicillin allergy labels is accurate?

a. Most people with a penicillin label are truly allergic, so testing is rarely worthwhile in hospital

b. Most people with a penicillin label tolerate penicillin when evaluated, and false labels are linked to harm

c. A penicillin label has no effect on care, because many other antibiotics work equally well for all infections

d. A penicillin label can be removed by the nurse once the patient says the reaction was mild

Answer: b — More than 80% of people reporting penicillin allergy have negative skin tests and about 90% of adult inpatients tolerate penicillin after evaluation; false labels are linked to less effective antibiotics, resistant organisms and C. difficile (b) (section 21.2, Penicillin Allergy Labels). Option (a) is the reverse of the evidence. Alternative antibiotics are not equivalent and add risk (c). Removing a label is a prescriber or allergist decision made through the employer's process (d).

9. [CORE] A patient who has taken an angiotensin-converting enzyme (ACE) inhibitor for 6 years reports that her lower lip and tongue have been swelling over the last hour. She has no hives or itch. What should the nurse conclude?

a. ACE inhibitor angioedema is possible even after years on the drug, and tongue swelling is an airway emergency

b. The swelling cannot be related to her ACE inhibitor, because drug angioedema occurs only in the first week

c. Without hives, the swelling is not an allergic or drug reaction, so it can be reassessed at the next round

d. The swelling is most likely a type IV contact reaction to toothpaste and will settle without treatment

Answer: a — Up to one-third of ACE inhibitor angioedema cases appear months to years after starting the drug, hives are typically absent in bradykinin-mediated angioedema, and tongue swelling can progress to airway obstruction, so the nurse stays with the patient and calls for help at once (a) (section 21.2, Angioedema). Option (b) ignores late cases. The absence of hives does not make swelling harmless (c). A contact reaction is delayed and does not cause tongue swelling over an hour (d).

10. [CORE] Which patient has the highest risk of latex allergy?

a. A 45-year-old office worker with seasonal allergic rhinitis and no surgical history

b. A 30-year-old with a peanut allergy who has never worn gloves at work

c. A 52-year-old operating room nurse with an allergy to avocado and kiwi

d. A 70-year-old who had cataract surgery once and reacts to adhesive tape

Answer: c — Health care workers and people allergic to foods such as banana, avocado, kiwi, passion fruit and chestnut have a higher risk of latex allergy (c) (section 21.2, Latex Allergy). Seasonal rhinitis (a) and peanut allergy (b) are not among the risk factors described in this section, and neither person has a higher-risk occupation. One surgery is not "many surgeries," and a reaction to tape adhesive is not a latex allergy (d).

11. [CORE] On day 12 of a sulfonamide antibiotic, a patient with deeply pigmented skin reports a sore mouth and gritty eyes. The nurse sees no obvious redness of the skin. What should the nurse do next?

a. Reassure the patient that a serious drug reaction is unlikely because the skin shows no redness or swelling

b. Ask the patient to rinse with salt water and recheck the mouth at the end of the shift

c. Document the findings and wait until the course is finished before reporting them

d. Look closely in good light for dusky or darker patches, blisters or ulcers, and report promptly

Answer: d — On darker skin, early SJS/TEN lesions may look darker and less distinct than red, and mouth or eye involvement may be the first clear sign, so the nurse inspects carefully and reports promptly (d) (section 21.2, Severe Cutaneous Adverse Reactions). Absence of redness does not rule out a reaction (a). Delays (b, c) allow a life-threatening reaction to progress.

12. [CORE] An RPN on a medical unit notices that a patient started on carbamazepine 10 days ago now has a fever of 38.8 °C and new blisters on the chest. The patient's next dose is due. Which action is appropriate?

a. Give the dose, because only the physician can decide to stop a drug, and report the findings afterward

b. Hold the dose according to employer policy, notify the RN and prescriber immediately, and document

c. Give half the dose to reduce the risk of reaction while waiting to hear from the prescriber

d. Discontinue the order in the electronic record and add carbamazepine to the allergy list

Answer: b — Fever with blistering after a new high-risk drug suggests SJS/TEN. Every nurse who notices a possible severe reaction acts at once: the RPN holds the dose under employer policy, reports to the RN and prescriber, and documents (b) (section 21.2, Severe Cutaneous Adverse Reactions; Chapter 1, section 1.3). Giving the dose (a) could worsen the reaction. Changing the dose (c) is not within the nurse's authority. Discontinuing an order (d) is the prescriber's decision, although the nurse documents the reaction.

13. [CORE] A patient with a history of anaphylaxis to bee stings is being discharged with an epinephrine autoinjector. Which actions should the nurse include in teaching? Select all that apply.

a. Carry two autoinjectors at all times and wear medical identification

b. Inject into the outer thigh, through clothing if necessary

c. Take an antihistamine first and use the autoinjector only if symptoms worsen

d. Call 9-1-1 after using the autoinjector, even if symptoms improve

e. Store the autoinjector in the refrigerator to protect the medicine

f. Check that the liquid is clear and replace the device before its expiry date

Answer: a, b, d, f — The EpiPen monograph advises carrying two devices and wearing medical identification (a), injecting into the outer thigh, through clothing if needed (b), and checking the liquid and expiry date (f). Patients call 9-1-1 and go to hospital after use, even if they feel better (d) (section 21.2, Patient Education box). Epinephrine is used first at the first sign of a reaction; an antihistamine must never delay it (c). The device is kept at room temperature and must not be refrigerated (e).

14. [CORE] A 34-year-old has had four sinus infections and two pneumonias in the past 18 months, each treated with antibiotics. Which test would the nurse expect the prescriber to order to look for an antibody deficiency?

a. Serum immunoglobulin levels (IgG, IgA and IgM)

b. Serum tryptase drawn within 2 hours of symptoms

c. Skin prick testing to common airborne allergens

d. Patch testing for contact allergens on the back

Answer: a — Repeated sinus and lung infections are warning signs of an antibody deficiency such as common variable immunodeficiency, and serum immunoglobulin levels are measured (a) (sections 21.1 and 21.3). Tryptase helps confirm mast cell activation in suspected anaphylaxis (b). Skin prick testing looks for IgE-mediated allergy (c). Patch testing looks for type IV contact allergy (d).

15. [CORE] A patient receiving a TNF inhibitor every 2 weeks arrives for the next dose. Which finding should the nurse report to the prescriber before giving it?

a. Mild redness at the previous injection site that faded within 2 days

b. A blood pressure of 128/78 mm Hg, unchanged from the last visit

c. A new cough with a temperature of 37.9 °C that began 3 days ago

d. Fatigue after a long work week that has improved with rest

Answer: c — TNF inhibitors raise the risk of serious infections, including TB, and should not be given during an active infection, so a new cough with a raised temperature must be reported before the dose (c) (section 21.3, Recognizing Infection When Immunity Is Low). A resolved local reaction (a), a stable blood pressure (b) and fatigue that improved with rest (d) do not need to delay the dose, although the nurse documents them.

16. [CORE] A man who is about to start a TNF inhibitor asks whether his wife and teenage children should be vaccinated. Which response is consistent with the Canadian Immunization Guide?

a. "Your family should avoid all vaccines while you are on treatment, so they cannot pass anything to you."

b. "Only you need vaccines; your family's immunization status does not affect your risk of infection."

c. "Your family should delay their vaccines until your treatment ends, then catch up all at once."

d. "Your family should keep their vaccines up to date, including a yearly flu shot, to help protect you."

Answer: d — The Canadian Immunization Guide advises vaccinating family members and other close contacts of immunocompromised people and strongly encourages annual influenza vaccination (d) (section 21.3, Nursing Care and Teaching). Avoiding (a) or delaying (c) family vaccines removes a layer of protection. Close contacts' immunity does affect the patient's exposure (b).

17. [CORE] A 68-year-old patient asks whether she is "too old" for the shingles vaccine. Which response by the nurse is accurate?

a. "The shingles vaccine works only before age 60, because the virus is no longer active after that."

b. "NACI recommends the recombinant zoster vaccine for adults aged 50 and older, and it stays effective across older age groups."

c. "Older adults should receive the live zoster vaccine instead, because it works better than the non-live vaccine in people over 70."

d. "Shingles is uncommon after 65, so most older adults do not need to be vaccinated against it."

Answer: b — NACI recommends the recombinant zoster vaccine for adults 50 and older without contraindications, and its effectiveness remains higher across age groups than the live vaccine's (b) (section 21.1, The Aging Immune System). The virus can reactivate at any age, and risk rises with age (a, d). The live vaccine is less effective in adults over 70 (c).

18. [RN] A patient with suspected anaphylaxis to an intravenous antibiotic has received emergency treatment and is now stable. The physician orders a serum tryptase. Which nursing action best supports interpretation of the result?

a. Wait 24 hours so that the tryptase level has time to peak, then draw the sample with morning bloodwork

b. Draw the sample only if the patient's blood pressure falls again, because tryptase rises only with hypotension

c. Ask the laboratory to cancel the test, because a normal tryptase would rule out anaphylaxis and change nothing

d. Draw the sample as soon as possible and record both the time symptoms began and the time the sample was taken

Answer: d — An acute tryptase is drawn as early as possible, ideally within 2 hours after symptoms begin, and compared with a later baseline level, so recording both times is essential (d) (section 21.1, Going Deeper box). A level drawn 24 hours later serves as the baseline, not the acute sample (a). Tryptase is not limited to hypotensive reactions (b). A normal level does not rule out anaphylaxis, but an elevated one supports the diagnosis (c).

19. [RN] **A patient with seasonal allergies asks why her first bee sting caused no reaction but the second caused hives and wheezing. Which explanation is most accurate?**

a. "The first sting led your body to make IgE that coated mast cells; the second sting linked that IgE and the cells released histamine."

b. "The first sting used up your body's histamine, so the second sting caused an overload when your stores were refilled."

c. "Your T cells attacked your own skin cells after the second sting, which takes about two days to cause symptoms."

d. "The second sting contained more venom than the first, so the reaction was simply a larger toxic effect of the venom."

Answer: a — Type I reactions need sensitization: the first exposure leads to IgE that binds mast cells and basophils, and on re-exposure the allergen cross-links IgE and the cells release histamine and other mediators within minutes (a) (section 21.1, Going Deeper box). Histamine depletion (b) is not the mechanism. A T cell-mediated delayed reaction (c) describes type IV. A dose-related toxic effect (d) is not an allergy.

20. [RN] **A patient on an ACE inhibitor has rapidly increasing tongue swelling without hives. The team has given an antihistamine and a corticosteroid, but the swelling is worsening and the patient's voice is now muffled. What is the RN's priority?**

a. Give a second dose of the antihistamine now, because the first dose may not yet have been fully absorbed from the gut

b. Reassure the patient that the corticosteroid will take effect within the next few hours

c. Call for urgent airway support from the rapid response or anesthesia team and prepare for airway management

d. Hold the next ACE inhibitor dose and reassess the swelling at the next scheduled vital signs

Answer: c — ACE inhibitor angioedema is driven by bradykinin, not histamine, so antihistamines and corticosteroids cannot be relied on, and a muffled voice signals airway involvement that can quickly become fatal (c) (section 21.2, Angioedema; Chapter 6). Repeating the antihistamine (a) or waiting for the corticosteroid (b) delays airway care. The ACE inhibitor must be stopped, but waiting until the next vital signs (d) ignores an airway emergency.

Case: Martin Leclerc (Questions 21–26): Martin Leclerc, 44, comes to the emergency department in Kingston, Ontario, with 3 weeks of dry cough, breathlessness that is worse on stairs, evening fevers and a 6-kg weight loss. He has no known medical conditions and has never had an HIV test. At rest: temperature 38.4 °C, heart rate 106, respiratory rate 26, blood pressure 118/72 mm Hg, SpO2 93% on room air. After walking 30 m, his SpO2 falls to 85%. White plaques cover his tongue and the inside of his cheeks. A chest x-ray shows diffuse haziness in both lungs.

21. [CORE] **The nurse reviews Martin's assessment. Which findings are cues that need follow-up? Select all that apply.**

a. SpO2 falling from 93% to 85% after walking 30 m

b. Respiratory rate of 26 breaths per minute at rest

c. White plaques on the tongue and inside the cheeks

d. Blood pressure of 118/72 mm Hg

e. Weight loss of 6 kg over 3 weeks

f. No known medical conditions

Answer: a, b, c, e — A sharp drop in SpO2 with exertion (a) and a fast respiratory rate at rest (b) show impaired gas exchange, a typical pattern in Pneumocystis pneumonia (section 21.5). White plaques suggest oral candidiasis (c), and unexplained weight loss (e) is a sign of a serious underlying illness; both raise the possibility of a weakened immune system (sections 21.4 and 21.5). His blood pressure (d) is within normal limits. Having no known medical conditions (f) is history, not a finding that needs follow-up, although it is consistent with undiagnosed HIV.

22. [RN] **Martin's arterial blood gas on room air shows pH 7.48, PaCO2 30 mm Hg, $HCO3^-$ 23 mmol/L and PaO2 58 mm Hg. How should the nurse interpret these results?**

a. Metabolic alkalosis with partial respiratory compensation, and adequate oxygenation for his age

b. Respiratory acidosis caused by hypoventilation, with hypoxemia that needs oxygen therapy

c. Respiratory alkalosis from rapid breathing, with hypoxemia that needs oxygen therapy

d. Metabolic acidosis with full respiratory compensation, with mild hypoxemia on room air

Answer: c — The pH is high and the PaCO2 is low, so the alkalosis is respiratory: Martin is breathing fast because he is hypoxemic, and the bicarbonate is normal, so the kidneys have not compensated (c). A PaO2 of 58 mm Hg is hypoxemia. Option a is wrong because the bicarbonate is normal, not raised, and oxygenation is not adequate. Option b is wrong because a low PaCO2 reflects hyperventilation, not hypoventilation. Option d is wrong because the pH is alkalotic, not acidotic, and the bicarbonate is normal (section 21.5; Chapter 3 covers acid–base balance).

23. [CORE] Considering all of Martin's findings, which hypothesis should the nurse rank highest?

a. Pneumocystis pneumonia linked to an immune deficiency that has not yet been diagnosed, such as HIV

b. Heart failure with fluid in both lungs, causing breathlessness when he climbs stairs

c. An asthma exacerbation set off by a viral cold, causing a cough and low oxygen levels

d. A pulmonary embolism from reduced mobility, causing sudden chest pain and breathlessness on exertion

Answer: a — A subacute dry cough, fever, weight loss, oxygen saturation that drops with exertion, diffuse changes in both lungs and oral thrush together point to Pneumocystis pneumonia in a person with an undiagnosed immune deficiency, most often HIV (a; sections 21.4 and 21.5). Heart failure (b) does not explain the fever, thrush and weight loss. Asthma (c) usually causes wheeze and does not explain the thrush or weight loss. A pulmonary embolism (d) usually begins suddenly, and Martin's illness developed over 3 weeks with no reported immobility.

24. [CORE] Martin agrees to HIV testing, and the fourth-generation test is reactive; confirmatory testing is under way. His CD4 count is 80 cells/µL, and induced sputum confirms Pneumocystis pneumonia. Intravenous trimethoprim-sulfamethoxazole and oxygen are ordered. Which actions should the nurse include in the plan of care? Select all that apply.

a. Give oxygen as ordered and titrate it to the ordered SpO2 target

b. Wear double gloves and a gown for all contact because he is living with HIV

c. Before the first dose, ask about any sulfonamide allergy and confirm the order with the pharmacist

d. Cluster care and pace activities to limit drops in oxygen saturation with exertion

e. Tell his sister about the HIV result when she visits so that she can support him

f. Offer a private space for his questions and connect him with the HIV care team and peer support

Answer: a, c, d, f — Oxygen titrated to the ordered target (a) and pacing activity (d) address impaired gas exchange (section 21.5). Trimethoprim-sulfamethoxazole is a sulfonamide, so checking allergies and confirming the order before the first dose is safe practice (c; section 21.2 covers allergy histories). Privacy, time for questions and early links to HIV care and peer support are part of good care after a new diagnosis (f; sections 21.4 and 21.5). Routine practices are all that HIV requires; double gloves and a gown for all contact are unnecessary and stigmatizing (b). Disclosure is Martin's decision, and telling his sister without consent breaches his privacy (e; section 21.5; Chapter 1).

25. [CORE] On the evening of day 2, Martin's respiratory rate is 34, his SpO2 is 86% on 4 L/min by nasal prongs, he is using his neck muscles to breathe, and he is newly confused. What should the nurse do first?

a. Let him rest for 30 minutes and recheck his vital signs before making any calls about the change

b. Increase oxygen within the ordered range and escalate at once by calling the rapid response team

c. Hold the next dose of trimethoprim-sulfamethoxazole, since the drug may be causing the breathlessness

d. Give the as-needed lorazepam that is ordered for anxiety, since he is restless and confused tonight

Answer: b — Rising respiratory rate, falling SpO2, accessory muscle use and new confusion are signs of respiratory failure. The nurse acts within the order to improve oxygenation and escalates immediately, using the rapid response team or the facility's escalation process (b; Chapter 6). Waiting to recheck (a) delays care for a deteriorating patient. Holding the antimicrobial (c) withholds treatment for the cause of his illness without an order. A sedative (d) can depress breathing and mask worsening hypoxemia, which is likely causing the confusion.

26. [CORE] Martin is treated in the intensive care unit and returns to the medical unit. Which finding on day 9 best shows that his treatment is working?

a. His CD4 count has risen to 350 cells/µL since admission

b. He says he is less worried about his diagnosis than before

c. A repeat HIV test is still reactive and his viral load is high

d. His SpO2 stays at 95% on room air while he walks the hallway

Answer: d — The main problem in Pneumocystis pneumonia is hypoxemia, especially with exertion, so a normal SpO2 on room air while walking shows that gas exchange has improved (d; section 21.5). CD4 counts recover slowly after ART starts, often by about 50 to 150 cells/µL in the first year, so a rise to 350 cells/µL within days (a) is not expected and does not measure the pneumonia. Reduced worry (b) is welcome but does not show that the infection is resolving. A reactive HIV test and high viral load (c) are expected before ART takes effect and do not reflect the pneumonia.

27. [CORE] The nurse is teaching the partner of a man who is living with HIV. Which statement by the partner shows correct understanding of how HIV is transmitted?

a. "I should use a separate bathroom from him at home to keep myself safe from HIV."

b. "We can hug and share food, because HIV is not spread by everyday contact."

c. "I could get HIV from kissing him, so I should avoid kissing him on the mouth."

d. "Mosquitoes could carry HIV from him to me during the summer when we're outside."

Answer: b — HIV spreads through blood, semen, vaginal and rectal fluids and human milk, not through casual contact such as hugging or sharing food (b; section 21.4). Toilet seats (a) do not transmit HIV, so a separate bathroom is not needed. Kissing (c) is casual contact that does not transmit HIV. Mosquitoes (d) do not transmit HIV.

28. [CORE] A woman had condomless sex with a new partner 10 days ago. A fourth-generation HIV test today is non-reactive. Which response by the nurse is correct?

a. "This result rules out HIV, so you do not need any further testing for this exposure."

b. "A fourth-generation test only detects older infections, so we should also do a rapid test today."

c. "You should start post-exposure prophylaxis today, because it works best after 10 days."

d. "The test may not detect a very recent infection yet, so we'll repeat it later on."

Answer: d — The window period can last up to 12 weeks, so a non-reactive test 10 days after an exposure needs to be repeated (d; section 21.4). A single early negative test does not rule out HIV (a). Fourth-generation tests detect infection earlier than rapid antibody tests, not later (b). Post-exposure prophylaxis must start within 72 hours of the exposure, so at 10 days it is too late (c).

29. [CORE] A man calls the clinic 30 hours after condomless anal sex with a partner whose HIV status is unknown. What is the nurse's best response?

a. "Please come in now. Medication to prevent HIV can still be started, and it should begin as soon as possible."

b. "It is too late for preventive medication. Please come in for an HIV test 12 weeks after the exposure."

c. "Ask your partner to get tested first. If their result is positive, we can start medication at that point."

d. "Book your next routine visit, and we can talk then about daily pre-exposure prophylaxis to prevent HIV."

Answer: a — Post-exposure prophylaxis can be started up to 72 hours after an exposure and works best when started as soon as possible, so 30 hours is still within the window (a; section 21.4). Telling him it is too late (b) is incorrect. Waiting for the partner's result (c) or for a routine visit (d) could push him past the 72-hour limit, although PrEP may be discussed later.

30. [CORE] A patient who has lived with HIV for 8 years asks whether he can pass HIV to his partner through sex. His viral load has been below 200 copies/mL on every test for 3 years. What should the nurse explain?

a. "HIV can still pass on through sex, so your partner will need to take pre-exposure prophylaxis daily."

b. "Your risk is low but not zero, so you should only have sex after your next viral load test."

c. "You will not pass HIV on through sex while you take treatment and your viral load stays suppressed."

d. "Your treatment has cured the HIV, so you no longer need to have your viral load tested every year."

Answer: c — PHAC describes U=U as the scientific consensus that a person who takes ART as prescribed does not pass HIV on through sex while keeping a viral load below 200 copies/mL, checked every 4 to 6 months (c; section 21.4). The partner does not need PrEP to prevent sexual transmission (a). Timing sex around tests (b) is not needed, because protection depends on ongoing suppression. A suppressed viral load is not a cure, and regular testing continues (d).

31. [CORE] A patient is starting daily oral pre-exposure prophylaxis. Which follow-up tests does the Canadian guideline call for? Select all that apply.

a. HIV test 30 days after starting and then every 3 months

b. Serum creatinine to monitor kidney function

c. Screening for gonorrhea, chlamydia and syphilis

d. CD4 count every 3 months

e. Hepatitis B testing at baseline and yearly if susceptible

f. Chest x-ray every 6 months

Answer: a, b, c, e — The 2025 Canadian guideline calls for HIV testing at baseline, at 30 days and then every 3 months on oral PrEP (a), creatinine monitoring (b), screening for sexually transmitted infections every 3 to 4 months (c) and hepatitis B testing at baseline and yearly for people who remain susceptible (e) (section 21.4). CD4 counts (d) monitor the immune system in people living with HIV, not in people taking PrEP. Routine chest x-rays (f) are not part of PrEP monitoring.

32. [CORE] An RPN is caring for a patient living with HIV who will have nothing by mouth before surgery tomorrow. The patient's once-daily ART is due at 0800. What should the RPN do?

a. Skip the 0800 dose, since a single missed dose of ART is harmless, and give it after surgery when he eats

b. Ask the RN and the prescriber, with the pharmacist, how to give the dose before 0800 rather than omit it

c. Give the ART dose with a full glass of water and a snack, since the medication must be taken with food

d. Tell the patient to bring his own supply from home and decide himself when to take it after surgery

Answer: b — ART is never stopped or interrupted without a prescriber's order, and doses are given on time; the RPN consults the RN and prescriber and involves the pharmacist when a patient cannot take anything by mouth (b; section 21.5). Missed doses can lead to resistance, so skipping (a) is unsafe. Giving food (c) breaks the order to have nothing by mouth. Leaving the decision to the patient (d) does not address the order or medication safety.

33. [CORE] An RPN working in a community clinic in Ontario is asked to give a Tdap vaccine to an adult. What does the RPN need before giving it?

a. Nothing further, because Tdap is a routine vaccine that any nurse may give on their own judgment

b. Nothing, because RPNs are not authorized to give vaccines, and the RN must give every injection

c. A prescription written by an authorized RN prescriber, because only RN prescribers can order a vaccine

d. An order from an authorized professional, the competence to give it safely and employer support

Answer: d — In Ontario, giving a vaccine by injection is a controlled act; RNs and RPNs may carry it out with an order (a direct order or a directive) from an authorized health care professional, when they are competent, including in managing anaphylaxis, and the setting supports it (d; Scope in Practice box, section 21.6). A nurse cannot give it on their own judgment without an order (a). RPNs are authorized with an order (b). Physicians, nurse practitioners and other authorized prescribers can order vaccines, not only RN prescribers (c).

34. [CORE] The clinic's vaccine refrigerator reads 11 °C when the nurse arrives in the morning. What should the nurse do?

a. Give the vaccines today before they lose any more potency, and then call to have the refrigerator repaired

b. Move the vaccines to the freezer to bring them back down to the right temperature more quickly

c. Label the vaccines "do not use", keep them refrigerated and contact public health or the supplier

d. Throw out all the vaccines right away and order a new supply from the local public health unit

Answer: c — Refrigerated vaccines must stay between +2 °C and +8 °C. After a cold chain break, the nurse sets the vaccines apart, labels them "do not use", keeps them cold and asks public health or the supplier whether they can be used (c; section 21.6). Giving them (a) risks giving ineffective vaccine. Freezing (b) can damage vaccines. Throwing them out (d) may waste usable vaccine before their integrity has been assessed.

35. [CORE] A 62-year-old patient with rheumatoid arthritis is about to start a biologic drug that suppresses the immune system. She asks whether she can get the shingles vaccine. What should the nurse tell her?

a. "The recombinant zoster vaccine is non-live and is recommended for adults who are or will be immunocompromised."

b. "All shingles vaccines are live vaccines, so you will never be able to have one while you take your arthritis drug."

c. "You only need a shingles vaccine if you have had shingles before, so ask your family to check your history."

d. "You will need to wait until after your 65th birthday, because the vaccine is not recommended before that age."

Answer: a — The Canadian Immunization Guide recommends two doses of recombinant zoster vaccine for adults aged 50 and older and for adults 18 and older who are or will be immunocompromised; it is non-live and ideally given before immunosuppression starts (a; sections 21.3 and 21.6). The recombinant vaccine is not live (b). A past episode of shingles is not a requirement (c). Ontario funds the vaccine at ages 65 to 70, but the recommendation begins at age 50, and earlier for immunocompromised adults (d).

36. [CORE] A nurse hears a colleague at the nursing station tell a visitor, "Be careful in room 8, he has AIDS." What should the nurse do first?

a. Put a sign on the door of room 8 so that all visitors know to take extra precautions

b. Tell the visitor that HIV is not easily spread, and leave the matter there to avoid conflict with the colleague

c. Write an incident report and avoid speaking with the colleague directly about what was said

d. Ask the colleague to talk privately, and address the breach of privacy and the stigmatizing words

Answer: d — The colleague disclosed personal health information and used stigmatizing language. The nurse addresses it promptly and privately, and involves the charge nurse or manager under policy if needed (d; section 21.5; Chapter 1). A sign (a) adds a further breach and implies precautions that HIV does not need. Reassuring the visitor (b) does not stop the breach from happening again. An incident report may be needed under policy, but avoiding the colleague (c) misses the chance to stop the behaviour.

37. [CORE] A patient says, "I'm not sure about vaccines. I read that they cause more problems than they prevent." Which response by the nurse best follows the Canadian Immunization Guide's advice?

a. "That's misinformation. The science is settled, so you should get your vaccines today."

b. "Can you tell me more about what you read and what worries you most about vaccines?"

c. "If you don't get vaccinated, I'll need to note in your chart that you refused my advice."

d. "Many people feel that way at first, so let's skip vaccines for now and not talk about it."

Answer: b — The guide advises finding the source of a person's hesitancy, listening without judgment and clarifying why a belief is held before offering clear information (b; section 21.6). Dismissing the concern (a) or using pressure (c) damages trust. Dropping the subject (d) misses the chance to give accurate information, although the person's final decision is respected.

38. [RN] A patient has taken ART for 2 years with an undetectable viral load. Today's viral load is 640 copies/mL, and a repeat test 4 weeks later is 710 copies/mL. Which interpretation and next step are correct?

a. This is a viral blip, so the nurse reassures the patient and plans the next routine viral load test in 6 months

b. This shows the regimen is working, because any viral load below 1,000 copies/mL counts as suppressed

c. This is virologic rebound, so the nurse explores adherence and interactions and expects resistance testing

d. This is immune reconstitution inflammatory syndrome, so the nurse expects the prescriber to stop ART

Answer: c — A confirmed viral load of 200 copies/mL or more after suppression is virologic rebound, a form of virologic failure. The nurse explores missed doses and new interacting drugs, and resistance testing is done, ideally while the person is still on the regimen (c; section 21.5, Going Deeper box). A blip (a) is a single detectable result that returns to undetectable. Suppression is defined well below 1,000 copies/mL (b). IRIS (d) is an inflammatory reaction soon after ART starts, and ART is not stopped without a prescriber's order.

39. [RN] Which patient living with HIV meets the current DHHS indication for primary Pneumocystis pneumonia prophylaxis with trimethoprim-sulfamethoxazole?

a. A newly diagnosed adult with a CD4 count of 150 cells/µL who is starting ART this week

b. An adult on ART for 2 years with a CD4 count of 260 cells/µL and a suppressed viral load

c. An adult on ART for 5 years whose CD4 count has stayed above 350 cells/µL for 3 years

d. A newly diagnosed adult with a CD4 count of 420 cells/µL who is starting ART this month

Answer: a — The DHHS guideline recommends prophylaxis for adults with a CD4 count below 200 cells/µL who are not on ART or are starting it (a; section 21.5). People on ART whose CD4 count is 200 cells/µL or more (b, c) do not need prophylaxis; for people on ART, prophylaxis is started if the count falls below 100 cells/µL, or to 100 to 200 cells/µL with a rising viral load. A CD4 count of 420 cells/µL (d) is above the threshold.

40. [RN] A patient who takes rilpivirine as part of their ART is admitted with gastrointestinal bleeding. An order for intravenous pantoprazole is written. What should the nurse do?

a. Give the pantoprazole now and give the rilpivirine 4 hours later, so that the two doses are separated in time

b. Hold the pantoprazole and call the prescriber and pharmacist, because it is contraindicated with rilpivirine

c. Give the pantoprazole and hold the rilpivirine until discharge, since ART can be paused safely in hospital

d. Give the pantoprazole as ordered, since an intravenous drug cannot interact with an oral antiretroviral regimen

Answer: b — The rilpivirine monograph lists proton pump inhibitors as contraindicated because raising gastric pH lowers rilpivirine levels and risks treatment failure and resistance; the nurse holds the dose and contacts the prescriber and pharmacist so a safe alternative can be chosen (b; section 21.5). Spacing the doses (a) is the advice for antacids and H2-receptor antagonists, not proton pump inhibitors. ART is never paused without a prescriber's order (c). The interaction depends on gastric acid suppression, not on the route of the acid suppressant (d).

22 Diabetes

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how the body regulates glucose and how type 1, type 2 and other types of diabetes develop, and apply Canadian diagnostic criteria in SI units.
2. Monitor glucose with meters, continuous glucose monitoring, A1C and ketone testing, and interpret results against individualized targets.
3. Give insulin and non-insulin medications safely, treating insulin as a high-alert medication and teaching self-administration.
4. Recognize and treat hypoglycemia promptly, including in older adults and people with impaired awareness.
5. Recognize DKA and HHS, and provide nursing care and escalation using the CJMM.
6. Manage glucose in hospital, prevent and detect chronic complications, and teach foot care and sick-day guidance.
7. Support self-management with attention to access, cost and food security, with a distinctions-based, strengths-based lens for First Nations, Inuit and Métis communities.
8. Distinguish RN and RPN roles in insulin administration and adjustment using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4, 5, 6	Clinician; Scholar	Foundations of Practice
3, 6, 7	Educator; Advocate	Foundations of Practice; Ethical Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Nurses meet diabetes on every unit. A patient admitted with pneumonia, a hip fracture or a heart attack may also live with diabetes, and the illness, the hospital routine and new medications can all push glucose too high or too low. In Canada, about 3.9 million people aged 1 year and older (9.7%) were living with diagnosed diabetes in 2023–2024, and about 260,000 people were newly diagnosed that year (Public Health Agency of Canada [PHAC], 2025). Nurses check glucose at the bedside, give insulin and other glucose-lowering drugs, recognize emergencies early and teach people to manage a lifelong condition at home.

This chapter is the book's home for diabetes in adults. Section 22.1 explains how the body controls glucose, how the main types of diabetes develop, who is at risk in Canada and how diabetes is diagnosed. Section 22.2 covers glucose meters, continuous glucose monitoring, the A1C test and ketone testing. Section 22.3 describes insulin and the non-insulin medications and how to give insulin safely. The second half of the chapter turns to hypoglycemia (22.4), the hyperglycemic emergencies diabetic ketoacidosis and hyperglycemic hyperosmolar state (22.5), and glucose management in hospital, chronic complications, foot care and self-management (22.6).

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1 (sections 1.3 to 1.5), and cultural safety, Indigenous health and food insecurity in Chapter 2. Acid–base balance, the anion gap and potassium are explained in Chapter 3, sepsis in Chapter 4, and recognizing deterioration in Chapter 6. Perioperative care, including when to hold some diabetes drugs before procedures, is in Chapter 7, and older adults and deprescribing are in Chapter 8. Heart, kidney, eye and wound complications are taught in the chapters for those systems.

22.1 Glucose Regulation and Types of Diabetes

How the Body Regulates Glucose

Glucose is a key fuel, especially for the brain, so the body keeps blood glucose within a narrow band through day and night. Two hormones from the islets of the pancreas do most of this work, pulling in opposite directions (Röder et al., 2016).

Insulin, made by the beta cells, is released when glucose rises after a meal. It lets muscle and fat cells take up glucose, tells the liver to stop releasing glucose and to store the extra as glycogen, and promotes the storage of fat and protein. Insulin also holds back the breakdown of fat. This last effect matters at the bedside: when insulin is missing and glucagon is high, fat breaks down without restraint and the liver turns the released fatty acids into **ketones**, acids that can build up in the blood (Goguen & Gilbert, 2018; section 22.5).

Glucagon, made by the alpha cells, rises between meals and overnight. It tells the liver to break down glycogen and to make new glucose from other sources, keeping glucose up while a person is not eating (Röder et al., 2016). Acute illness also pushes glucose up: stress hormones (catecholamines) can suppress insulin release, and infection, heart attack and stroke are common triggers of hyperglycemic emergencies (Goguen & Gilbert, 2018). Corticosteroid drugs raise glucose as well (Malcolm et al., 2018; section 22.6).

The gut takes part as well. After a meal, intestinal hormones called **incretins**, mainly glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), boost insulin release when glucose is high. GLP-1 also lowers glucagon and slows stomach emptying (Röder et al., 2016). Several diabetes medications act on this system (section 22.3).

Types of Diabetes

Diabetes is a group of metabolic disorders that share hyperglycemia caused by too little insulin secretion, poor insulin action, or both. Over time, high glucose damages the eyes, kidneys and nerves and raises cardiovascular risk (Punthakee et al., 2018).

- **Type 1 diabetes:** the beta cells are destroyed, usually by an autoimmune process (section 21.6), leaving the person with little or no insulin. People with type 1 diabetes are prone to ketoacidosis and need insulin for life (Punthakee et al., 2018). About 3 in 4 people with type 1 diabetes were diagnosed before age 20 (PHAC, 2025). Diabetes Canada also places latent autoimmune diabetes in adults (LADA), an autoimmune diabetes that begins in adulthood, within type 1 (Punthakee et al., 2018).
- **Type 2 diabetes:** the main problems are **insulin resistance**, in which cells respond poorly to insulin, and a beta-cell defect that leaves insulin output too low for the body's needs. The balance between the two varies from person to person, and ketoacidosis is less common (Punthakee et al., 2018). Beta-cell function tends to decline over the years, so many people need more medications, including insulin, as time passes. Type 2 is usually diagnosed after age 40; more than 80% of people with type 2 diabetes were diagnosed after that age (PHAC, 2025).
- **Prediabetes:** glucose or A1C values above normal but below the diabetes range. It marks a high risk of developing diabetes, although not everyone with prediabetes goes on to develop it (Punthakee et al., 2018).
- **Gestational diabetes:** glucose intolerance first recognized during pregnancy (Chapter 29).
- **Other specific types:** diabetes caused by diseases of the exocrine pancreas, such as pancreatitis or cystic fibrosis; by drugs, such as glucocorticoids; or by rare single-gene (monogenic) defects in beta-cell function (Punthakee et al., 2018).

Who Is at Risk in Canada

The 3.9 million Canadians with diagnosed diabetes combine type 1 and type 2 and exclude gestational diabetes (PHAC, 2025). Others have diabetes but do not know it: in national data for adults aged 20 to 79, collected from 2007 to 2019, an estimated 1.9% had undiagnosed diabetes and 6.3% had prediabetes (PHAC, 2025).

Diabetes Canada lists these risk factors for type 2 diabetes (Ekoé et al., 2018):

- age 40 years or older, or a first-degree relative with type 2 diabetes;
- membership in a population at high risk, which the guideline gives as Indigenous peoples; people of African, Arab, Asian, Hispanic or South Asian descent; and people with low socioeconomic status;

- a history of prediabetes, of gestational diabetes or of giving birth to a large baby;
- signs of end-organ damage, such as retinopathy, neuropathy, kidney disease or cardiovascular disease;
- vascular risk factors: low high-density lipoprotein (HDL) cholesterol, high triglycerides, hypertension, overweight, abdominal obesity and smoking;
- associated conditions, including pancreatitis, polycystic ovary syndrome, acanthosis nigricans, gout, fatty liver disease, some mental illnesses, HIV infection, obstructive sleep apnea and cystic fibrosis;
- drugs such as glucocorticoids, atypical antipsychotics, statins, antiretroviral therapy and anti-rejection drugs.

The population groups in this list describe risk, not biology. Higher rates in these communities follow from conditions that people live with, including poverty, food insecurity, racism and unequal access to care. For Indigenous peoples, Diabetes Canada, citing the World Health Organization, recognizes colonization, including residential schools, forced relocation and the banning of ceremonies, as "the most significant social determinant of health" (Crowshoe et al., 2018; Chapter 2).

Diabetes Canada recommends that everyone's risk be reviewed each year, and that people aged 40 and older, or at high risk on a risk calculator, be screened with a fasting glucose and/or A1C every 3 years. Earlier or more frequent testing (every 6 to 12 months) is considered for people at very high risk or with additional risk factors. The Canadian Diabetes Risk Assessment Questionnaire (CANRISK) estimates risk in Canada's multi-ethnic population (Ekoé et al., 2018). A hospital stay is also a chance to find risk: the nurse asks about family history, reviews medications such as corticosteroids and antipsychotics, notes raised glucose results and makes sure follow-up testing is arranged.

Diagnosis

When glucose rises above what the kidneys can reabsorb, glucose spills into the urine and pulls water and electrolytes with it. The person passes large amounts of urine, becomes thirsty and may feel weak (Goguen & Gilbert, 2018). Type 1 diabetes often develops over days to weeks, and some people are first diagnosed when they arrive with ketoacidosis (section 22.5). Type 2 diabetes develops slowly. Many people have no symptoms at all and are diagnosed through screening, during an admission for another illness, or only after a complication has appeared.

Diabetes Canada's criteria use plasma glucose and A1C in SI units (Table 22.1). One result in the diabetes range is enough when the person has symptoms of hyperglycemia. Without symptoms, the result is confirmed by a repeat test on another day. When type 1 diabetes is suspected, treatment is never delayed for a confirmatory test, especially if ketones are present (Punthakee et al., 2018).

Table 22.1 Diagnosing diabetes and prediabetes in adults (Punthakee et al., 2018)

Test	Prediabetes	Diabetes	Notes
Fasting plasma glucose	6.1–6.9 mmol/L (impaired fasting glucose)	7.0 mmol/L or higher	Fasting means no food or caloric drinks for at least 8 hours
A1C	6.0–6.4%	6.5% or higher	Adults only, with a standardized laboratory test; not used when type 1 diabetes is suspected; can mislead with hemoglobin variants, some anemias and severe kidney or liver disease
2-hour plasma glucose in a 75 g oral glucose tolerance test	7.8–11.0 mmol/L (impaired glucose tolerance)	11.1 mmol/L or higher	Blood drawn 2 hours after a standard glucose drink
Random plasma glucose	Not used	11.1 mmol/L or higher	Any time of day, whatever the timing of the last meal
Confirming the diagnosis	Not applicable	One result is enough with symptoms; otherwise repeat on another day	The same test is preferred for the repeat, but a random value without symptoms is confirmed with a different test

Acanthosis nigricans is a skin sign of insulin resistance and a listed risk factor (Ekoé et al., 2018). The nurse looks for thick, velvety patches in skin folds such as the back and sides of the neck, the armpits and the groin. The colour change can be subtle, especially on

brown and black skin, where the patches may differ little from the surrounding skin. Because visual assessment alone is unreliable, the nurse uses good lighting, compares the area with nearby unaffected skin and feels for the velvety texture (Pusey-Reid et al., 2023). The nurse never mistakes it for poor hygiene, since washing does not remove it.

CANADIAN CONTEXT

Diabetes in First Nations, Inuit and Métis Communities

Diabetes Canada describes Indigenous peoples in Canada as among the populations at highest risk of diabetes and its complications, and recommends earlier and more frequent screening (Crowshoe et al., 2018). The guideline places the cause in history and living conditions: colonization, residential schools, forced relocation, poverty, food insecurity and racism in health care.

Rates differ across First Nations, Inuit and Métis peoples, so data are reported by distinct group. In the First Nations Regional Health Survey (RHS) Phase 3 (2015–2016), 19.2% of First Nations adults living on reserve and in northern First Nations communities had diabetes (age-standardized), a steady trend compared with 20.7% in Phase 2 (2008–2010) and 20.1% in Phase 1 (2002–2003) (First Nations Information Governance Centre [FNIGC], 2018). The RHS is owned and governed by First Nations under the principles of ownership, control, access and possession (OCAP®) (Rosella et al., 2020). In the 2009–2010 Canadian Community Health Survey, the age-standardized prevalence among Métis was 7.3%, compared with 5.0% among non-Indigenous people. Among Inuit aged 15 and older, self-reported prevalence in the 2006 Aboriginal Peoples Survey was about 4%, double the 2001 figure, and PHAC described the age-adjusted rate as comparable to that of the general population (PHAC, 2011). These Métis and Inuit figures are now more than 15 years old.

Communities lead much of the response. The Kahnawake Schools Diabetes Prevention Project, run since 1994 under a community advisory board in Kahnawà:ke, combines Kanien'kehá:ka knowledge with research to promote healthy eating and activity in schools and families (McComber & Macaulay, 2016). Nurses support such programs and offer culturally safe care (Chapter 2).

22.2 Monitoring Glucose

Meters and Point-of-Care Testing

A glucose meter measures glucose in a drop of capillary blood (Figure 22.1). In hospital this is **point-of-care glucose testing**: testing at the bedside with a meter that the laboratory approves and checks for quality. Employer policy sets who may test, how often the meter is checked, how results are documented and which values must be reported at once.

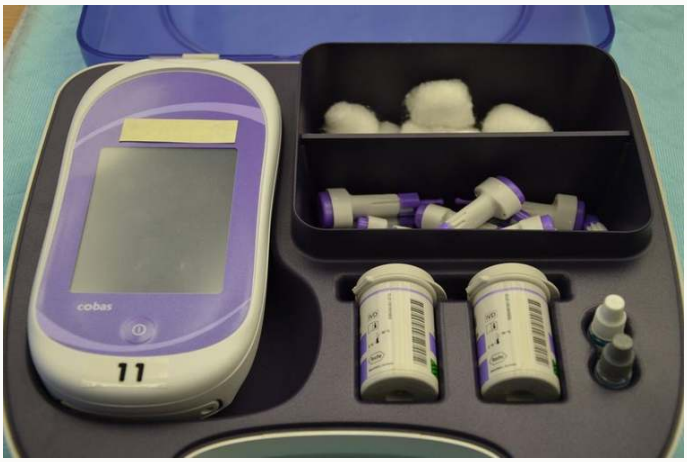

Figure 22.1 A point-of-care glucose meter with lancets, test strips and cotton balls. The meter must be one the laboratory approves, and the nurse follows the unit's quality-control routine. (credit: “A blood glucose monitoring machine with cotton balls, lancets, and reagent strips” by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Technique affects the result. In one study, sugar left on the fingers after touching fruit produced a falsely high first-drop reading in most participants, and squeezing the finger also distorted results. The nurse therefore has the patient wash and dry their hands, uses the first drop, and avoids hard squeezing (Hortensius et al., 2011). The fingertip is preferred when glucose may be changing quickly, such as after a meal, after exercise or during suspected hypoglycemia, because forearm or thigh samples lag behind (Berard et al., 2018).

Meters are less exact than laboratory tests. Diabetes Canada accepts a difference of less than 15% between a meter and a simultaneous fasting laboratory glucose at values above 4.2 mmol/L (Berard et al., 2018). Its 2021 update advises comparing meter results with a simultaneous laboratory glucose when readings seem inaccurate or do not match the A1C (Cheng et al., 2021). When a reading does not fit how the patient looks, the nurse acts on the

patient, repeats the test and sends a laboratory sample as policy directs. People on insulin more than once a day are advised to check at least three times daily, including before and after meals (Berard et al., 2018; Cheng et al., 2021).

Continuous Glucose Monitoring

Continuous glucose monitoring (CGM) uses a small sensor inserted under the skin that measures glucose in the interstitial fluid every few minutes. Real-time systems send readings to a reader or phone automatically and can sound alarms for high or low values. Intermittently scanned ("flash") systems display readings when the sensor is scanned (Figure 22.2). Diabetes Canada recommends CGM for people with type 1 diabetes who use insulin injections or a pump (Halperin et al., 2025), and its 2021 update states that, for people with type 2 diabetes on basal-bolus insulin, real-time or flash CGM may be used to cut the time spent in hypoglycemia (Cheng et al., 2021). Costs and provincial coverage are discussed in section 22.6.

Figure 22.2 An intermittently scanned (flash) glucose sensor on the upper arm. Holding the reader or a phone near the sensor shows the current glucose and its trend. (credit: “FreeStyle libre am Oberarm und Auslesegerät-4” by Thirunavukkarasye-Raveendran/Wikimedia Commons, CC BY 4.0)

Interstitial glucose trails blood glucose. In fasting healthy adults the delay was about 5 to 6 minutes (Basu et al., 2013), and the gap between sensor and fingerstick values is largest when glucose is rising or falling quickly. If a sensor reading does not match symptoms, the nurse checks capillary glucose.

In hospital, patients may keep using their own CGM if hospital protocol allows. A current guideline advises confirming sensor values with point-of-care tests before insulin doses are adjusted. Some medications can distort readings, as can extensive skin infection, poor perfusion and vasopressor drugs, and sensors may need to be replaced after magnetic resonance imaging (MRI) and some other imaging (Korytkowski et al., 2022). The nurse follows employer policy and documents which value guided each decision.

CGM reports summarize glucose as **time in range**, the percentage of readings between 3.9 and 10.0 mmol/L. A time in range of 70% corresponds to an A1C of about 7.0% (Cheng et al., 2021), and each 5% gain in time in range brings clinically meaningful benefit (Halperin et al., 2025). The Going Deeper box explains the full report.

A1C and Targets

A1C (glycated hemoglobin) is the percentage of hemoglobin that has glucose attached. Because red cells live for months, A1C reflects average glucose across roughly the past 8 to 12 weeks, with the last 30 days contributing about half (Berard et al., 2018). It is checked at least every 3 months while targets are not being met, and every 6 months may be enough once targets are met consistently. Conditions that change red cell lifespan or hemoglobin structure, such as some anemias and hemoglobin variants, can make A1C misleading; meter or CGM data then carry more weight.

Diabetes Canada states that glycemic targets should be individualized. For most adults with type 1 or type 2 diabetes, the A1C target is 7.0% or less, with a fasting or before-meal glucose of 4.0 to 7.0 mmol/L and a glucose 2 hours after meals of 5.0 to 10.0 mmol/L. An A1C of 6.5% or less may be targeted in some people with type 2 diabetes at low risk of hypoglycemia. Higher targets protect people for whom hypoglycemia is the greater danger: 7.1% to 8.0% for people who are functionally dependent, and 7.1% to 8.5% for those with recurrent severe hypoglycemia, limited life expectancy, or frailty or dementia (Imran et al., 2018). Targets for older adults are covered in the Lifespan Considerations box in section 22.6.

Ketone Testing

Ketones form when the body burns fat because insulin is lacking. Blood ketone meters measure beta-hydroxybutyrate, the main ketone in ketoacidosis, and Diabetes Canada states that blood testing may be preferred to urine strips because it detects ketosis earlier (Berard et al., 2018). People with type 1 diabetes are advised to check ketones during acute illness with high glucose, when

glucose before meals stays above 14.0 mmol/L, or when symptoms of diabetic ketoacidosis appear, such as nausea, vomiting or abdominal pain (Berard et al., 2018). Diabetes Canada's type 1 guideline also asks people with type 1 diabetes who take a sodium-glucose cotransporter-2 (SGLT2) inhibitor to have a blood ketone meter and a written plan for ketone levels above 1.0 mmol/L (Halperin et al., 2025). In hospital, the nurse checks ketones as ordered or under a medical directive and reports rising values promptly (section 22.5).

GOING DEEPER

Reading a CGM Report

Required for RN students; optional for PN students.

An international consensus, which Diabetes Canada uses for its sensor targets, set out the core measures of a CGM report (Battelino et al., 2019; Cheng et al., 2021; Halperin et al., 2025). The standard one-page report, the ambulatory glucose profile, overlays 14 days of readings as if they were one day, so patterns by time of day stand out. Data are trusted when the sensor was worn for at least 70% of those 14 days.

Targets for most adults with type 1 or type 2 diabetes:

- **Time in range (3.9–10.0 mmol/L):** more than 70%, about 16 hours 48 minutes a day.
- **Time below range:** under 4% below 3.9 mmol/L, and under 1% below 3.0 mmol/L.
- **Time above range:** under 25% above 10.0 mmol/L, and under 5% above 13.9 mmol/L.
- **Glycemic variability:** a coefficient of variation of 36% or less.

For older or high-risk adults, the consensus relaxes the targets: time in range above 50% and time below 3.9 mmol/L under 1%.

The **glucose management indicator (GMI)** estimates A1C from the sensor's mean glucose. It may differ from a laboratory A1C, which can itself be thrown off by conditions such as some anemias (Punthakee et al., 2018).

The nurse reads hypoglycemia first, because lows are the immediate danger. A cluster of lows at 0300, for example, points to the evening basal or bedtime dose, not the lunch dose.

22.3 Insulin and Non-Insulin Medications

Insulin Types

Everyone with type 1 diabetes needs insulin. In type 2 diabetes, insulin is started at once when glucose is very high with symptoms or the person is metabolically unstable, and later when targets are not met despite other drugs (Butalia et al., 2024). It may also be used for a time during illness, surgery or other stress (Lipscombe et al., 2018).

Insulin regimens copy the body's normal pattern.

- **Basal insulin** provides a steady background level that controls glucose between meals and overnight.
- **Bolus (prandial) insulin** is given with meals to cover the rise in glucose from food.
- **Correction insulin** is an extra amount of rapid- or short-acting insulin, added to the scheduled dose when glucose is above target.

In type 2 diabetes, insulin often starts as one daily injection of basal insulin added to other drugs (Lipscombe et al., 2018). Diabetes Canada suggests long-acting analogues rather than NPH to lower the risk of hypoglycemia. It also advises stopping sulfonylureas and meglitinides once bolus insulin is added (Shah et al., 2024).

Insulins are grouped by how fast they start, when they peak and how long they last (Table 22.2). These times are averages: they vary between people and with the dose, injection site and activity (Diabetes Canada, n.d.-a). Rapid-acting, short-acting and long-acting insulins are clear; intermediate-acting (NPH) and premixed insulins are cloudy.

Biosimilars are insulins highly similar to an original brand, such as Basaglar and Semglee for glargine, and Admelog, Trurapi and Kirsty for lispro and aspart. They cost less than the original products (Butalia et al., 2024; Halperin et al., 2025). Concentrated insulins hold more units in each millilitre (U-200, U-300 and U-500). The dose is still ordered and dialled in units, never in

millilitres. A once-weekly basal insulin, icodec (Awiqli), has been authorized in Canada (Health Canada, n.d.-b); Diabetes Canada's 2024 update made no recommendation about it (Butalia et al., 2024).

Table 22.2 Insulin types and what the nurse watches for (aspart times from the NovoRapid product monograph, Novo Nordisk Canada, 2026; all other times from Diabetes Canada, n.d.-a)

Type	Canadian examples	Onset, peak and duration (as stated)	Nursing points
Rapid-acting analogue (bolus; clear)	Aspart (NovoRapid; biosimilars Trurapi, Kirsty); lispro (Humalog U-100 and U-200; biosimilar Admelog)	Aspart: onset within 10–20 min, maximum effect 1–3 h, duration 3–5 h (monograph). Lispro: onset 10–15 min, peak 1–2 h, duration 3–4.75 h	Aspart is given immediately before a meal, no more than 5–10 min ahead, or right after the meal when necessary; confirm food is present and the patient can eat
Faster-acting analogue (bolus; clear)	Faster-acting aspart (Fiasp)	Onset 4 min, peak 0.5–1.5 h, duration 3–5 h	Fastest onset of all; the same meal checks apply
Short-acting (bolus; clear)	Regular insulin (Humulin R, Novolin ge Toronto)	Onset 30 min, peak 2–3 h, duration 6.5 h	Slower to start than analogues, so it is timed further ahead of meals as ordered; IV use only by order and protocol
Intermediate-acting (basal; cloudy)	NPH (Humulin N, Novolin ge NPH)	Onset 1–3 h, peak 5–8 h, duration up to 18 h	Its peak can cause hypoglycemia many hours after a dose; check the label, since Humulin N and Humulin R have been mixed up
Long-acting analogue (basal; clear)	Glargine U-100 (Lantus; biosimilars Basaglar, Semglee); glargine U-300 (Toujeo); degludec U-100 and U-200 (Tresiba)	Onset 90 min; no peak; duration 24 h (glargine U-100), more than 30 h (glargine U-300), 42 h (degludec)	Usually continued when the patient is not eating, at the ordered dose (section 22.6); clear like rapid-acting insulin, so check the name every time
Premixed (cloudy)	Humulin 30/70, Novolin ge 30/70; NovoMix 30; Humalog Mix25	Fixed proportions of a rapid- or short-acting insulin with an intermediate-acting insulin; action reflects both parts	Given with meals; a missed or late meal raises the risk of hypoglycemia
Concentrated	Lispro U-200; glargine U-300; degludec U-200; regular U-500 (Entuzity)	Regular U-500: onset 15 min, peak 4–8 h, duration 17–24 h	Dose in units from the pen as ordered; never withdraw insulin from a pen or cartridge with a syringe

Giving Insulin Safely

Insulin is a **high-alert medication**: a drug with a heightened risk of serious harm when used in error. ISMP Canada has identified insulin as high-alert in the community, and it is repeatedly linked to harmful incidents in hospitals (Canadian Society of Hospital Pharmacists Ontario Branch & ISMP Canada, 2014; Kasprzak & Ho, 2016). Common errors include choosing the wrong product, such as one look-alike name for another; reading a dose in millilitres instead of units; and using an old order after the regimen has changed. An excessive dose can cause life-threatening seizures and coma (Kasprzak & Ho, 2016).

The nurse applies the usual medication checks with extra care:

- **Right product and strength:** read the full name, the type and the concentration on every vial or pen. Colour coding on caps is not a safe check.
- **Units only:** orders and records say "units", written in full; "U" can be misread as a zero.
- **One pen, one patient:** a pen carries a patient-specific label on the barrel, not the cap, and is never used for another patient, even with a new needle. Using one pen for several patients can spread bloodborne infections. Insulin is never drawn from a pen or cartridge with a syringe (Canadian Society of Hospital Pharmacists Ontario Branch & ISMP Canada, 2014).
- **Needles:** a new pen needle is used for each injection. A 4 mm pen needle, held at 90 degrees to the skin, reaches the subcutaneous tissue in adults of any body size (Bari et al., 2020) (Figure 22.3).

Lipohypertrophy is a lump of thickened fatty tissue that forms under skin injected repeatedly at the same spot. Insulin is absorbed poorly and unpredictably from these lumps, raising the risk of both high glucose and hypoglycemia. In one Canadian study, 37% of people who noticed lumps still injected into them (Bari et al., 2020). The nurse looks at and feels injection areas, injects only into healthy tissue and teaches rotation across as large an area as possible.

Figure 22.3 An insulin pen with a pen needle and its outer cap. A new needle is attached for every injection, and the pen is labelled for one patient only. The round device on the left is an injection port, which some people use to reduce skin punctures. (credit: "I-Port Advance and insulin pen (Novorapid), with needle cover" by Marius Vassnes/Wikimedia Commons, CC BY-SA 4.0)

Timing with meals is a common source of harm. Before giving bolus insulin, the nurse confirms the meal tray is present, the patient can eat and no test or procedure will interrupt the meal. When a patient is not eating or is fasting for a procedure, the nurse follows the order or policy and consults the prescriber rather than guessing (sections 22.4 and 22.6). Correction insulin and the problems with sliding-scale insulin alone are discussed in section 22.6.

Employer policy decides which insulin doses need an independent double check by a second nurse. A provincial roundtable judged double checks valuable but not feasible for every subcutaneous dose (Canadian Society of Hospital Pharmacists Ontario Branch & ISMP Canada, 2014). The nurse gives insulin intravenously only when an order, the product monograph and hospital protocol allow it (section 22.5). Patients may keep wearing their own insulin pump or CGM in hospital, or give their own insulin through a self-administration program, only as hospital policy allows. Hospital policies should also say how insulin pumps are managed during MRI and computed tomography (CT) (Korytkowski et al., 2022). The Scope in Practice box in section 22.6 explains who may give and adjust insulin.

Teaching People to Use Insulin

Starting insulin is a big change, and many people worry about needles, low glucose or what insulin says about their illness. The nurse first learns what the person can see, read and do: vision, hand strength and dexterity, memory, language and literacy, and who helps at home. Teaching is short, practical and repeated. The person handles the actual pen or syringe they will use at home, gives a return demonstration and explains the steps back in their own words. An interpreter is used when needed (Chapter 2).

Before discharge the person should be able to give a dose, rotate sites and check for lumps, check glucose, and recognize and treat a low (section 22.4). The person also needs to know what to do on sick days (section 22.6) and whom to call with questions. A hospital self-administration program, where policy allows, lets people practise under supervision. The cost of insulin and supplies can decide whether a plan works, so the nurse asks about coverage and links people to help (section 22.6). Older adults may need simpler regimens and support from family or home care (Chapter 8).

CLINICAL SAFETY

Insulin Is a High-Alert Medication

Most insulin errors follow a few patterns. Each has a simple defence.

- **Look-alike names:** Humulin N and Humulin R, or two clear basal insulins, have been confused (Kasprzak & Ho, 2016). The nurse reads the full product name and type aloud at the bedside and compares it with the order.
- **Units and volume:** an order written as "4 mL" when 4 units was meant is a hundredfold error. The nurse never gives insulin from an order in millilitres or one using "U", and clarifies with the prescriber.
- **Shared or unlabelled devices:** a pen or syringe without the patient's label is not used. Syringes are filled at the bedside, never drawn up ahead and carried unlabelled (Canadian Society of Hospital Pharmacists Ontario Branch & ISMP Canada, 2014).

- **Concentrated products:** U-200, U-300 and U-500 insulins are dialled in units with the pen made for them; insulin is never drawn from a pen or cartridge with a syringe (Canadian Society of Hospital Pharmacists Ontario Branch & ISMP Canada, 2014).
- **Timing:** bolus insulin is given when the meal is in front of the patient, not when the tray is expected.
- **Changes in the plan:** after a new order, the nurse checks that old doses have been stopped in the medication record.

When an error or near miss happens, the nurse checks the patient's glucose, monitors for hypoglycemia, tells the prescriber, and reports the event through the employer's incident system.

Non-Insulin Medications

Most people with type 2 diabetes start with non-insulin drugs. Diabetes Canada recommends metformin as the first glucose-lowering drug. It also recommends specific GLP-1 receptor agonists and SGLT2 inhibitors for heart and kidney protection, whatever the A1C. The guideline's 2024 update advises a GLP-1 receptor agonist or an SGLT2 inhibitor with proven benefit for people at high cardiovascular risk. For people with heart failure or chronic kidney disease, it advises an SGLT2 inhibitor with proven benefit (Shah et al., 2024). Proven benefit belongs to particular drugs. Liraglutide, dulaglutide and injectable semaglutide reduced major cardiovascular events, and canagliflozin, dapagliflozin and empagliflozin protected the kidneys. At the time of the 2024 update, oral semaglutide had not been shown to affect cardiorenal outcomes (Shah et al., 2024; Butalia et al., 2024). Heart failure use is taught in Chapter 18 and kidney disease in Chapter 27.

The nurse needs to know which drugs can cause hypoglycemia. Insulin and the **insulin secretagogues**, drugs that make the pancreas release insulin whatever the glucose level (sulfonylureas and meglitinides), carry the highest risk. Metformin, dipeptidyl peptidase-4 (DPP-4) inhibitors, GLP-1 receptor agonists, SGLT2 inhibitors and thiazolidinediones rarely cause hypoglycemia on their own, but they add to the risk when combined with insulin or a secretagogue (Shah et al., 2024). Weight effects also matter to patients. Insulin, sulfonylureas and thiazolidinediones cause the most weight gain, and GLP-1-based drugs and SGLT2 inhibitors cause weight loss (Shah et al., 2024).

Using the CJMM (Chapter 1, section 1.4), the nurse links each drug to the cues it can produce: a secretagogue with sweating before lunch, an SGLT2 inhibitor with vomiting and fast breathing, a GLP-1 receptor agonist with nausea and poor intake. Several drugs need specific nursing attention:

- **Metformin:** stomach upset is common when it is started. Canadian monographs advise stopping it at the time of or before a procedure with iodinated contrast, holding it for 48 hours afterward, and restarting only once kidney function has been rechecked and found normal. Vitamin B12 is checked at least every 1 to 2 years during long-term use (sanofi-aventis Canada, 2018).
- **SGLT2 inhibitors:** these drugs make the kidneys excrete glucose, so genital yeast infections and urinary tract infections are more common, and fluid loss can lower blood pressure (Lipscombe et al., 2018). They carry a rare but serious risk of **euglycemic diabetic ketoacidosis**: ketoacidosis with glucose that is only mildly raised or even normal. They are held during acute illness with a risk of dehydration, during fasting, and before major surgery (Butalia et al., 2024). Perioperative holds are in Chapter 7, sick-day guidance is in section 22.6 and ketoacidosis is in section 22.5.
- **GLP-1 receptor agonists and tirzepatide:** nausea, vomiting and diarrhea are common, especially as doses rise, so doses are increased slowly (Butalia et al., 2024). Because these drugs slow stomach emptying (Röder et al., 2016), aspiration risk before anesthesia is a concern; planning for procedures is in Chapter 7. Tirzepatide acts on both the GIP and GLP-1 receptors (Butalia et al., 2024).

MEDICATIONS

Non-Insulin Drug Classes

Canadian generic examples, with one key nursing point for each class (Lipscombe et al., 2018; Shah et al., 2024; Butalia et al., 2024). Doses follow the prescriber's order and the Canadian monograph.

- **Biguanide (metformin):** the first-line drug. Stomach upset is common, especially at the start. Held around iodinated contrast as ordered, and the nurse watches for low vitamin B12.
- **SGLT2 inhibitors (canagliflozin, dapagliflozin, empagliflozin):** protect heart and kidneys. The nurse teaches genital hygiene, watches for dehydration and reports nausea, vomiting, abdominal pain or unusual tiredness, which may signal ketoacidosis even when glucose is near normal.

- **GLP-1 receptor agonists (liraglutide, semaglutide; oral semaglutide):** most are given by injection, some once weekly. Nausea is common at the start. They are not combined with DPP-4 inhibitors and are avoided in people with a personal or family history of medullary thyroid cancer.
- **GIP/GLP-1 receptor agonist (tirzepatide):** a once-weekly injection with similar stomach effects. Diabetes Canada's 2024 user's guide noted no data yet showing cardiovascular benefit.
- **DPP-4 inhibitors (alogliptin, linagliptin, saxagliptin, sitagliptin):** taken by mouth, weight-neutral and low in hypoglycemia risk; pancreatitis is rare.
- **Sulfonylureas (gliclazide, glimepiride, glyburide):** insulin secretagogues that cause hypoglycemia, especially with missed meals. Gliclazide is preferred over glyburide.
- **Meglitinide (repaglinide):** a short-acting secretagogue taken with meals; like sulfonylureas it can cause hypoglycemia, so the nurse confirms the patient is eating.
- **Thiazolidinedione (pioglitazone):** the nurse watches for edema and weight gain, which may signal heart failure.

22.4 Hypoglycemia

Definition and Causes

Hypoglycemia is a blood glucose level low enough to cause symptoms or put a person at risk of harm. Insulin and the insulin secretagogues (sulfonylureas and meglitinides; section 22.3) can both cause it, so prevention, quick recognition and prompt treatment all matter (Lega et al., 2023).

Diabetes Canada's 2023 update uses an alert value below 3.9 mmol/L to classify hypoglycemia and grades its severity in three levels (Lega et al., 2023):

- **Level 1:** glucose below normal, often 3.0 to 3.9 mmol/L, with autonomic symptoms.
- **Level 2:** glucose below normal, often below 3.0 mmol/L, with neuroglycopenic symptoms.
- **Level 3 (severe):** any glucose reading with a marked change in mental or physical status, so that the person needs someone else's help to treat it.

Level 3 is defined by the need for help, not by a number.

In hospital, lows usually come from a mismatch between glucose-lowering drugs and glucose supply:

- **Meals:** a tray that is missed, late or only partly eaten after mealtime insulin is given (see the Practice Story in section 22.6).
- **Nothing by mouth (NPO):** fasting for a test or surgery while insulin or a secretagogue continues (Chapter 7); these patients need ready access to oral or IV glucose (Malcolm et al., 2018).
- **Interrupted feeds:** when enteral or parenteral nutrition is stopped, the patient may need IV dextrose so that glucose does not fall (Malcolm et al., 2018).
- **Kidney function:** falling kidney function reduces the clearance of sulfonylureas, and chronic kidney disease raises the risk of severe hypoglycemia (Diabetes Canada, n.d.-b; Lega et al., 2023).
- **Corticosteroid changes:** insulin increased for steroid-induced hyperglycemia must come down when the steroid is tapered or stopped (Malcolm et al., 2018).

Diabetes Canada also lists risk factors for severe hypoglycemia: earlier severe episodes, impaired awareness, long duration of diabetes or of insulin use, autonomic neuropathy, chronic kidney disease, advanced age and frailty, cognitive impairment, low health literacy, food insecurity and a low A1C (Lega et al., 2023). Food insecurity is a structural cause: a person who cannot count on regular meals cannot safely match insulin to food (Chapter 2).

Recognizing Hypoglycemia

Symptoms fall into two groups (Lega et al., 2023):

- **Autonomic (adrenergic):** trembling, palpitations, sweating, anxiety, hunger, nausea and tingling.

- **Neuroglycopenic:** from the brain's shortage of glucose: difficulty concentrating, confusion, weakness, drowsiness, vision changes, slurred speech, headache and dizziness.

Sweating is felt as well as seen: on every skin tone the skin is cool, damp and clammy to touch. Pallor is harder to see on darker skin, where it may appear ash grey or yellow-brown rather than pale, so the nurse inspects the conjunctiva, lips and oral mucosa and compares them with the patient's usual colour (Pusey-Reid et al., 2023).

Impaired awareness of hypoglycemia means the early warning symptoms are blunted or missing, so a person may first show confusion or even lose consciousness (Lega et al., 2023). Diabetes Canada recommends screening people at risk of severe hypoglycemia for impaired awareness at each visit, by history or a questionnaire such as the Gold or Clarke score. Everyone treated with insulin or a secretagogue is also screened for fear of hypoglycemia, which may affect up to about 30% of them. Fear can lead people to aim for higher glucose levels, take less insulin, limit exercise or overeat (Lega et al., 2023).

Some patients need extra vigilance:

- **Older adults:** frail older adults treated with insulin or secretagogues are at particular risk (Lega et al., 2023). Because confusion and drowsiness are neuroglycopenic symptoms, the nurse checks glucose whenever an older adult with diabetes becomes confused, sleepy or unsteady, before the change is put down to delirium (Chapter 8).
- **Beta-blockers:** Canadian monographs warn that beta-blockers may mask early signs of hypoglycemia, such as a fast heart rate, and delay recovery (Sivem Pharmaceuticals, 2021), so other cues matter more.
- **Sleeping patients:** lows can go unnoticed; continuous glucose monitoring (CGM; section 22.2) or more frequent checks, including overnight, help find them (Lega et al., 2023).

Treatment

The nurse treats first and investigates after, following the hospital's hypoglycemia protocol; Diabetes Canada recommends protocols with nurse-initiated treatment (Malcolm et al., 2018). Treatment depends on whether the person can swallow safely (Lega et al., 2023):

- **Level 1 or 2:** give 15 g of fast-acting carbohydrate, preferably glucose or sucrose tablets or solution. Recheck glucose after 15 minutes and give another 15 g if it is still below 3.9 mmol/L.
- **Level 3, conscious and able to swallow:** give 20 g of oral carbohydrate, preferably glucose tablets. Recheck in 15 minutes and give another 15 g of glucose if it is still below 3.9 mmol/L. Glucagon is an alternative.
- **Unable to swallow or unconscious:** give nothing by mouth. Without IV access, give glucagon 1 mg subcutaneously or intramuscularly, or 3 mg intranasally, and call for help (in hospital, the rapid response team, Chapter 6; in the community, 9-1-1). With IV access, IV dextrose is given as ordered or by protocol.

Once glucose is corrected, the person eats the next scheduled meal or snack. If the meal is more than an hour away, they have a snack with 15 g of carbohydrate and a protein source (Lega et al., 2023). Overtreatment is avoided because it causes rebound hyperglycemia.

Nasal glucagon (Baqsimi) is marketed in Canada (Health Canada, n.d.-a). The recommended dose is 3 mg into the nose for adults, and the person does not have to breathe in for it to work (Amphastar Pharmaceuticals, 2024). An unconscious person is turned on their side and given oral carbohydrate once able to swallow safely. The two injectable glucagon products once sold in Canada were discontinued in 2023 and 2024. Health Canada has let a company import a US glucagon injection since May 2023, an arrangement that runs until December 31, 2026, and in June 2026 it authorized a new Canadian glucagon for injection whose launch date had not been announced (Health Canada, 2026). Glucagon works less well after more than two standard drinks of alcohol, prolonged fasting or advanced liver disease (Lega et al., 2023).

Afterward, the nurse documents values, treatment, times and response, reports the episode to the prescriber, and looks for the cause so the order can be reviewed.

Prevention and Teaching

People at risk of severe hypoglycemia should have glucagon prescribed, and support persons should learn to give it; for people at high risk, Diabetes Canada recommends CGM together with a structured education program (Lega et al., 2023). The nurse teaches the person to carry fast-acting glucose, know their own early symptoms, report lows and wear diabetes identification, such as a medical alert bracelet (Lega et al., 2023).

Diabetes Canada's driving chapter advises people taking insulin or secretagogues to consider checking glucose just before driving and at least every 4 hours while driving, and not to drive with glucose below 4.0 mmol/L (Houlden et al., 2018). After treating a low, they wait until glucose is at least 5.0 mmol/L and 40 minutes have passed. Fast-acting carbohydrate stays within reach in the vehicle; if a low starts while driving, they stop safely, remove the keys and treat it.

CLINICAL JUDGMENT

Sweaty and Confused at 0400

Names and details are fictional; this is a composite story.

Mr. Samuel Mensah, 71, has type 2 diabetes and is on day 3 of treatment for pneumonia on a medical unit. He takes evening basal insulin and gliclazide. He ate little at supper. At 0400 the nurse finds him awake, picking at his sheets and unsure where he is.

- **Recognize cues:** His dark-brown skin is cool and damp to touch, and his lips and oral mucosa look ash grey rather than their usual colour. His heart rate is 104. His creatinine rose yesterday. The point-of-care glucose is 2.6 mmol/L.
- **Analyze cues:** Poor intake, a sulfonylurea, basal insulin and falling kidney function all point to hypoglycemia. New confusion could also be delirium or worsening infection, but the glucose explains it and can be treated at once.
- **Prioritize hypotheses:** Severe (level 3) hypoglycemia is the priority, because he needs help to treat it and his brain is short of glucose now.
- **Generate solutions:** He is drowsy but sits up and swallows water safely, so oral glucose is possible. If he could not swallow, glucagon or IV dextrose by protocol would be needed.
- **Take action:** Following the hypoglycemia protocol, the nurse gives 20 g of glucose tablets, stays with him and rechecks in 15 minutes: 4.6 mmol/L. Because breakfast is more than an hour away, she gives a snack with 15 g of carbohydrate and some protein. She informs the most responsible provider using SBAR (Chapter 6), noting the gliclazide and the rising creatinine.
- **Evaluate outcomes:** At 0445 he is oriented and his glucose is 6.1 mmol/L. The nurse documents the event, increases glucose checks as ordered, and confirms with the prescriber how the gliclazide and insulin will be changed before the next doses.

22.5 Hyperglycemic Emergencies: DKA and HHS

How DKA and HHS Develop

Diabetic ketoacidosis (DKA) and **hyperglycemic hyperosmolar state (HHS)** are the two hyperglycemic emergencies of diabetes. Both begin when insulin action falls far short of the body's needs. High glucose spills into the urine and carries water and electrolytes with it, so the person becomes dehydrated (Goguen & Gilbert, 2018).

In DKA, insulin deficiency and high glucagon levels drive the breakdown of fat. The liver turns fatty acids into ketones, mainly beta-hydroxybutyrate and acetoacetate, which are acids. As ketones build up, a metabolic acidosis with a high anion gap develops (Chapter 3). Potassium shifts out of cells, so the serum potassium may be normal or even high at first, although the body as a whole has lost potassium. Diabetes Canada gives typical potassium deficits of 2 to 5 mmol/kg in DKA and 4 to 6 mmol/kg in HHS (Goguen & Gilbert, 2018).

In HHS, a longer period of relative insulin insufficiency, together with too little fluid intake, pushes glucose higher than in DKA. The main features are severe fluid loss and high plasma osmolality, with little or no acidosis. HHS occurs far less often than DKA, and in up to 20% of cases the person had no known diabetes (Goguen & Gilbert, 2018).

DKA is more common in type 1 diabetes, with a reported incidence of 4.6 to 8.0 per 1,000 patient-years, than in type 2 diabetes, where estimates range from 0.32 to 2.0 per 1,000 patient-years (Goguen & Gilbert, 2018). Common triggers include:

- a new diagnosis of diabetes;

- missed insulin doses;
- infection (Chapter 4), heart attack, stroke, an abdominal crisis or trauma;
- thyrotoxicosis, cocaine use and some drugs, such as glucocorticoids and atypical antipsychotics;
- possibly problems with an insulin pump.

HHS shares these triggers and can also follow cardiac surgery or the use of diuretics or lithium. Infection is present in about 40% to 60% of HHS cases (Goguen & Gilbert, 2018).

Euglycemic diabetic ketoacidosis is DKA with a normal or only mildly raised glucose. SGLT2 inhibitors (section 22.3) lower the threshold for DKA, although it was uncommon in trials (no more than 0.1% of treated people). Usual triggers are reducing or omitting insulin, surgery, alcohol, strenuous exercise and eating little carbohydrate (Goguen & Gilbert, 2018). Because the glucose may not look alarming, Diabetes Canada recommends assessing for DKA in anyone taking an SGLT2 inhibitor who has symptoms, even if glucose is not high. Holding these drugs before procedures is covered in Chapter 7.

Recognizing DKA and HHS

Diabetes Canada lists these symptoms and signs of DKA (Goguen & Gilbert, 2018):

- increased urination and thirst, and weakness;
- air hunger, nausea, vomiting and abdominal pain;
- **Kussmaul respirations**, deep and rapid breathing that removes carbon dioxide to offset the acidosis (Chapter 3), and an acetone odour on the breath;
- an altered level of consciousness.

In HHS, fluid loss is usually more severe and consciousness more depressed; seizures or a stroke-like picture can occur. Because HHS develops over a longer period, the nurse asks about a gradual build-up of thirst, urination and drowsiness.

Signs of fluid loss include dry mucous membranes, a fast heart rate, low blood pressure that may drop on standing, and low urine output. On darker skin, changes in colour are less reliable, so the nurse checks the mucous membranes and conjunctiva (which may look ash grey), capillary refill, vital signs and urine output, and compares with the patient's baseline (Pusey-Reid et al., 2023).

Diabetes Canada's diagnostic criteria are summarized in Table 22.3 (Goguen & Gilbert, 2018). DKA is typically defined by an arterial pH of 7.3 or less, a serum bicarbonate of 15 mmol/L or less, an anion gap above 12 mmol/L, and positive serum or urine ketones. Plasma glucose is usually 14.0 mmol/L or higher but may be lower, especially with SGLT2 inhibitors. HHS is typically defined by a plasma glucose of 34.0 mmol/L or higher, a plasma osmolality above 320 mmol/kg, marked fluid loss and minimal acidosis.

Several testing points matter to the nurse. A venous blood gas is usually adequate. A point-of-care capillary beta-hydroxybutyrate test is sensitive and specific for DKA; negative urine ketones do not rule it out. Capillary glucose readings are unreliable in severe acidosis, so laboratory glucose guides treatment (Goguen & Gilbert, 2018).

Table 22.3 DKA and HHS compared at the bedside (Goguen & Gilbert, 2018; original wording)

Feature	DKA	HHS
Who	Much more common in type 1 diabetes; also occurs in type 2 diabetes and with SGLT2 inhibitors	Much less common; up to 20% have no known diabetes
Onset	Usually develops faster than HHS	Develops over a longer period of relative insulin shortage and poor fluid intake
Glucose	Usually 14.0 mmol/L or higher; can be near normal (euglycemic DKA)	Typically 34.0 mmol/L or higher
Ketones	Positive in serum or urine; capillary beta-hydroxybutyrate is a sensitive test	Minimal

Feature	DKA	HHS
Acid–base	pH 7.3 or less, bicarbonate 15 mmol/L or less, anion gap above 12 mmol/L	Minimal or no acidosis
Osmolality	May be raised	Above 320 mmol/kg
Dehydration	Present	Usually more severe
Mental status	Alert to drowsy; may be altered	More often depressed; seizures or stroke-like signs possible
Key treatment points	Fluids, potassium, IV insulin until the anion gap closes; dextrose added as glucose falls	Fluids individualized; potassium; insulin; slow fall in osmolality

Treatment Priorities and Nursing Care

DKA and HHS are treated with a written protocol, ideally in an intensive care unit (ICU) or step-down unit with specialist input. Diabetes Canada's protocol elements are fluid resuscitation, avoiding low potassium, insulin, avoiding a rapid fall in osmolality, and finding the trigger (Goguen & Gilbert, 2018). The nurse carries out each element by order and watches for the problems each one can cause:

- **Fluids first:** IV 0.9% sodium chloride restores circulating volume. The nurse tracks blood pressure, heart rate, urine output and lung sounds, watching for fluid overload in older adults and people with heart or kidney disease.
- **Potassium:** potassium is added to the IV fluid once urine output is established and the serum potassium is below about 5.0 to 5.5 mmol/L. If potassium is below 3.3 mmol/L, insulin is withheld until potassium reaches at least 3.3 mmol/L (Goguen & Gilbert, 2018). The nurse checks the latest potassium before the infusion starts and reports values outside the protocol's limits at once.
- **IV insulin:** a short-acting insulin infusion runs by protocol and continues until the anion gap returns to normal. Once glucose falls to about 14.0 mmol/L, dextrose is added to the IV fluid to hold glucose at 12.0 to 14.0 mmol/L while insulin continues (Goguen & Gilbert, 2018). Insulin infusions are high-alert medications (section 22.3).
- **Monitoring:** vital signs, fluid status, neurologic status, electrolytes, anion gap, osmolality and glucose are checked as often as every 2 hours at first (Goguen & Gilbert, 2018), and bedside glucose every 1 to 2 hours during IV insulin (Malcolm et al., 2018). The protocol sets the exact schedule.
- **Neurologic checks:** osmolality should fall no faster than about 3 mmol/kg per hour. Life-threatening cerebral edema is mainly a risk in children and adolescents; in adults, rapid fluid replacement was linked to it in one study but not another (Goguen & Gilbert, 2018). New headache, vomiting that returns, or a falling level of consciousness is reported at once.
- **Finding the trigger:** the team looks for infection, a cardiac event or another cause. The nurse asks without judgment why insulin was missed; cost, supply problems, fear of hypoglycemia or diabetes distress may lie behind it (section 22.6).

When the anion gap has closed and the person can eat, the team changes to subcutaneous insulin. The first subcutaneous dose overlaps the infusion so that the patient is never left without insulin. Diabetes Canada's in-hospital chapter describes giving short- or rapid-acting insulin 1 to 2 hours, or intermediate- or long-acting insulin 2 to 3 hours, before IV insulin is stopped (Malcolm et al., 2018); the hospital's protocol sets the exact timing.

Deaths from DKA and HHS still occur; about half happen in the first 48 to 72 hours, from the triggering illness, electrolyte problems (especially potassium) or cerebral edema (Goguen & Gilbert, 2018). Any nurse who sees falling consciousness, low blood pressure, falling urine output, chest pain or a potassium outside the protocol's limits calls the rapid response team and reports using SBAR (Chapter 6). Insulin infusions are often assigned to RNs by employer policy; an RPN caring for a patient who develops DKA acts at once and consults the RN as the patient's needs change (Chapter 1, section 1.3). Before discharge, the nurse reviews sick-day guidance (section 22.6).

> GOING DEEPER
>
> **Closing the Gap — Potassium and the Anion Gap in DKA**
>
> *Required for RN students; optional for PN students.*

Insulin moves potassium from the blood into cells. In DKA, the serum potassium often looks normal at first because acidosis and insulin deficiency have shifted potassium out of cells, while urine losses have emptied the body's stores (Goguen & Gilbert, 2018). Once fluids dilute the blood and the insulin infusion starts, potassium moves back into cells and the serum level can fall quickly. Starting insulin when potassium is already below 3.3 mmol/L risks dangerous hypokalemia, which can cause dysrhythmias; this is why insulin waits until potassium reaches at least 3.3 mmol/L (Chapter 3 explains potassium shifts).

Glucose falls faster than ketones clear. If the infusion were stopped when glucose reached a normal value, ketone production would restart. Diabetes Canada therefore uses the anion gap, not the glucose, as the endpoint: IV insulin continues until the anion gap returns to normal, and dextrose is added once glucose reaches about 14.0 mmol/L so that insulin can keep running without causing hypoglycemia (Goguen & Gilbert, 2018). The anion gap is calculated as sodium minus the sum of chloride and bicarbonate (Chapter 3). A gap that falls from 26 to 11 mmol/L shows that ketoacids are clearing, even if glucose has been near target for hours. Capillary beta-hydroxybutyrate may also be used to adjust the insulin.

22.6 Diabetes in Hospital, Complications and Living Well

Glucose Management in Hospital

Illness, stress, steroids, changes in eating and bed rest all disturb glucose control. Diabetes Canada recommends these targets for most adults in hospital, as long as they can be reached safely (Malcolm et al., 2018):

- **Not critically ill:** glucose of 5.0 to 8.0 mmol/L before meals and below 10.0 mmol/L at random times.
- **Critically ill:** glucose kept between 6.0 and 10.0 mmol/L, usually with an IV insulin infusion.

Bedside glucose checks are individualized: before meals and at bedtime for people who are eating, every 4 to 6 hours for people who are NPO or on continuous tube feeds, and every 1 to 2 hours during IV insulin or critical illness. An A1C is measured on admission if none was done in the previous 3 months (Malcolm et al., 2018).

Diabetes Canada recommends a proactive **basal-bolus insulin** plan with correction: basal insulin covers the body's background needs, bolus (mealtime) insulin covers food, and correction insulin treats a high reading before a meal. Basal insulin is not withheld when a person is eating poorly, even if the bolus dose is reduced. **Sliding-scale insulin**, a correction-only approach that gives insulin only after glucose is already high, is discouraged as the sole way to treat high glucose (Malcolm et al., 2018). It supplies no background insulin and reacts after the fact. For a person with type 1 diabetes, a correction-only order leaves them without basal insulin, the setting for DKA (section 22.5). The nurse who sees such an order questions it with the prescriber.

Other situations need planning:

- **Procedures and NPO:** Chapter 7 covers fasting plans and holding drugs before surgery.
- **Corticosteroids:** glucose monitoring may be considered for 48 hours after a steroid is started. A basal-bolus-correction plan works better and more safely than correction-only insulin. Insulin may need changing when the steroid dose changes, including at discharge (Malcolm et al., 2018).
- **Tube feeding:** when feeds are interrupted, IV dextrose may be ordered to keep glucose from falling.
- **Self-management in hospital:** a person who is mentally competent and able to inject insulin and check glucose may manage their own diabetes under hospital policy, with the team's agreement. People using insulin pumps (Figure 22.4) are encouraged to continue them when it is safe and feasible (Malcolm et al., 2018).

Discharge planning starts early. Diabetes Canada recommends written and spoken instructions on how often to check glucose, how to manage hypoglycemia, a reconciled medication list and whom to call, along with communication with the primary care provider, especially when steroids or insulin have changed (Malcolm et al., 2018).

Chronic Complications

Long-term high glucose damages large and small blood vessels and nerves. Coronary disease is covered in Chapter 17, hypertension and peripheral arterial disease in Chapter 19, kidney disease in Chapter 27 and retinopathy in Chapter 36.

Peripheral neuropathy is nerve damage from prolonged high glucose, most often in the feet and legs. High glucose, high triglycerides, a higher body mass index, smoking and hypertension raise its risk (Bril et al., 2018). People notice numbness, tingling and lost sensation in the toes and feet, or sharp, shooting or burning pain. Loss of protective sensation means a stone in a shoe or a burn from hot water can go unnoticed, which is why neuropathy raises the risk of foot ulcers and amputation. Diabetes Canada recommends yearly screening, starting at diagnosis in type 2 diabetes and 5 years after puberty in type 1 diabetes, by testing sensation to a 10 g monofilament or to vibration with a 128 Hz tuning fork at the great toe (Bril et al., 2018). Painful neuropathy may be treated with anticonvulsant or antidepressant drugs, among other options (Bril et al., 2018; Chapter 5).

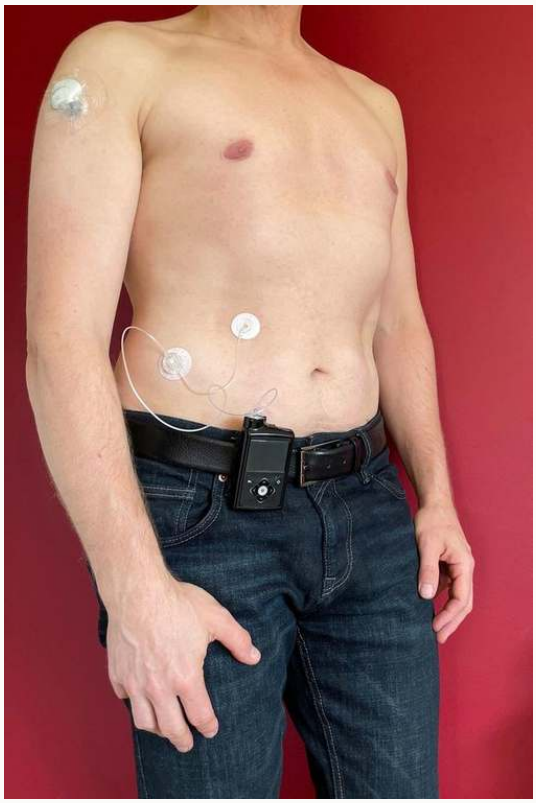

Figure 22.4 An adult with type 1 diabetes wearing an insulin pump on his waistband, with tubing to an infusion set on the abdomen, and a continuous glucose sensor. Pumps deliver rapid-acting insulin continuously, plus doses for meals. (credit: "Diabetic Type 1 adult man with insulin pump and CGM sensor" by Medtd1/Wikimedia Commons, CC BY-SA 4.0)

Autonomic neuropathy affects the nerves that control internal organs (Bril et al., 2018). Signs include:

- **Cardiovascular:** orthostatic hypotension (a systolic drop of more than 20 mm Hg on standing without an adequate rise in heart rate) and a resting heart rate above 100.
- **Gastrointestinal:** gastroparesis (slow stomach emptying), constipation and night-time diarrhea.
- **Bladder:** reduced sensation, incomplete emptying, overflow incontinence and urinary infections (Chapter 28).
- **Sexual:** erectile dysfunction.
- **Sweating:** less sweating in the hands and feet, more on the trunk, or sweating with meals.

These signs change nursing care. Orthostatic hypotension raises fall risk, so the nurse checks lying and standing blood pressure and teaches slow position changes. Autonomic neuropathy is also a risk factor for severe hypoglycemia (Lega et al., 2023).

Foot Care

Lower-limb complications are a major cause of illness and death in diabetes. In Canada, adults with diabetes are 20 times more likely than other adults to be hospitalized for a nontraumatic lower-limb amputation (Embil et al., 2018). Risk factors for ulcers and amputation include peripheral neuropathy, a previous ulcer or amputation, foot deformity, limited joint mobility, other microvascular complications, a higher A1C and fungal nail infection. Amputation rates are not shared equally; Chapter 19 describes higher rates among First Nations people in Ontario and in rural and remote regions.

Diabetes Canada recommends that health-care providers examine the feet at least yearly, and more often for people at high risk (Embil et al., 2018). The examination includes:

- **Neuropathy:** a person who cannot feel a 10 g monofilament on the sole is at higher risk of ulcers and amputation.
- **Skin:** calluses, blisters, cracks, ulcers and signs of infection, including between the toes.
- **Circulation:** pedal pulses and skin temperature (Chapter 19).
- **Structure:** deformities and the range of motion of the ankle and toe joints.
- **Footwear:** fit and wear.

Figure 22.5 A foot ulcer over a Charcot deformity, a collapse of the midfoot bones that can follow neuropathy. The ulcer sits where pressure falls on a foot that has lost sensation. (credit: "Diabetic Charcot Foot Deformity" by Medicalpal/Wikimedia Commons, CC BY-SA 4.0)

Wounds Canada's Inlow's 60-second Diabetic Foot Screen gives a quick, structured way to do this; it scores 12 elements for each foot, needs only a 10 g monofilament and clinical skill, and the scores guide follow-up (Wounds Canada, n.d.).

Redness does not look red on many skin tones. On darker skin, inflammation or infection may appear as a darker, purple or grey area. The nurse compares the area with the surrounding skin and the other foot, feels for warmth with the same hand, and looks for swelling, tightness and pain (Wounds International, 2023). Because neuropathy dulls pain, an ulcer or infection may hurt very little. Diabetes Canada recommends prompt treatment of ulcers or infection by an interprofessional team even when there is no pain. An uninfected neuropathic foot ulcer does not need antibiotics; care includes removing dead tissue, keeping the wound moist and taking pressure off it (offloading) (Embil et al., 2018). A hot, swollen foot may be an acute Charcot foot, which needs immobilization, often for months. Signs of poor circulation call for prompt referral to a vascular specialist. Wound care is covered in depth in Chapter 35.

A **diabetic foot ulcer** is a break in the skin of the foot in a person with diabetes, usually from pressure on a foot that has lost sensation (Figures 22.5 and 22.6). People at high risk need teaching about foot care and footwear fitted by a professional, with early referral to a foot care professional when problems appear (Embil et al., 2018).

Self-Management, Access and Equity

People with diabetes make most of their care decisions themselves, every day. Diabetes Canada recommends collaborative, interactive self-management education and support, delivered by an interprofessional team in groups, one-to-one or both, and supported by text messages or apps (Sherifali et al., 2018). Culturally appropriate programs, which may use peer or lay educators, and materials written for people with lower literacy and numeracy improve results. Gains are seldom kept after 3 months without ongoing support, so the nurse connects the person with a diabetes education program before discharge. Community-led programs in First Nations, Inuit and Métis communities are described in section 22.1.

Sick-day medication guidance tells people which medications to stop for a short time when they are ill and cannot keep up their fluid intake. Dehydration can reduce kidney function, and some drugs then harm the kidneys or build up in the body (Diabetes Canada, n.d.-b). Table 22.4 summarizes the guidance.

Figure 22.6 An arterial ulcer for comparison: a round, punched-out wound on the foot with little drainage, caused by poor blood flow rather than pressure. Many people with diabetes have both neuropathy and arterial disease (Chapter 19). (credit: "Arterial ulcer peripheral vascular disease" by Jonathan Moore/Wikimedia Commons, CC BY 3.0)

Cost shapes self-management. Supplies, CGM sensors and newer drugs are expensive, and public coverage differs across provinces and territories and changes often. In Ontario, for example, the Assistive Devices Program began funding real-time CGM in March 2022 for some people with type 1 diabetes at high risk from hypoglycemia, and as of 2022 the Ontario Drug Benefit program

covered flash glucose monitors for eligible recipients (Ontario Ministry of Health, 2022); coverage has continued to change since then. Diabetes Canada urges care teams to ask about affordability (Robinson et al., 2023), and food insecurity raises the risk of severe hypoglycemia (Lega et al., 2023; Chapter 2).

Living with diabetes is hard work. **Diabetes distress** is the negative emotion and burden of self-management that come from living with diabetes; it affects about one-third (36%) of people with diabetes (Robinson et al., 2023). Diabetes Canada recommends screening everyone with diabetes for distress at appropriate intervals, with tools such as the Diabetes Distress Scale or the Problem Areas in Diabetes scale, and regular screening for symptoms of mental health conditions such as depression. Distress and stigma can make people reluctant to start insulin, and some people use less insulin than prescribed because of its cost (Robinson et al., 2023). The nurse listens without blame, names distress as common, and refers the person for support.

Table 22.4 Sick-day guidance for adults with diabetes (Diabetes Canada, n.d.-b; Goguen & Gilbert, 2018; original wording)

What to do	Why	When to get help
Stop certain medications for a short time if unable to keep up fluids: angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), direct renin inhibitors, diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs) and SGLT2 inhibitors	These drugs raise the risk of reduced kidney function; SGLT2 inhibitors also raise the risk of ketoacidosis	Discuss every medication change, including when to restart, with the care team
Stop metformin and sulfonylureas (gliclazide, glimepiride, glyburide) for a short time if unable to keep up fluids	Reduced clearance raises the risk of adverse effects	Call the care team if glucose runs too high or too low
Follow the sick-day plan for insulin; doses may need adjusting	Missed insulin is a common trigger for DKA	Call the care team for insulin dose advice when glucose is running high or low
Check glucose more often than usual, such as every 2 to 4 hours	Illness can push glucose up or down quickly	Glucose that stays high or low despite treatment
In type 1 diabetes, check blood ketones when glucose stays above 14.0 mmol/L or symptoms of DKA appear	Ketones are an early sign of DKA	Blood ketones above 1.5 mmol/L need further testing for DKA; vomiting, abdominal pain or fast, deep breathing need prompt assessment
Check with a pharmacist before using over-the-counter pain or cold remedies	Many contain NSAIDs	Any doubt about an over-the-counter product

PATIENT EDUCATION

Caring for Your Feet

Diabetes can reduce feeling in your feet and slow blood flow, so you may not notice an injury. These steps protect your feet (Embil et al., 2018):

- Look at your feet and legs every day, including the soles and between the toes.
- Watch for any change in colour (on darker skin, an area may look darker, purple or grey rather than red), warmth, swelling, a blister, a cut or drainage.
- Test bath water with your hand before you step in.
- Wear shoes that fit properly. If your feet are at high risk, ask about professionally fitted footwear.
- Care for your nails regularly. Do not cut corns, calluses or ingrown toenails yourself; see your health-care provider or a foot care specialist.
- Have your feet checked by a health-care provider at least once a year, and more often if you have been told your feet are at high risk.
- See a health-care provider right away if a foot is swollen, warm, discoloured or painful, or if you find a sore, even if it does not hurt.

LIFESPAN CONSIDERATIONS

Older Adults With Diabetes

Targets for older adults depend on health and function, not age alone (Meneilly et al., 2018):

- **Functionally independent older adults:** an A1C of 7.0% or less is suggested when treatment does not include insulin or a sulfonylurea, with glucose of 4 to 7 mmol/L before meals.
- **Frail older adults or those with dementia:** an A1C below 8.5% with low-risk treatment, or 7.1% to 8.5% if treatment includes insulin or a sulfonylurea, with glucose of 6 to 9 mmol/L before meals.
- **End of life:** A1C is not measured; the aim is to avoid symptomatic hyperglycemia and any hypoglycemia.

Older adults with diabetes are at greater risk of falls and fractures, and insulin and sulfonylureas add to that risk. Among the sulfonylureas, Diabetes Canada prefers gliclazide and glimepiride to glyburide in older people (Meneilly et al., 2018). Frail residents of long-term care (LTC) remain at high risk of hypoglycemia; Diabetes Canada recommends avoiding sliding-scale and correction-only insulin protocols for them and suggests regular rather than "diabetic" diets. Deprescribing and falls are covered in Chapter 8.

SCOPE IN PRACTICE

Insulin, Medical Directives and Who Adjusts Doses

Whether a nurse performs a task depends on **authority, competence and context** (Chapter 1, section 1.3); employer policy and the province or territory also matter.

- **Authority to give insulin:** in Ontario, administering a substance by injection is a controlled act that the *Nursing Act, 1991* authorizes for registered nurses (RNs) and registered practical nurses (RPNs) when it is ordered or permitted by regulation (College of Nurses of Ontario [CNO], 2025). Insulin needs a direct (client-specific) order or a directive.
- **Adjusting doses:** a nurse changes an insulin dose only as an order or a medical directive allows, for example a correction-insulin order or a titration protocol. A **medical directive** (CNO's term is "directive") is an order for a group of patients who meet stated conditions; the provider who issues it stays responsible for it (CNO, n.d.-b).
- **Prescribing:** Ontario RNs who prescribe may do so only for the purposes listed in the regulation, such as immunization, contraception and smoking cessation; managing diabetes is not one of the listed purposes (CNO, n.d.-a). RN prescribing is not used in public hospitals.
- **Hypoglycemia protocols:** nurse-initiated treatment by protocol is recommended in hospital (Malcolm et al., 2018).
- **Safeguards:** independent double checks of insulin and insulin infusions follow employer policy (section 22.3).
- **Context:** many employers assign insulin infusions to RNs; an RPN consults the RN when glucose is unstable or the patient's needs change. Rules differ in other provinces and territories.

PRACTICE STORY

The Supper Tray Came Late

Names and details are fictional; this is a composite story.

Nurse: Tomasz Nowak, RN. Years in practice: 4. Setting: medical unit, Ontario.

Mrs. Evelyn Mercier is 76 and was admitted with a urinary infection. She has type 2 diabetes and takes basal insulin at bedtime and insulin aspart with meals. At 1655 I heard the supper cart in the hall. Her glucose was 6.4 mmol/L, so I checked her order, gave her mealtime insulin and moved on to my next patient.

The cart was not ours. It belonged to the unit next door. Our trays were held up because the kitchen was short-staffed, and Mrs. Mercier's tray was being remade after her diet order changed that afternoon.

At 1730 her call bell rang. She said she felt "shaky and hollow." Her hands trembled and her forehead was damp. Her glucose was 3.6 mmol/L.

I knew what had happened. The monograph for insulin aspart says to give it no more than 5 to 10 minutes before a meal, and its onset is within 10 to 20 minutes (Novo Nordisk Canada, 2026). I had given it before I could see her food.

I followed our hypoglycemia protocol. I gave her 15 g of glucose tablets from the unit kit and stayed with her. At 1745 her glucose was 5.2 mmol/L, and her tray arrived a few minutes later. I sat with her while she ate and rechecked her glucose an hour later. It was 7.8 mmol/L.

I told the charge nurse and the physician, documented the event, and filed an incident report. I also apologized to Mrs. Mercier and explained what had gone wrong. She said, "Well, at least you came quickly."

> Our unit now has a simple rule for rapid-acting insulin: the tray is at the bedside, the patient is ready to eat, and then the insulin is given. For a patient who eats unpredictably, we ask the prescriber whether the dose can be given right after the meal. I still hear carts in the hall. I just don't trust them anymore.
>
> Reflect: What cues should the nurse confirm before giving mealtime insulin? If an RPN had given the insulin, which actions would be within the RPN's scope, and when should the RPN involve the RN?

Chapter 22 Summary

Introduction

- About 3.9 million people in Canada aged 1 year and older (9.7%) were living with diagnosed diabetes in 2023–2024.
- Nurses check glucose, give glucose-lowering drugs safely, recognize emergencies and support self-management on every unit.

22.1 Glucose Regulation and Types of Diabetes

- Insulin lowers glucose and holds back fat breakdown and ketone formation; glucagon and stress hormones raise glucose; incretins boost insulin after meals.
- Type 1 diabetes is mainly autoimmune beta-cell destruction with insulin deficiency; type 2 combines insulin resistance with a beta-cell defect.
- Diabetes Canada's risk factors include age 40 or older, family history, membership in listed high-risk populations, prediabetes, vascular risk factors, some conditions and some drugs; higher rates in some communities reflect structural causes, not biology.
- Diabetes is diagnosed by fasting glucose of 7.0 mmol/L or higher, A1C of 6.5% or higher, or a 2-hour or random glucose of 11.1 mmol/L or higher, confirmed on another day when there are no symptoms.
- First Nations data are governed under OCAP®; communities lead prevention programs such as the Kahnawake Schools Diabetes Prevention Project.

22.2 Monitoring Glucose

- Point-of-care glucose testing follows hospital policy; washing and drying hands, using the first drop and avoiding squeezing improve accuracy.
- CGM measures interstitial glucose, which trails blood glucose; symptoms that do not match a sensor reading call for a capillary check.
- Time in range (3.9–10.0 mmol/L) above 70% is the target for most adults, with lows kept under 4% and 1%.
- A1C reflects average glucose over 8 to 12 weeks; targets are individualized, usually 7.0% or less, and higher for frail older adults.
- Blood ketone testing is preferred to urine testing during illness with high glucose in type 1 diabetes.

22.3 Insulin and Non-Insulin Medications

- Insulins are grouped as rapid-acting, short-acting, intermediate-acting, long-acting, premixed and concentrated; the nurse knows each one's onset, peak and duration.
- Insulin is a high-alert medication: read the full product name, use "units", keep pens to one patient and time bolus insulin with the meal.
- Rotating sites and avoiding lipohypertrophy keeps insulin absorption predictable.
- Metformin is first-line; specific SGLT2 inhibitors and GLP-1 receptor agonists are recommended for heart and kidney protection whatever the A1C.
- Insulin and secretagogues cause hypoglycemia; SGLT2 inhibitors can cause euglycemic ketoacidosis; GLP-1-based drugs cause stomach effects.

22.4 Hypoglycemia

- Diabetes Canada's 2023 update uses an alert value below 3.9 mmol/L and three levels; level 3 means the person needs help, whatever the reading.
- In hospital, lows usually come from late or missed meals, NPO status, interrupted feeds, falling kidney function and steroid tapers; food insecurity raises risk at home.
- Autonomic and neuroglycopenic symptoms can be weak or absent with impaired awareness, in frail older adults and with beta-blockers; clammy skin is felt on every skin tone.
- Treat at once by protocol: 15 g of fast-acting carbohydrate (20 g for level 3 if able to swallow), recheck in 15 minutes, then a meal or snack; glucagon or IV dextrose if the person cannot swallow.
- Glucagon 1 mg injected or 3 mg intranasally; nasal glucagon is marketed in Canada, while injectable glucagon has relied on imports since the Canadian products were discontinued in 2023 and 2024.
- Teaching covers carrying glucose, wearing diabetes identification, glucagon for support persons, CGM for high-risk people and Diabetes Canada's driving advice.

22.5 Hyperglycemic Emergencies: DKA and HHS

- DKA combines hyperglycemia, ketones and a high anion gap acidosis; HHS combines extreme hyperglycemia and high osmolality with minimal acidosis.
- Triggers include missed insulin, new diabetes and infection; SGLT2 inhibitors can cause DKA with a near-normal glucose.
- Kussmaul respirations, vomiting, abdominal pain, dehydration and altered consciousness are key signs; HHS causes more severe dehydration and depressed consciousness.
- Treatment follows a protocol: fluids first, potassium replacement, insulin held if potassium is below 3.3 mmol/L, IV insulin until the anion gap closes, and dextrose once glucose reaches about 14.0 mmol/L.
- The nurse monitors closely, watches for falling potassium and neurologic change, finds the trigger and escalates deterioration at once.

22.6 Diabetes in Hospital, Complications and Living Well

- In-hospital targets are 5.0 to 8.0 mmol/L before meals and below 10.0 mmol/L at random times for most patients, and 6.0 to 10.0 mmol/L for critically ill patients.
- Basal-bolus-correction insulin is recommended; sliding-scale insulin alone is discouraged, and basal insulin is not withheld when intake is poor.
- Peripheral and autonomic neuropathy raise the risk of foot ulcers, falls and unpredictable glucose; screening uses a 10 g monofilament or a 128 Hz tuning fork.
- Feet are examined at least yearly; signs of infection are judged by warmth, swelling and change from surrounding skin on every skin tone, and ulcers get prompt interprofessional care.
- Self-management education, sick-day guidance, attention to cost and food security, and screening for diabetes distress support living well.
- RNs and RPNs give and adjust insulin only by order or directive; employer policy and province shape who manages infusions.

Key Terms (41)

A1C: the percentage of hemoglobin with glucose attached, reflecting average glucose over the previous 8 to 12 weeks

acanthosis nigricans: thick, velvety, darker skin in body folds such as the neck and armpits; a sign of insulin resistance

anion gap: the difference between measured positive and negative ions (sodium minus chloride and bicarbonate); a raised gap in DKA shows unmeasured ketoacids, and its return to normal marks resolution (see Chapter 3).

autonomic neuropathy: damage to the nerves that control internal organs, causing problems such as orthostatic hypotension, gastroparesis, bladder dysfunction and sweating changes.

basal insulin: background insulin that controls glucose between meals and overnight

basal-bolus insulin: an insulin plan that combines background (basal) insulin, mealtime (bolus) insulin and correction insulin for high readings.

biosimilar: a lower-cost insulin highly similar to an original brand-name insulin

bolus (prandial) insulin: insulin given with meals to cover the rise in glucose from food

continuous glucose monitoring (CGM): measurement of interstitial glucose every few minutes by a sensor under the skin

correction insulin: extra rapid- or short-acting insulin added to the scheduled dose when glucose is above target

diabetes distress: the negative emotions and burden of self-management that come from living with diabetes.

diabetic foot ulcer: a break in the skin of the foot in a person with diabetes, usually from pressure on a foot that has lost sensation.

diabetic ketoacidosis (DKA): a hyperglycemic emergency in which insulin deficiency leads to ketone production, metabolic acidosis with a high anion gap, and dehydration.

euglycemic diabetic ketoacidosis: ketoacidosis with glucose only mildly raised or normal, a rare risk with SGLT2 inhibitors

euglycemic diabetic ketoacidosis: DKA with a normal or only mildly raised glucose, seen especially with SGLT2 inhibitors.

GLP-1 receptor agonist: a drug that copies the incretin GLP-1, boosting glucose-dependent insulin release, lowering glucagon and slowing stomach emptying

glucagon: the alpha-cell hormone that raises glucose between meals by making the liver release and produce glucose

glucagon: a hormone that raises blood glucose by releasing liver glycogen; given by injection or intranasally to treat severe hypoglycemia when a person cannot swallow.

glucose management indicator (GMI): an estimate of A1C calculated from the mean glucose on a CGM report

high-alert medication: a drug with a heightened risk of serious harm when used in error

hyperglycemic hyperosmolar state (HHS): a hyperglycemic emergency with very high glucose, high plasma osmolality and severe dehydration, but minimal or no acidosis.

hypoglycemia: a blood glucose level low enough to cause symptoms or risk harm; Diabetes Canada's 2023 update uses an alert value below 3.9 mmol/L and grades severity in three levels.

impaired awareness of hypoglycemia: weak or absent warning symptoms of a low glucose, so that confusion or loss of consciousness may be the first sign.

incretins: gut hormones, mainly GLP-1 and GIP, released after meals that boost insulin release when glucose is high

insulin: the beta-cell hormone that moves glucose into cells, stops the liver releasing glucose and holds back fat breakdown and ketone formation

insulin resistance: a reduced response of body cells to insulin, so more insulin is needed to keep glucose normal

insulin secretagogue: a drug, such as a sulfonylurea or meglitinide, that makes the pancreas release insulin whatever the glucose level

ketones: acids made by the liver from fatty acids when insulin is lacking; beta-hydroxybutyrate is the main one in ketoacidosis

Kussmaul respirations: deep, rapid breathing that removes carbon dioxide to offset a metabolic acidosis, as in DKA.

lipohypertrophy: a lump of thickened fatty tissue at an overused injection site, from which insulin is absorbed poorly and unpredictably

medical directive: an order that authorizes care for a group of patients who meet stated conditions; the provider who issues it remains responsible for it.

monofilament testing: a screening test of protective sensation in which a 10 g nylon filament is pressed against the foot; loss of sensation predicts ulcers and amputation.

peripheral neuropathy: nerve damage from prolonged high glucose, mainly in the feet and legs, causing numbness, tingling, pain or loss of protective sensation.

point-of-care glucose testing: bedside measurement of capillary glucose with a meter approved and quality-checked under hospital policy

prediabetes: impaired fasting glucose, impaired glucose tolerance or an A1C of 6.0% to 6.4%; a high risk of developing diabetes

SGLT2 inhibitor: a drug that lowers glucose by making the kidneys excrete it, and protects the heart and kidneys

sick-day medication guidance: advice on which medications to pause for a short time when a person with diabetes is ill and cannot keep up fluids.

sliding-scale insulin: a correction-only approach that gives insulin only after glucose is already high; discouraged as the sole treatment in hospital.

time in range: the percentage of CGM readings between 3.9 and 10.0 mmol/L

type 1 diabetes: diabetes caused mainly by destruction of the pancreatic beta cells, usually autoimmune, leading to insulin deficiency and a tendency to ketoacidosis

type 2 diabetes: diabetes caused by insulin resistance together with a beta-cell defect that leaves insulin output too low

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Gérald Beaulieu (Questions 1–4): Mr. Gérald Beaulieu, 76, has had type 2 diabetes for 14 years and takes metformin and gliclazide. He was admitted to a medical unit in Ontario with a lower leg infection, and his A1C is 9.6%. Before discharge, the prescriber orders insulin glargine once daily at bedtime and asks the registered practical nurse (RPN) to teach him to use a pen. He lives with his wife and has mild arthritis in his hands.

1. [CORE] Which statement by Mr. Beaulieu shows that he understands the purpose of his new insulin?

a. "I take this insulin right before supper so my sugar does not go up after I eat."

b. "If my sugar is normal when I get up, I can skip that night's injection."

c. "Once I start this insulin, I won't need to check my sugar with my meter in the mornings or at bedtime any more."

d. "This insulin works slowly in the background to keep my sugar steady overnight and between meals."

Answer: d — Glargine is a long-acting basal insulin with no peak that controls glucose between meals and overnight (d) (section 22.3, Table 22.2). Covering a meal (a) is the job of a bolus insulin. Basal insulin is not skipped because one reading is normal (b); the prescriber's plan guides any change. Starting insulin makes glucose checks more important, not less (c) (section 22.2).

2. [CORE] During a return demonstration, which action by Mr. Beaulieu requires further teaching?

a. He attaches a new pen needle before the injection.

b. He injects into the same spot near his navel each night because it hurts less there.

c. He inserts the short pen needle straight in at a 90-degree angle.

d. He keeps the pen for his own use and does not lend it to his wife, even with a fresh needle.

Answer: b — Injecting repeatedly into one spot causes lipohypertrophy, from which insulin is absorbed poorly and unpredictably; he needs to rotate across a wide area (b) (section 22.3). A new needle for each injection (a), a 4 mm needle at 90 degrees (c) and never sharing a pen (d) are all correct practice.

3. [CORE] Which teaching point about hypoglycemia is most important for Mr. Beaulieu now that he is starting insulin?

a. Hypoglycemia is unlikely with glargine because it has no peak, so shakiness or sweating at night needs no action.

b. Shakiness, sweating or confusion means checking his meter and treating a low at once, since gliclazide adds to the risk.

c. Low glucose happens mainly in type 1 diabetes, so he can rely on his wife to notice any warning signs and tell him.

d. If he feels unwell or shaky during the night, he should take an extra metformin tablet to steady his glucose until morning.

Answer: b — Insulin and sulfonylureas such as gliclazide carry the highest risk of hypoglycemia, and the risk adds up when they are combined and when meals are missed (b) (section 22.3; recognition and treatment in section 22.4). Basal insulin can still cause hypoglycemia (a). Hypoglycemia occurs in type 2 diabetes treated with insulin or secretagogues (c). Extra metformin does not treat symptoms and is not part of his plan (d).

4. [CORE] Mr. Beaulieu asks the RPN, "If my morning readings are high at home, can I just add a few units on my own?" Which response is most appropriate?

a. "Yes. Most people add 2 units each night until the morning reading is normal, so you can start that at home."

b. "You should never change your insulin dose under any circumstances."

c. "Your prescriber will give you a written plan for changes. Let's confirm you have it and a follow-up visit booked."

d. "If your morning reading is over 10 mmol/L, double that night's dose and call the clinic if it stays high after a week."

Answer: c — Changing an insulin dose requires an order or a written titration plan from the prescriber, and follow-up to review home readings is part of a safe discharge (c) (section 22.3; Scope in Practice box in section 22.6). The RPN cannot invent a titration rule (a, d). Many people safely adjust their own doses using a written plan, so "never" (b) is inaccurate and discourages self-management.

5. [CORE] A 52-year-old man with no symptoms has a fasting plasma glucose of 7.4 mmol/L at a routine visit. What does the nurse expect to happen next?

a. Repeat testing on another day to confirm the result

b. Diagnosis of type 2 diabetes based on this single result

c. Diagnosis of prediabetes, because he has no symptoms

d. No further testing, because one fasting value cannot diagnose diabetes

Answer: a — Without symptoms, a single result in the diabetes range is confirmed by a repeat test on another day, preferably the same test (a) (section 22.1, Table 22.1). One result is enough only when symptoms are present (b). A fasting value of 7.0 mmol/L or higher is in the diabetes range, not the prediabetes range (c). Fasting glucose is a valid test; it needs confirmation, not abandonment (d).

6. [CORE] A 47-year-old woman's A1C is 6.2%. Which interpretation is correct?

a. Prediabetes

b. Normal glucose regulation

c. Type 2 diabetes

d. Well-controlled type 1 diabetes

Answer: a — An A1C of 6.0% to 6.4% falls in the prediabetes range (a) (section 22.1, Table 22.1). It is above normal (b). Diabetes requires an A1C of 6.5% or higher (c). A1C is not used to diagnose or classify suspected type 1 diabetes, and nothing suggests she has it (d).

7. [CORE] Which findings in a 45-year-old patient's history are risk factors for type 2 diabetes listed by Diabetes Canada? Select all that apply.

a. Mother has type 2 diabetes

b. Takes prednisone daily for an inflammatory condition

c. Childhood asthma, now resolved

d. Velvety, darker patches of skin at the back of the neck

e. Age over 40 years

f. Eats a vegetarian diet

Answer: a, b, d, e — A first-degree relative with type 2 diabetes (a), glucocorticoid use (b), acanthosis nigricans (d) and age 40 or older (e) are on Diabetes Canada's list (section 22.1). Past asthma (c) and a vegetarian diet (f) are not listed risk factors.

8. [CORE] A patient on a medical unit has just eaten an orange when the nurse arrives to check her capillary glucose before lunch. What should the nurse do?

a. Wipe the fingertip with an alcohol swab and use the second drop
b. Use her forearm instead of her fingertip
c. Have her wash and dry her hands, then test using the first drop
d. Squeeze the fingertip firmly to get a large drop quickly

Answer: c — Sugar on the skin can falsely raise a reading, so washing and drying the hands and using the first drop gives the most accurate result (c) (section 22.2). Wiping and using a second drop (a) is a fallback only when hands are not visibly soiled or exposed to sugar. Forearm samples lag behind fingertip values (b). Hard squeezing distorts results (d).

9. [CORE] A patient with type 1 diabetes wears a continuous glucose monitor. The sensor shows 4.8 mmol/L, but the patient is sweaty, shaky and says, "I feel low." What should the nurse do first?

a. Check a capillary glucose with the point-of-care meter
b. Reassure the patient that the sensor shows a normal value
c. Remove the sensor and send it back to the manufacturer
d. Wait 30 minutes and recheck the sensor reading

Answer: a — Sensor glucose lags behind blood glucose, especially when glucose is falling fast, so symptoms that do not match the sensor call for a capillary check right away (a) (section 22.2). Reassurance (b) or waiting (d) could delay treatment of hypoglycemia. The sensor may be working correctly; removing it (c) does not help the patient.

10. [CORE] A patient with type 1 diabetes has had vomiting since yesterday and a glucose of 16.5 mmol/L. Which test does the nurse expect to perform, as ordered?

a. A1C
b. Urine glucose
c. Blood ketones
d. Oral glucose tolerance test

Answer: c — People with type 1 diabetes check ketones during illness with high glucose, and blood ketone testing detects ketosis earlier than urine testing (c) (section 22.2; section 22.5). A1C (a) shows average glucose over months, not the current risk. Urine glucose (b) adds nothing to a known high blood glucose. An oral glucose tolerance test (d) is a diagnostic test and is unsafe in this situation.

11. [CORE] An 84-year-old resident with type 2 diabetes, moderate dementia and frailty has an A1C of 7.9%. Which statement about the target is consistent with Diabetes Canada's guidance?

a. An A1C of 7.1% to 8.5% may be an appropriate target, to avoid hypoglycemia.
b. The A1C should be lowered to 7.0% or less, as for most adults.
c. The A1C should be lowered to 6.5% or less to prevent complications.
d. A1C targets do not apply to people with dementia, so glucose is not monitored.

Answer: a — Diabetes Canada suggests 7.1% to 8.5% for frail older adults or people with dementia, because hypoglycemia is the greater danger (a) (section 22.2). The usual target of 7.0% or less (b) and the tighter 6.5% (c) increase hypoglycemia risk in this person. Targets are individualized, not abandoned (d).

12. [CORE] Which medication in a patient's list carries the highest risk of hypoglycemia?

a. Metformin
b. Sitagliptin
c. Empagliflozin
d. Gliclazide

Answer: d — Gliclazide is a sulfonylurea, an insulin secretagogue that makes the pancreas release insulin whatever the glucose level (d) (section 22.3). Metformin (a), the DPP-4 inhibitor sitagliptin (b) and the SGLT2 inhibitor empagliflozin (c) rarely cause hypoglycemia on their own.

13. [CORE] A nurse finds an insulin pen labelled for another patient in a patient's bedside drawer and learns that a colleague used it, with a new needle, to give this patient's dose. What is the most appropriate action?

a. Accept the practice, since a new needle was attached
b. Put the pen back in the correct patient's bin
c. Remove the pen from use, report the event through the incident system and notify the charge nurse
d. Wipe the pen's rubber seal with an alcohol swab and return the pen to the patient it is labelled for

Answer: c — Insulin pens are single-patient devices; sharing one, even with a new needle, can transmit bloodborne infection, so the pen is removed from use and the event is reported (c) (section 22.3). A new needle does not make sharing safe (a). Returning (b) or wiping (d) the pen leaves both patients at risk and hides the event.

14. [CORE] An RPN reviews an order that reads "insulin glargine 14U subcut at bedtime." What should the RPN do?

a. Give 14 units, since the meaning is clear
b. Give 140 units, since "U" is read as a zero
c. Hold the dose and document in the record that the order was unclear, then reassess at the next shift
d. Contact the prescriber to clarify the order and have it written with "units" spelled out

Answer: d — "U" can be misread as a zero, turning 14 units into 140; the safe action is to clarify the order with the prescriber so that "units" is written in full (d) (section 22.3, Clinical Safety box). Giving either dose from an unsafe order (a, b) risks harm. Holding without contacting the prescriber (c) leaves the patient without basal insulin and the order uncorrected.

15. [CORE] A practical nurse (PN) is caring for a patient with type 2 diabetes who takes dapagliflozin. The patient now has nausea, abdominal pain and rapid breathing, and the capillary glucose is 9.8 mmol/L. What is the PN's most appropriate action?

a. Reassure the patient that the glucose is acceptable and offer an antiemetic as ordered
b. Report the findings to the RN or prescriber at once, because they may signal ketoacidosis
c. Give the next dose of dapagliflozin and recheck the glucose before supper
d. Encourage the patient to rest and reassess at the end of the shift

Answer: b — SGLT2 inhibitors can cause euglycemic diabetic ketoacidosis, in which glucose is only mildly raised; these symptoms need urgent escalation and ketone testing as ordered (b) (section 22.3; section 22.5). A near-normal glucose does not rule out ketoacidosis (a). Giving another dose (c) or waiting (d) delays treatment of a possible emergency.

16. [CORE] A patient who takes metformin is scheduled for a CT scan with iodinated contrast. Which nursing action is appropriate?

a. Give metformin as usual, because iodinated contrast does not interact with it and kidney function is unaffected

b. Confirm the order to hold metformin around the scan and that kidney function is rechecked before restarting

c. Stop metformin permanently after the scan

d. Give a double dose of metformin the morning after the scan to make up for the dose held before it

Answer: b — Canadian monographs advise stopping metformin at the time of or before an iodinated contrast procedure, holding it for 48 hours and restarting only after kidney function is confirmed normal (b) (section 22.3). Giving it as usual (a) ignores this advice. The hold is temporary (c). Doubling a dose (d) is never a way to make up a held dose unless ordered.

17. [CORE] A patient starting a once-weekly GLP-1 receptor agonist asks about side effects. Which response is accurate?

a. "Nausea is common, so the dose is raised slowly over several weeks; call if vomiting stops you keeping fluids down."

b. "This medicine often causes low blood sugar on its own, so you will need a snack every 2 hours, including during the night."

c. "The most common side effect is weight gain from fluid retention, so weigh yourself daily and watch your portions."

d. "Side effects are rare, so you do not need to report anything new."

Answer: a — Stomach effects such as nausea, vomiting and diarrhea are common, especially at higher doses, so doses are increased slowly, and vomiting that prevents drinking needs attention (a) (section 22.3). GLP-1 receptor agonists rarely cause hypoglycemia on their own (b) and lead to weight loss, not gain (c). New symptoms should be reported (d).

18. [RN] A patient's 14-day CGM report shows the sensor was worn 92% of the time, time in range 58%, time above 10.0 mmol/L 36%, time below 3.9 mmol/L 6% and time below 3.0 mmol/L 2.5%, with most lows between 0200 and 0500. Which interpretation should the nurse share with the prescriber?

a. The report cannot be used, because time in range is below 70%.

b. Overnight hypoglycemia exceeds the targets and is the first problem to address, even though high values are also common.

c. High glucose is the main problem, so bolus insulin should be increased first.

d. Time below range is within target because it is under 10%.

Answer: b — The report has enough data (worn more than 70% of the time). Time below 3.9 mmol/L should be under 4% and time below 3.0 mmol/L under 1%, so overnight lows are unsafe and are addressed first (b) (section 22.2, Going Deeper box). A low time in range (a) is a finding, not a reason to discard the report. Increasing insulin first (c) could deepen the lows. The targets for time below range are 4% and 1%, not 10% (d).

19. [RN] A patient receives NPH insulin at 0800 and eats breakfast at 0815. When is the patient at greatest risk of hypoglycemia from this dose?

a. 0830 to 0930

b. 1000 to 1100

c. 1300 to 1600

d. 2200 to 0200

Answer: c — NPH insulin peaks 5 to 8 hours after injection, so the highest risk from a 0800 dose falls in the early to mid afternoon, and a late or missed lunch adds to it (c) (section 22.3, Table 22.2). NPH starts working 1 to 3 hours after injection, so the morning hours (a, b) come before its peak. Its action lasts up to 18 hours, but by late evening (d) the effect is waning.

20. [RN] A patient with type 2 diabetes who takes empagliflozin has had a poor appetite for 3 days. Results show glucose 10.8 mmol/L, blood beta-hydroxybutyrate 4.2 mmol/L and a serum bicarbonate of 12 mmol/L. How should the nurse interpret these findings?

a. Glucose is only mildly raised, so ketoacidosis is unlikely.

b. The findings fit hyperglycemic hyperosmolar state.

c. The findings suggest starvation ketosis, which needs only a snack.

d. The findings suggest euglycemic diabetic ketoacidosis, which needs urgent treatment even though glucose is modest.

Answer: d — High blood ketones with a low bicarbonate show ketoacidosis; with an SGLT2 inhibitor and poor intake, it can occur with only a mildly raised glucose (d) (section 22.3; section 22.5; acid–base in Chapter 3). A modest glucose does not exclude it (a). Hyperglycemic hyperosmolar state involves extreme hyperglycemia without significant ketosis (b). Ketones this high with a low bicarbonate are not simple starvation ketosis (c).

Case: Jordan Tremblay (Questions 21–26): Jordan Tremblay, 22, has had type 1 diabetes for 10 years. He comes to the emergency department after 2 days of vomiting; he stopped his insulin because he was not eating. He is drowsy but answers questions. Vital signs: temperature 37.4 °C, heart rate 118, respiratory rate 30 with deep breaths, blood pressure 98/60 mm Hg. Laboratory results: glucose 28.4 mmol/L, venous pH 7.12, bicarbonate 9 mmol/L, sodium 132 mmol/L, chloride 97 mmol/L, potassium 4.8 mmol/L, capillary beta-hydroxybutyrate 5.8 mmol/L.

21. [CORE] Which findings require immediate follow-up? Select all that apply.

a. Respiratory rate of 30 with deep breaths
b. Temperature of 37.4 °C
c. Glucose of 28.4 mmol/L
d. Capillary beta-hydroxybutyrate of 5.8 mmol/L
e. Potassium of 4.8 mmol/L
f. Blood pressure of 98/60 mm Hg with a heart rate of 118

Answer: a, c, d, f — Deep, rapid breathing, high glucose, high ketones and low blood pressure with tachycardia together show ketoacidosis and fluid loss that need treatment now (section 22.5). The temperature is close to normal, although infection is still looked for as a trigger. A potassium of 4.8 mmol/L is within range at this moment; it becomes important once insulin starts, but it is not itself abnormal yet.

22. [CORE] Which explanation best accounts for Jordan's breathing pattern?

a. He is anxious and hyperventilating because of abdominal pain.
b. Fluid is collecting in his lungs because of dehydration.
c. He is breathing off carbon dioxide to offset a metabolic acidosis.
d. Ketones in his blood are irritating his airways and causing bronchospasm.

Answer: c — Kussmaul respirations are deep, rapid breaths that remove carbon dioxide and partly offset the acidosis caused by ketones (section 22.5; Chapter 3). Anxiety does not explain a pH of 7.12. Dehydration does not cause fluid in the lungs. Ketones do not cause bronchospasm.

23. [CORE] Which problem should the nurse treat as the first priority?

a. Fluid loss severe enough to lower his blood pressure
b. Knowledge gap about managing insulin during illness
c. Risk of hypoglycemia once insulin treatment has begun
d. Potential for skin breakdown from drowsiness

Answer: a — Fluid loss with hypotension and tachycardia threatens circulation now, and fluids are the first element of Diabetes Canada's protocol (section 22.5). Sick-day teaching matters before discharge, not first. Hypoglycemia is a later risk that the protocol manages with dextrose. Skin breakdown is a lower priority.

24. [CORE] Which order should the nurse expect to carry out first?

a. A dose of rapid-acting insulin injected subcutaneously
b. An infusion of 0.9% sodium chloride intravenously
c. An infusion of sodium bicarbonate intravenously
d. Oral fluids with electrolytes, encouraged as tolerated

Answer: b — Diabetes Canada's protocol starts with IV 0.9% sodium chloride to restore volume (section 22.5). Insulin is not the first step; it starts after fluids are running and the potassium is confirmed to be at least 3.3 mmol/L. Bicarbonate is considered only for shock or a pH of 7.0 or less. A vomiting, drowsy patient cannot rehydrate by mouth.

25. [CORE] Six hours later, Jordan's insulin infusion is running. His glucose is 13.6 mmol/L and his anion gap is 18 mmol/L. Which action should the nurse anticipate?

a. Stopping the insulin infusion because glucose is now below 14.0 mmol/L
b. Giving his usual long-acting insulin and stopping the infusion right away
c. Adding dextrose to the IV fluid while the insulin infusion continues
d. Lowering the IV fluid rate and giving juice to prevent hypoglycemia

Answer: c — When glucose reaches about 14.0 mmol/L, dextrose is added so that insulin can continue until the anion gap returns to normal (section 22.5). An anion gap of 18 mmol/L shows that ketoacids are still present, so stopping the infusion would let ketosis return. Changing to subcutaneous insulin waits until the gap has closed. Juice does not replace the protocol's dextrose and he may still be vomiting.

26. [CORE] The next morning, which findings show that Jordan's treatment is working? Select all that apply.

a. Anion gap of 11 mmol/L
b. Respiratory rate of 18 with normal depth
c. Potassium of 3.1 mmol/L
d. Alert, oriented and asking for breakfast
e. Urine output of 60 mL per hour
f. Glucose of 3.4 mmol/L

Answer: a, b, d, e — A normal anion gap, normal breathing, improved alertness and good urine output show that acidosis and fluid loss are resolving (section 22.5). A potassium of 3.1 mmol/L shows that potassium has fallen as insulin moved it into cells; it is below the protocol's limit and must be reported at once. A glucose of 3.4 mmol/L is hypoglycemia and needs treatment, not reassurance.

27. [CORE] A patient taking insulin says he feels shaky and sweaty. His glucose is 3.4 mmol/L, and he is alert and able to swallow. What should the nurse do first?

a. Give 15 g of fast-acting carbohydrate and recheck glucose in 15 minutes.
b. Give glucagon 1 mg intramuscularly and call the rapid response team.
c. Ask the kitchen to send his supper tray early and recheck glucose when it arrives.
d. Give 30 g of carbohydrate with protein and recheck in 1 hour.

Answer: a — An alert patient with a level 1 low takes 15 g of fast-acting carbohydrate, preferably glucose, with a recheck after 15 minutes (section 22.4). Glucagon is for people who cannot swallow. Waiting for a tray delays treatment. A larger amount risks rebound hyperglycemia, and a 1-hour recheck is too late.

28. [CORE] Fifteen minutes after treatment for hypoglycemia, a patient's glucose is 5.1 mmol/L. Supper will not arrive for 90 minutes. What should the nurse do next?

a. Give another 15 g of glucose tablets.
b. Hold the patient's mealtime insulin at supper.
c. Recheck glucose in 15 minutes without giving food.
d. Give a snack with 15 g of carbohydrate and a protein source.

Answer: d — Once glucose is corrected, a snack with 15 g of carbohydrate and protein is given if the next meal is more than an hour away (section 22.4). More glucose is not needed at 5.1 mmol/L. Holding insulin is a prescriber's decision. Rechecking alone ignores the long wait before supper.

29. [CORE] A nurse finds a patient with diabetes unresponsive. The point-of-care glucose is 1.9 mmol/L, and the patient has no IV access. Which action is most appropriate?

a. Place glucose gel inside the patient's cheek and wait 15 minutes.
b. Give glucagon 3 mg intranasally and call for help.
c. Start an IV and recheck glucose before giving any treatment.
d. Give juice through a syringe into the side of the mouth.

Answer: b — For an unconscious person without IV access, Diabetes Canada recommends glucagon 1 mg subcutaneously or intramuscularly or 3 mg intranasally, and calling for help (section 22.4). Nothing is given by mouth to an unconscious person because of the risk of aspiration. Starting an IV first delays treatment.

30. [CORE] A patient with type 1 diabetes is NPO for a procedure. The prescriber's order reads "correction insulin by scale only; hold all other insulin." What should the nurse do?

a. Follow the order, because a patient who is not eating does not need insulin.
b. Give half the usual basal insulin without consulting the prescriber.
c. Give the correction scale only if glucose rises above 14.0 mmol/L.
d. Contact the prescriber to question withholding all basal insulin.

Answer: d — Diabetes Canada discourages correction-only insulin as the sole treatment and advises that basal insulin is not withheld when a person is not eating (section 22.6). A person with type 1 diabetes without basal insulin is at risk of DKA. The nurse cannot change the dose on their own. Waiting for a high glucose leaves the patient without basal insulin.

31. [CORE] Which glucose target does Diabetes Canada recommend before meals for most adults in hospital who are not critically ill?

a. 5.0 to 8.0 mmol/L
b. 4.0 to 7.0 mmol/L
c. 6.0 to 10.0 mmol/L
d. 8.0 to 12.0 mmol/L

Answer: a — Diabetes Canada recommends a premeal glucose of 5.0 to 8.0 mmol/L and random values below 10.0 mmol/L if they can be reached safely (section 22.6). A range of 6.0 to 10.0 mmol/L is the target for critically ill patients. The other ranges are not the in-hospital targets.

32. [CORE] A patient with diabetes has the flu and cannot keep fluids down. She takes metformin, ramipril, empagliflozin and insulin glargine. Which statement shows that she understands sick-day guidance?

a. "I will stop all my diabetes medications, including my insulin, until I can eat and drink normally again."
b. "I will keep taking all my pills but skip my insulin to avoid a low."
c. "I will double my metformin, because being sick raises my blood sugar."
d. "I will keep taking my insulin and pause the metformin, ramipril and empagliflozin for now."

Answer: d — When a person cannot keep up fluids, Diabetes Canada's sick-day list advises pausing metformin, ACE inhibitors such as ramipril and SGLT2 inhibitors such as empagliflozin, while insulin continues with dose advice from the team (section 22.6). Stopping insulin risks DKA. Continuing the pills risks kidney injury and ketoacidosis. Doubling metformin is unsafe.

33. [CORE] Which instructions should the nurse include when teaching foot care to a patient with peripheral neuropathy? Select all that apply.

a. Check the bath water with your hand before stepping in.
b. Look at the soles and between the toes every day.
c. Soak your feet in hot water every evening to improve circulation.
d. Remove corns and calluses yourself with a sterile blade.
e. See a provider right away for a sore, even if it does not hurt.
f. Wear shoes that fit properly every time you are on your feet.

Answer: a, b, e, f — Daily inspection, testing water with the hand, properly fitting footwear and seeking care for painless sores protect a foot that has lost sensation (section 22.6). Hot soaks risk burns that the person cannot feel. Corns and calluses are treated by a provider or foot care specialist, not cut at home.

34. [CORE] During a foot examination, a patient cannot feel the 10 g monofilament on several sites on both soles. How should the nurse interpret this finding?

a. The patient has lost protective sensation and is at higher risk of foot ulcers.
b. The patient has peripheral arterial disease and needs an urgent vascular referral.
c. The finding is expected with age and needs no further action.
d. The patient has an active foot infection that needs antibiotics.

Answer: a — Being unable to feel the 10 g monofilament predicts ulcers and amputation and calls for education, footwear and closer follow-up (section 22.6). The monofilament tests sensation, not circulation, which is assessed with pulses and skin temperature. The finding is not a normal part of ageing and does not show infection.

35. [CORE] An older adult is admitted with confusion and severe dehydration. Glucose is 41.0 mmol/L, plasma osmolality is 345 mmol/kg, pH is 7.36 and serum ketones are trace. Which condition do these findings suggest?

a. Diabetic ketoacidosis
b. Euglycemic diabetic ketoacidosis
c. Hyperglycemic hyperosmolar state
d. Level 2 hypoglycemia

Answer: c — A glucose of 34.0 mmol/L or higher, osmolality above 320 mmol/kg, marked dehydration and minimal acidosis match Diabetes Canada's description of HHS (section 22.5). DKA requires acidosis and positive ketones. Euglycemic DKA has a near-normal glucose with acidosis. Hypoglycemia is a low glucose.

36. [CORE] An RPN on a medical unit finds a patient sweaty and confused. The glucose is 2.8 mmol/L. The patient can swallow. The unit has a nurse-initiated hypoglycemia protocol. What should the RPN do first?

a. Ask the RN to assess the patient before any treatment is given.
b. Page the physician for an order before giving glucose.
c. Recheck the glucose in 15 minutes to confirm the reading.
d. Treat the low according to the protocol, then inform the RN and prescriber.

Answer: d — Hospital hypoglycemia protocols allow nurses to start treatment at once (section 22.4), and the RPN has the authority, through the protocol, and the competence to do so (section 22.6). Waiting for the RN or a physician delays treatment of a brain short of glucose. Rechecking without treating wastes time. The RPN then reports the event so the cause can be reviewed.

37. [CORE] An RPN notes that a patient's premeal glucose has been above 14.0 mmol/L at every check for 2 days. There is a correction-insulin order but no order to change the basal dose. What should the RPN do?

a. Increase the bedtime basal insulin by a small amount, since the high pattern is clear and consistent.

b. Give the correction dose as ordered and report the pattern to the RN and prescriber.

c. Hold the next meal and offer only sugar-free fluids to bring the glucose down.

d. Give an extra dose of mealtime insulin at bedtime.

Answer: b — Nurses adjust insulin only as an order or medical directive allows (section 22.6). The RPN gives the ordered correction dose and reports the pattern so the prescriber can change the basal or bolus insulin. Changing the basal dose or giving extra insulin without an order is outside the nurse's authority. Holding a meal is unsafe.

38. [RN] A patient with DKA has a glucose of 9.8 mmol/L. Sodium is 138 mmol/L, chloride 104 mmol/L and bicarbonate 14 mmol/L. The insulin infusion is running with dextrose. What should the nurse anticipate?

a. Continuing the insulin infusion, because the anion gap is still raised

b. Stopping the infusion, because the glucose is now within the target range

c. Changing to subcutaneous insulin now, because the glucose is below 10.0 mmol/L

d. Removing the dextrose from the IV fluid, because glucose is falling too fast

Answer: a — The anion gap is 138 − (104 + 14) = 20 mmol/L, which shows that ketoacids are still present, so IV insulin continues until the gap returns to normal (section 22.5, Going Deeper). Glucose is not the endpoint. The change to subcutaneous insulin waits until the gap closes. Dextrose stays in the IV fluid so insulin can continue safely.

39. [RN] A patient with DKA has a potassium of 3.0 mmol/L before the insulin infusion is started. What should the nurse anticipate?

a. Starting the insulin infusion at once, because insulin will correct the potassium

b. Holding the insulin and giving potassium until it reaches at least 3.3 mmol/L

c. Giving an insulin bolus before replacing potassium

d. Withholding all IV fluids until the potassium is corrected

Answer: b — Diabetes Canada advises withholding insulin until potassium is at least 3.3 mmol/L, because insulin moves potassium into cells and can cause dangerous hypokalemia and dysrhythmias (section 22.5). Insulin lowers potassium further rather than correcting it. Diabetes Canada finds no conclusive evidence for an insulin bolus in adults, and any insulin now would worsen hypokalemia. Fluids continue because the patient is dehydrated.

40. [RN] A patient with suspected HHS has a sodium of 150 mmol/L and a glucose of 48.0 mmol/L. Using Diabetes Canada's formula for effective plasma osmolality, what is the result?

a. 198 mmol/kg

b. 300 mmol/kg

c. 348 mmol/kg

d. 396 mmol/kg

Answer: c — Effective plasma osmolality is (2 × sodium) + glucose: (2 × 150) + 48.0 = 348 mmol/kg, above the HHS threshold of 320 (section 22.5). The value 198 adds sodium and glucose without doubling sodium. The value 300 counts sodium only. The value 396 doubles both sodium and glucose.

23 Thyroid, Parathyroid, Adrenal and Pituitary Disorders

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain endocrine feedback and interpret thyroid, calcium, cortisol and water-balance tests in SI units, recognizing that ranges vary by laboratory.
2. Recognize and care for adults with hypothyroidism and hyperthyroidism, and respond to myxedema coma and thyroid storm.
3. Provide safe care after thyroid and parathyroid surgery, including early recognition of neck hematoma and hypocalcemia.
4. Recognize adrenal insufficiency, adrenal crisis and Cushing syndrome, and teach safe glucocorticoid use and sick-day rules.
5. Care for patients with pituitary tumours and after transsphenoidal surgery, and distinguish SIADH from arginine vasopressin deficiency.
6. Teach patients about endocrine medications, monitoring and emergency identification, with attention to older adults.
7. Distinguish RN and RPN roles in endocrine emergencies using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5	Clinician; Scholar	Foundations of Practice
4, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Hormones from small glands in the neck, the abdomen and the base of the brain set the pace of metabolism, keep calcium and water within narrow limits and help the body survive stress. When one of these glands makes too much or too little hormone, the effects reach every system. The heart may race or slow, thinking may become anxious or dulled, and fluids and electrolytes may shift. Many endocrine disorders develop slowly and are easy to mistake for ageing, depression or another illness. Others, such as thyroid storm, myxedema coma and adrenal crisis, are emergencies in which early recognition by the nurse can save a life.

This chapter covers the thyroid, parathyroid, adrenal and pituitary glands. Section 23.1 explains how feedback loops control hormone levels and how common endocrine tests are collected and read. Section 23.2 covers hypothyroidism, hyperthyroidism and their emergencies, with thyroid nodules and cancer in brief. Section 23.3 describes nursing care after thyroid surgery, including two complications every nurse must recognize early, bleeding into the neck and low calcium, and then the parathyroid disorders. Section 23.4 turns to the adrenal glands, including adrenal insufficiency, adrenal crisis and Cushing syndrome. Section 23.5 covers pituitary tumours and the disorders of water balance.

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1 (sections 1.3 to 1.5). Sodium and calcium imbalances, including the bedside signs of low calcium and the safe limits for correcting low sodium, are in Chapter 3. Recognizing deterioration and calling for help are in Chapter 6, perioperative care in Chapter 7 and older adults in Chapter 8. Atrial fibrillation is in section 16.6, hypertension in Chapter 19, autoimmunity in section 21.6 and steroid-induced high blood glucose in Chapter 22.

23.1 Endocrine Feedback and Testing

Hormones and Feedback Loops

A **hormone** is a chemical messenger that a gland releases into the blood and that acts on target cells elsewhere in the body. Many endocrine glands are controlled through a chain of command called an **axis**. The hypothalamus, at the base of the brain, releases a hormone that stimulates the anterior pituitary gland. The pituitary then releases a stimulating hormone that travels to a target gland, such as the thyroid or the adrenal cortex, which makes the final hormone (Figure 23.1).

The final hormone signals back to the hypothalamus and pituitary. This is **negative feedback**: when the level of the final hormone rises, the hypothalamus and pituitary release less of their stimulating hormones, and when it falls, they release more. Like a thermostat, negative feedback keeps hormone levels within a narrow range.

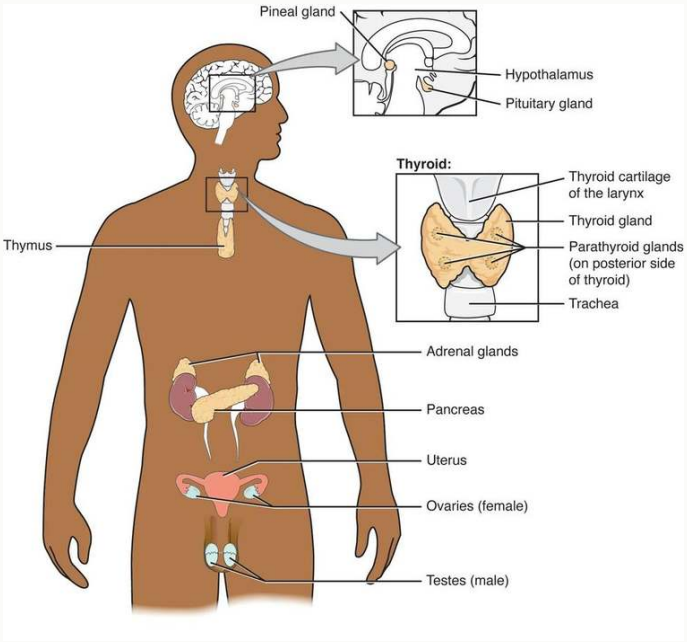

Figure 23.1 The main endocrine glands. The hypothalamus and pituitary at the base of the brain control the thyroid, adrenal cortex and gonads through feedback loops; the parathyroid glands respond directly to blood calcium. (credit: Figure 17.2, “Endocrine System,” in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

In the thyroid axis, the pituitary releases **thyroid-stimulating hormone (TSH)**, also called thyrotropin. TSH drives the thyroid to make thyroxine (T4) and smaller amounts of triiodothyronine (T3). Much of the T4 is converted to the more active T3 in the tissues. Almost all thyroid hormone in the blood is bound to carrier proteins; the small unbound fraction of T4, **free T4**, is the part available to cells.

Because the pituitary responds quickly to small changes in free thyroid hormone, TSH is the most reliable single test of thyroid function in most people (Choosing Wisely Canada, n.d.; Ross et al., 2016). In primary hypothyroidism, the failing thyroid makes too little hormone and the pituitary responds with a high TSH. In hyperthyroidism, excess thyroid hormone suppresses TSH to a low or undetectable level. This mirror-image pattern breaks down when the problem lies in the pituitary or hypothalamus (central disease). Then TSH may be low, normal or only mildly raised even though free T4 is low, so free T4, not TSH, guides care (Garber et al., 2012; Choosing Wisely Canada, n.d.).

Not every gland sits in an axis. The parathyroid glands respond directly to the blood calcium level. When calcium falls, they release more **parathyroid hormone (PTH)**, which raises calcium through bone, the kidneys and activated vitamin D (Chapter 3, section 3.6). The posterior pituitary releases arginine vasopressin, the antidiuretic hormone, in response to the concentration of the blood (section 23.5).

Endocrine Tests the Nurse Sees

Results are always read against the reporting laboratory's reference range, because ranges vary with the laboratory, the method and the population. Typical adult values below come from one Canadian teaching reference (University of Ottawa, 2022).

- **TSH:** 0.4 to 5.0 mU/L (also written mIU/L). TSH is the first test for suspected thyroid disease and for monitoring levothyroxine in primary hypothyroidism. Choosing Wisely Canada (n.d.), with the Canadian Society of Endocrinology and Metabolism, advises against routinely ordering free T4 or T3 with TSH, because the extra tests rarely change management unless disease of the pituitary or hypothalamus is suspected or known.
- **Free T4:** 8.5 to 15.2 pmol/L. Free T4 is added when TSH is outside the reference range, or when disease of the pituitary or hypothalamus is suspected or known (Choosing Wisely Canada, n.d.).

- **Calcium:** total 2.12 to 2.52 mmol/L; ionized 1.14 to 1.28 mmol/L. **Ionized calcium** is the free, active form. Because much of the remaining calcium travels on albumin, a low albumin lowers the total calcium even when ionized calcium is normal. Albumin-adjusted ("corrected") calcium estimates allow for this but can mislead, so ionized calcium is more reliable when results do not fit the patient (Chapter 3, section 3.6).
- **PTH:** read together with a calcium drawn at the same time. A high calcium with a high or "inappropriately normal" PTH points to primary hyperparathyroidism (Bilezikian et al., 2022). A low calcium with a low or inappropriately normal PTH points to hypoparathyroidism (Khan et al., 2022).
- **Cortisol:** a morning serum cortisol, typically 185 to 624 nmol/L. Cortisol is normally highest in the early morning, so the time of collection matters. Stimulation tests, which measure cortisol after a dose of synthetic pituitary hormone, are ordered by specialists; adrenal testing is discussed in section 23.4.
- **Sodium and osmolality:** serum sodium 136 to 144 mmol/L and serum osmolality 275 to 295 mmol/kg, read with urine tests in water-balance disorders (section 23.5).

Much of the nurse's role in testing concerns timing and preparation. The nurse:

- collects time-sensitive samples, such as a morning cortisol, at the ordered time and records the collection time;
- follows the laboratory's instructions about fasting and the timing of medications before a sample;
- asks about **biotin** (vitamin B7) supplements, which are common in hair, skin and nail products. Biotin can interfere with the immunoassays used for thyroid tests and produce false results. The Canadian levothyroxine monograph advises stopping biotin supplements at least 2 days before blood is drawn, when possible (BGP Pharma ULC, 2024);
- tells the prescriber when a result does not fit the patient's condition, because drugs, acute illness and assay problems can all distort endocrine tests.

23.2 Thyroid Disorders

Hypothyroidism

Hypothyroidism is a deficiency of thyroid hormone. When thyroid hormone is low, metabolism slows in every tissue: heat production falls, the heart slows, the gut moves more slowly and thinking can feel dull. Most cases are primary, arising in the thyroid itself. Worldwide, the leading cause is iodine deficiency. Where diets contain enough iodine, the most common cause is **Hashimoto thyroiditis** (chronic autoimmune thyroiditis), in which the immune system gradually destroys thyroid tissue (Garber et al., 2012; section 21.6). About 75% of people with this condition have raised levels of antibodies against the thyroid, such as antibodies to the enzyme thyroid peroxidase (TPO). Other causes include radioactive iodine or surgery for hyperthyroidism, nodules or cancer; radiation to the head and neck; and drugs such as amiodarone, lithium, interferon alfa and some tyrosine kinase inhibitors used in cancer care (Garber et al., 2012). Central hypothyroidism from pituitary disease is uncommon (section 23.5). Canadian data on thyroid disease appear in the Canadian Context box in this section.

Common manifestations are fatigue, feeling cold, dry skin, muscle cramps, a change in the voice and constipation. Others include low mood, menstrual changes, raised cholesterol and slow relaxation of the ankle reflex. Severe disease can cause carpal tunnel syndrome, sleep apnea and low sodium (Garber et al., 2012). These symptoms overlap with many common conditions, especially in older adults. The skin may feel dry, cool and rough. Pallor is easier to see on lighter skin, so on darker skin the nurse checks the inner eyelids, lips and nail beds. Some patients have a **goitre**, an enlarged thyroid seen or felt as fullness at the front of the neck. Because a goitre is confirmed by inspection of the neck's contour and by palpation rather than by colour, it is assessed the same way on every skin tone.

A high TSH with a low free T4 confirms overt primary hypothyroidism. A TSH above the reference range with a normal free T4 is **subclinical hypothyroidism** (Garber et al., 2012; Going Deeper box).

Levothyroxine, a synthetic form of T4, is the standard replacement. It has a narrow therapeutic index, so small changes in dose or absorption change its effect. Products from different manufacturers should not be interchanged without retesting (BGP Pharma ULC, 2024). The dose is adjusted to TSH, which is checked about 6 to 8 weeks after each change and at least yearly once stable. Older

adults and people with heart disease start at lower doses (BGP Pharma ULC, 2024; Garber et al., 2012). Adrenal insufficiency must be treated before levothyroxine starts, because thyroid hormone can trigger an adrenal crisis (BGP Pharma ULC, 2024; section 23.4). Overtreatment is harmful: atrial fibrillation is the most common dysrhythmia in overtreated patients, and long-term overtreatment can reduce bone density. The monograph's boxed warning states that thyroid hormone must not be used to treat obesity or for weight loss (BGP Pharma ULC, 2024).

When TSH swings for no clear reason, the nurse first reviews how the patient takes the drug (Patient Education box). Nursing care also includes tracking energy, bowel pattern, weight, heart rate, mood and cognition, and keeping the patient warm.

Myxedema Coma

Myxedema coma is the most severe form of hypothyroidism, an emergency in which body systems slow to the point of failure. It is rare. The typical patient is an older woman, often with known hypothyroidism, and it often presents in winter. Mortality is high: in one Japanese cohort, 30% died (Ylli et al., 2019). A trigger is usually added to untreated or undertreated disease: cold exposure, infection (especially pneumonia), sedatives and other drugs that depress breathing, low blood glucose, low sodium, or stopping thyroid medication (Ylli et al., 2019).

Despite its name, coma is not required. The cues are:

- a falling level of consciousness, from lethargy to coma, sometimes with seizures;
- hypothermia, which can hide infection because fever and a fast heart rate may be absent;
- bradycardia;
- slow, shallow breathing with carbon dioxide retention;
- low sodium and low blood glucose;
- constipation or ileus, and edema (Ylli et al., 2019).

There is no single confirming test, so treatment starts on clinical suspicion, in an intensive care unit (ICU). The team gives IV thyroid hormone, with lower doses for older adults and people with heart disease. Hydrocortisone is given after a baseline cortisol is drawn, because adrenal insufficiency may coexist and thyroid hormone alone could trigger an adrenal crisis. Broad-spectrum antibiotics are usually started even without fever, and mechanical ventilation is often needed (Ylli et al., 2019). The nurse rewarms passively with ordinary blankets; rapid warming, such as with an electric heating blanket, can dilate blood vessels and cause low blood pressure or shock. Low sodium is corrected slowly (Chapter 3, section 3.4), and fluids are given cautiously (Ylli et al., 2019).

Nursing priorities are airway and breathing (respiratory rate, depth, oxygen saturation and level of consciousness), continuous cardiac monitoring, temperature, glucose and sodium checks, and protecting the skin and airway of a patient who cannot move or swallow safely. The nurse avoids sedatives unless clearly ordered, and calls for help early when a patient with hypothyroidism becomes drowsy, cold or slow to breathe (Chapter 6).

Hyperthyroidism

Thyrotoxicosis is the state caused by too much thyroid hormone acting on the tissues. **Hyperthyroidism** is thyrotoxicosis caused by a gland that makes too much hormone. The main causes are:

- **Graves disease:** an autoimmune disorder in which antibodies (TSH receptor antibodies, or TRAb) stimulate the thyroid like TSH does. It is the most common cause in the United States (Ross et al., 2016).
- **Toxic nodular goitre:** one or more nodules that make hormone on their own. It becomes more common with age and may outnumber Graves disease in older adults (Ross et al., 2016).
- **Thyroiditis:** inflammation that releases stored hormone for a time without increased production. It may be painless, painful (subacute, thought to follow a viral illness) or caused by drugs such as amiodarone. In one Toronto series, painless thyroiditis accounted for 6% of patients with thyrotoxicosis (Ross et al., 2016).

Excess hormone speeds metabolism and causes adrenergic symptoms. Common features include weight loss despite a bigger appetite, palpitations and a fast heart rate, nervousness or anxiety, tremor, muscle weakness, heat intolerance, sweating and diarrhea or more frequent bowel movements (BGP Pharma ULC, 2024; Ross et al., 2016). Untreated disease can cause atrial fibrillation (AF)

with embolic events, bone loss and, rarely, cardiovascular collapse (Ross et al., 2016; section 16.6). The skin may feel warm and moist from sweating. Flushing shows as redness on lighter skin but may be hard to see on darker skin, so the nurse feels for warmth and moisture and asks about heat intolerance.

Thyroid eye disease is an autoimmune disorder of the tissues around the eyes that is closely linked to Graves disease. It causes eyelid retraction, bulging eyes (proptosis), swelling around the eyes, pain, redness and double vision, and rarely damages the cornea or compresses the optic nerve. Smoking, uncontrolled thyroid function and radioactive iodine raise the risk (Burch et al., 2022). Redness of the eyelids may be subtle on darker skin, so the nurse also asks about pain, pressure and changes in vision. Care includes smoking cessation support, avoiding second-hand smoke, lubricants and night-time eye masks, and urgent referral for any threat to sight (Burch et al., 2022; Chapter 36).

TSH is low, often undetectable, with a high free T4, T3 or both. The cause is found with TRAb testing, a radioactive iodine uptake test or ultrasound (Ross et al., 2016).

Treatment has several options (Ross et al., 2016):

- **Beta-blockers** relieve palpitations, tremor and anxiety, especially in older adults and patients with a resting heart rate over 90 beats per minute or heart disease. Nonselective beta-blockers are generally avoided in asthma.
- **Antithyroid drugs** block hormone synthesis. **Methimazole** is preferred for nearly all patients. **Propylthiouracil (PTU)** is preferred in the first trimester of pregnancy and in thyroid storm; the Canadian monograph otherwise reserves it for people who cannot tolerate methimazole, because it can cause severe, sometimes fatal liver injury (Phebra Canada, 2021). Both drugs can cause **agranulocytosis**, a severe drop in neutrophils that is rare but life-threatening and usually appears within the first 3 months (Knight Therapeutics, 2025; Phebra Canada, 2021). The Canadian monographs tell patients to report fever, sore throat or other signs of infection right away; a white blood cell count with differential is checked, and the drug is stopped if agranulocytosis is suspected or found (Knight Therapeutics, 2025; Phebra Canada, 2021). The ATA guideline advises patients to stop the drug and call their physician when such symptoms appear (Ross et al., 2016). A baseline complete blood count and liver tests are recommended (Ross et al., 2016).
- **Radioactive iodine therapy (RAI)** is an oral dose of radioactive iodine that destroys overactive thyroid tissue. It is contraindicated in pregnancy and breastfeeding. Patients receive written radiation safety instructions, and another treatment is chosen if they cannot follow them. Most patients become hypothyroid, usually within 2 to 6 months, and need lifelong levothyroxine. Conception is delayed until thyroid function is stable (Ross et al., 2016). RAI can worsen eye disease, and glucocorticoid prophylaxis may be used (Burch et al., 2022).
- **Surgery** removes most or all of the gland (section 23.3).

Nursing care includes a cool, quiet environment, rest, adequate nutrition, daily weights, heart rate and rhythm checks, eye protection and teaching about adherence, since stopping antithyroid drugs can trigger thyroid storm (Ylli et al., 2019).

Thyroid Storm

Thyroid storm is life-threatening thyrotoxicosis with failure of one or more organs, often set off by another illness (Satoh et al., 2016). It occurs in about 1% to 2% of hospital admissions for thyrotoxicosis (Ylli et al., 2019). In Japanese national surveys, about 11% of patients died, most often from multiple organ failure or heart failure (Satoh et al., 2016). Triggers include stopping antithyroid drugs, infection, surgery, trauma, emotional stress, RAI and large iodine loads (Ylli et al., 2019). Thyroid surgery in a patient who is not yet prepared is a risk, which is why patients are made euthyroid first (Ross et al., 2016).

The cues are an exaggeration of thyrotoxicosis: high fever, marked tachycardia or AF, agitation progressing to delirium or coma, heart failure, nausea, vomiting, diarrhea, jaundice, dehydration and shock. Older adults may present less dramatically (Ylli et al., 2019). Diagnosis is clinical; on the Burch-Wartofsky point scale, a score of 45 or more makes storm likely and 25 to 44 suggests impending storm (Ylli et al., 2019).

Treatment begins in the ICU without waiting for laboratory confirmation. The team blocks new hormone production with a high dose of methimazole or PTU, then gives iodine to block hormone release, at least 30 to 60 minutes after the antithyroid drug, because iodine given first can worsen storm. A beta-blocker controls heart rate, and a glucocorticoid is given. Fever is treated with

acetaminophen and cooling; aspirin is avoided because it raises free thyroid hormone. IV fluids containing dextrose, and treatment of the trigger, complete care (Ylli et al., 2019).

The nurse calls a rapid response (Chapter 6), maintains continuous cardiac monitoring, tracks temperature, fluid balance and mental status, keeps a delirious patient safe and gives drugs in the ordered sequence.

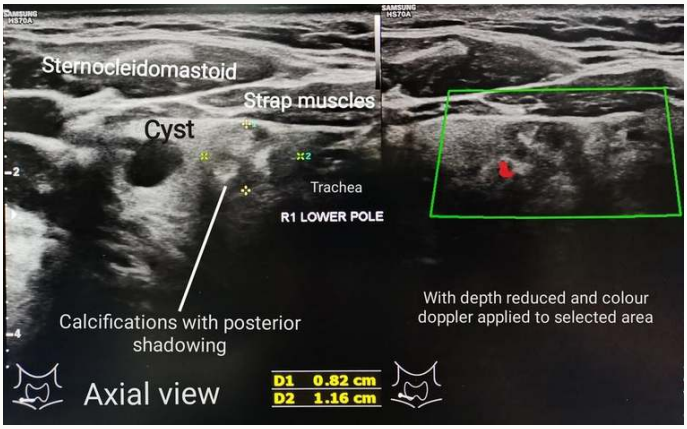

Figure 23.2 Ultrasound of the thyroid, viewed in cross-section: a fluid-filled cyst and a small nodule with bright calcifications. Ultrasound features help decide which nodules need fine-needle aspiration. (credit: "Ultrasound of thyroid showing right lower pole cyst and a calcified nodule" by Cerevisae/Wikimedia Commons, CC BY-SA 4.0)

Thyroid Nodules and Cancer in Brief

Thyroid nodules are a common clinical problem (Haugen et al., 2016). Evaluation aims to find the nodules that need treatment, using imaging (Figure 23.2) and, for selected nodules, **fine-needle aspiration (FNA)**, in which cells are drawn through a thin needle for examination (Haugen et al., 2016). In Canada outside Quebec, thyroid cancer incidence rose steeply from 1984 to 2013, likely because of overdiagnosis, mainly of papillary thyroid cancer. Since 2013, rates have fallen by about 5.4% per year in females, a significant decline, and by about 2.4% per year in males, a change that was not statistically significant (Demers et al., 2022). Cancer treatment is covered in Chapter 9, and care after thyroid surgery in section 23.3.

Table 23.1 Hypothyroidism and hyperthyroidism compared (BGP Pharma ULC, 2024; Garber et al., 2012; Ross et al., 2016; Ylli et al., 2019)

Feature	Hypothyroidism	Hyperthyroidism
Common causes	Hashimoto thyroiditis; after radioactive iodine or surgery; amiodarone or lithium	Graves disease; toxic nodular goitre; thyroiditis
Energy and mood	Fatigue, slowed thinking, low mood	Anxiety, restlessness, tremor
Heart	Slower heart rate; bradycardia in myxedema coma	Fast heart rate, palpitations, atrial fibrillation
Skin and hair	Dry, cool, rough skin	Warm, moist skin; flushing that may be hard to see on darker skin
Weight and appetite	Weight gain may occur	Weight loss, often with increased appetite
Temperature tolerance	Feels cold	Feels hot, sweats
Bowels	Constipation	Diarrhea or more frequent bowel movements
Key test pattern	High TSH, low free T4 (primary disease)	Low or undetectable TSH, high free T4 or T3
Emergency	Myxedema coma: hypothermia, bradycardia, hypoventilation, low sodium, drowsiness	Thyroid storm: fever, marked tachycardia, delirium, heart failure, GI symptoms

The two disorders are compared side by side (Table 23.1).

GOING DEEPER

Reading Thyroid Function Tests

Required for RN students; optional for PN students.

Thyroid tests are read as a pair, TSH with free T4, and always against the laboratory's own range (Garber et al., 2012; Ross et al., 2016).

- **High TSH, low free T4:** overt primary hypothyroidism. TSH is usually above 10 mIU/L.

- **High TSH, normal free T4:** subclinical hypothyroidism. The diagnosis needs stable results over weeks, a normal pituitary and no recent severe illness. Positive TPO antibodies predict a higher yearly rate of progression to overt disease.
- **Low TSH, high free T4 or T3:** overt hyperthyroidism. A mild case may show only a high T3.
- **Low or normal TSH, low free T4:** suggests central (pituitary or hypothalamic) disease. TSH cannot be used to monitor replacement; free T4 is followed instead.

TSH upper limits rise slightly with age, so a mildly raised TSH in a very old adult may not mean disease (Garber et al., 2012). After a dose change, TSH takes weeks to settle: the Canadian monograph advises checking 6 to 8 weeks after each adjustment (BGP Pharma ULC, 2024). A TSH drawn a week after a change is misleading. Biotin, recent dose changes, a switch of levothyroxine product and acute illness are common reasons for a result that does not fit the patient.

PATIENT EDUCATION

Taking Levothyroxine

The nurse teaches the following, using the Canadian monograph (BGP Pharma ULC, 2024):

- Take levothyroxine once a day, on an empty stomach, 30 minutes to 1 hour before breakfast, with water.
- Take it the same way, at the same time, every day.
- Take it at least 4 hours apart from calcium, iron, antacids and other medicines known to block absorption. Some foods, such as high-fibre foods, walnuts and calcium-fortified juice, can also reduce absorption.
- Do not switch brands or generic products without telling the prescriber; a blood test is needed after a switch.
- Expect a TSH test about 6 to 8 weeks after any dose change, and at least once a year when the dose is stable.
- Stop biotin supplements at least 2 days before thyroid blood tests, if possible, and tell the laboratory about them.
- Report a racing or irregular heartbeat, chest pain or tremor (dose may be too high), or tiredness, feeling cold or constipation (dose may be too low).
- Never take thyroid hormone to lose weight.
- Most people need levothyroxine for life; do not stop it without advice.

LIFESPAN CONSIDERATIONS

Thyroid Disease in Older Adults

Older adults. Thyroid disease is easy to miss in later life.

- **Hypothyroidism:** symptoms such as tiredness, constipation, dry skin and slowed thinking are often subtle and overlap with normal ageing, depression or dementia (Garber et al., 2012). A new decline in memory or function prompts a question about thyroid testing. Myxedema coma most often affects older women (Ylli et al., 2019).
- **Hyperthyroidism:** older adults often have fewer of the classic adrenergic symptoms. Weight loss, weakness or new atrial fibrillation may be the only clue (Ross et al., 2016; section 16.6). Toxic nodular goitre is a more common cause than in younger adults.
- **Starting replacement:** levothyroxine is started at a lower dose in older adults and people with heart disease, and the nurse watches for chest pain and palpitations (BGP Pharma ULC, 2024).
- **Overtreatment:** too much levothyroxine raises the risk of atrial fibrillation, and long-term overtreatment can reduce bone density (BGP Pharma ULC, 2024; Chapter 33).
- **Thyroid storm:** may present less dramatically, sometimes as "apathetic" thyrotoxicosis, so a high index of suspicion is needed (Ylli et al., 2019).

Medication reviews and simple written levothyroxine instructions support safe care (Chapter 8).

CANADIAN CONTEXT

Thyroid Disease and Thyroid Cancer in Canada

- **Thyroid cancer:** the Canadian Cancer Society estimates that in 2026, 6,100 people in Canada will receive a thyroid cancer diagnosis and 310 will die of the disease. The estimates are 4,400 diagnoses and 170 deaths in women, and 1,750 diagnoses and 140 deaths in men, reported by sex assigned at birth (Canadian Cancer Society, 2026). Five-year net survival for thyroid cancer in Canada is 97% (Canadian Cancer Society, n.d.).

- **Trends:** in Canada outside Quebec, thyroid cancer incidence rose until 2013 and has fallen since, significantly so in females. The earlier rise was likely due to overdiagnosis, mainly of papillary thyroid cancer (Demers et al., 2022; section 23.2).
- **Hypothyroidism in older adults:** in the Canadian Study of Health and Aging, an estimated 9.6% of people aged 65 and older had hypothyroidism, defined as taking thyroid hormone or having a TSH above 10 mU/L. Some were inadequately treated and some untreated (Krueger et al., 2001). These data are from the 1990s.
- **Equity:** data gaps remain for people who are transgender, non-binary or gender-diverse (Canadian Cancer Society, 2026). People in rural, remote and northern communities, including many First Nations, Inuit and Métis communities, may live far from laboratories, endocrinologists and emergency care. For them, an emergency injection kit, family training and a clear plan for follow-up blood tests close to home matter even more.

23.3 Thyroid and Parathyroid Surgery

Care After Thyroidectomy

Thyroidectomy is the removal of all (total) or part of the thyroid gland, for nodules, cancer, a large goitre or hyperthyroidism. Before surgery for Graves disease, patients are made euthyroid with antithyroid drugs and receive a short course of iodine just before the operation, and calcium and vitamin D levels are checked and corrected (Ross et al., 2016). General perioperative care, including airway care after anesthesia, is in Chapter 7 (Figure 23.3).

Figure 23.3 A healing scar 2 months after total thyroidectomy. The incision lies low across the front of the neck.

After surgery, the nurse watches closely for problems in the neck. A consensus guideline from the Difficult Airway Society and surgical partners recommends observations at least hourly for the first 6 hours, including inspection of the wound, an early warning score and a pain score. After that, frequency depends on the patient's risk and local policy (Iliff et al., 2021, 2022).

Neck hematoma is a collection of blood under the incision. Blood collecting in the closed space of the neck can press on the airway, so a hematoma is an airway emergency. Cues include:

- swelling of the neck or a tense, firm wound;
- pain, pressure or a feeling of tightness;
- difficulty swallowing or a change in the voice;
- noisy breathing (stridor), breathlessness or falling oxygen saturation;
- anxiety, agitation or discomfort that seems out of proportion (Iliff et al., 2021).

The dressing may look nearly dry, because the blood collects deep in the wound. When a hematoma is suspected, the nurse calls for help at once and stays with the patient. The guideline calls for immediate senior surgical review on site and senior anesthesia help if the airway is compromised. Meanwhile, the patient is nursed head-up (sitting up) and given oxygen (Iliff et al., 2021). In Canadian hospitals this usually means activating the rapid response or emergency team and calling the surgeon, following employer policy (Chapter 6).

The same guideline describes a bedside procedure to release the blood, summarized as SCOOP: skin exposure, cut sutures, open skin, open muscles, pack the wound. An emergency box with scissors, a staple remover, gauze and a copy of the procedure stays at the bedside (Iliff et al., 2021, 2022). Who may open the wound depends on employer policy, orders or medical directives, and the nurse's training (Clinical Safety box).

The **recurrent laryngeal nerves** run close behind the thyroid and control the vocal cords. Temporary or permanent injury to these nerves, or to the superior laryngeal nerve, is a recognized complication (Ross et al., 2016). The nurse compares the voice after surgery with the patient's usual voice and reports new hoarseness, a weak voice or cough, coughing when drinking or noisy breathing. A voice change together with neck swelling points to a hematoma and is treated as an emergency.

Low calcium is the other complication every nurse watches for. The parathyroid glands sit behind the thyroid and can be bruised, lose their blood supply or be removed during surgery, so PTH falls and calcium falls with it. Surgery causes about 75% of all cases of hypoparathyroidism, and about 70% to 80% of people with parathyroid failure after surgery recover within a month (Khan et al., 2022). Calcium, with or without PTH, is measured after surgery, and calcium and calcitriol are given according to the results or as prophylaxis (Ross et al., 2016).

Early cues are numbness and tingling around the mouth and in the fingers and toes, then muscle cramps or stiffness. Tetany and seizures can follow (Khan et al., 2022). The bedside signs of low calcium (Figure 3.5 shows a positive Trousseau sign) and IV calcium treatment are taught in Chapter 3. The nurse asks about tingling at every assessment and reports symptoms at once.

After a total thyroidectomy, the patient needs levothyroxine for life, started after surgery at a dose suited to the patient. Antithyroid drugs stop at surgery, and beta-blockers are tapered (Ross et al., 2016). Discharge teaching covers wound care, signs of bleeding, calcium symptoms, levothyroxine and follow-up blood tests. For patients from rural, remote and northern communities, including many First Nations and Inuit communities, surgery may be far from home, so the plan confirms where follow-up tests will be done.

Parathyroid Disorders

In **primary hyperparathyroidism**, one or more parathyroid glands make too much PTH, raising blood calcium. About 85% of sporadic cases are caused by a single benign adenoma (Bilezikian et al., 2022). Most cases are now found by chance, when a routine blood test shows a high calcium (Bilezikian et al., 2022). The diagnosis is a high albumin-adjusted calcium with a high or inappropriately normal PTH, confirmed on two occasions at least 2 weeks apart.

The old memory aid "stones, bones and groans" describes the effects. "Stones" are kidney stones, which are found without symptoms in up to 22% of people with asymptomatic disease. "Bones" refers to bone loss, with a higher risk of spine and other fractures. "Groans" refers to symptoms of high calcium, such as thirst, frequent urination, nausea, constipation and confusion (Bilezikian et al., 2022; Chapter 3, section 3.6).

Parathyroidectomy, removal of the overactive gland or glands, is the only cure. Surgery is recommended for people with symptoms, and for those without symptoms who meet set criteria. These include age under 50, a calcium more than 0.25 mmol/L above the upper limit of normal, osteoporosis or a spine fracture, and kidney stones or reduced kidney function (Bilezikian et al., 2022). People who do not have surgery have yearly calcium and kidney tests and bone density scans every 1 to 2 years. Cinacalcet can lower calcium when surgery is declined or not appropriate (Bilezikian et al., 2022). After parathyroidectomy, the nurse watches for neck hematoma and low calcium, as after thyroid surgery (Chapter 3).

Hypoparathyroidism is too little PTH, which leads to low calcium. It is most often caused by neck surgery and is considered permanent when it lasts more than 12 months after the operation. The diagnosis is a low calcium with a low or inappropriately normal PTH (Khan et al., 2022). Standard treatment is oral calcium with an active form of vitamin D such as calcitriol. The target is a calcium in the lower half of the normal range or just below it. PTH replacement is considered when standard therapy is not enough (Khan et al., 2022).

Overtreatment also harms: high urine calcium can cause kidney stones, calcium deposits in the kidneys and loss of kidney function, so calcium is checked within several days of any major change in treatment (Khan et al., 2022). The nurse teaches the patient to take calcium and calcitriol exactly as prescribed, to report tingling or cramps, and to report thirst, nausea, constipation or confusion, which can mean calcium is too high.

CLINICAL SAFETY

Swelling in the Neck After Thyroid Surgery

Bleeding into the neck after thyroid or parathyroid surgery can block the airway within minutes. The nurse treats any of these as an emergency (Iliff et al., 2021, 2022):

- swelling of the neck, a tense wound or a feeling of tightness or pressure;
- difficulty swallowing, a change in voice or noisy breathing;
- rising breathing rate, falling oxygen saturation, anxiety or agitation.

What the nurse does:

- Calls for help at once (rapid response or emergency team and the surgeon, following employer policy) and stays with the patient.
- Positions the patient head-up (sitting up) and gives oxygen.
- Brings the bedside emergency box and prepares for the airway team.
- Does not wait for a dressing to soak through; blood can collect deep in the wound.

The UK consensus guideline describes opening the wound at the bedside (SCOOP: skin exposure, cut sutures, open skin, open muscles, pack) and calls for training, ideally with simulation, for all staff who care for these patients (Iliff et al., 2021, 2022). In Canada, whether a nurse may open the wound depends on employer policy, an order or medical directive, and the nurse's own competence (Chapter 1, section 1.3). Every nurse can recognize the signs, call for help and prepare.

23.4 Adrenal Disorders

The Adrenal Glands

Each adrenal gland, on top of a kidney, has an outer **adrenal cortex**, which makes steroid hormones, and an inner **adrenal medulla**, which releases the catecholamines epinephrine and norepinephrine. Three hormone groups matter at the bedside:

- **Cortisol:** the main glucocorticoid, released under the control of adrenocorticotropic hormone (ACTH) from the pituitary (section 23.1). Without enough cortisol, blood pressure falls and fatigue and, at times, low glucose follow (Bornstein et al., 2016).
- **Aldosterone:** the main mineralocorticoid, controlled mostly by the renin–angiotensin system (Chapter 3). It makes the kidneys hold sodium and water and excrete potassium (Adler et al., 2025).
- **Catecholamines:** fast-acting stress hormones that raise heart rate and blood pressure; excess causes the pheochromocytoma episodes described below (Hypertension Canada, n.d.).

Illness, injury, surgery, procedures and labour all raise the need for cortisol. A person who cannot make extra cortisol can become dangerously ill from stress a healthy person would tolerate (Society for Endocrinology, n.d.).

Adrenal Insufficiency

Adrenal insufficiency means the adrenal glands do not supply enough cortisol, with or without enough aldosterone. Its cause determines which hormones are missing:

- **Primary adrenal insufficiency (Addison disease):** the adrenal cortex itself is damaged, so cortisol and often aldosterone are low, and ACTH and renin rise. In Western countries, autoimmune destruction causes up to 90% of cases; other causes include tuberculosis, removal of the adrenals, cancer, adrenal bleeding during anticoagulant therapy and genetic conditions. People with autoimmune adrenal disease are screened periodically for other autoimmune conditions such as thyroid disease and diabetes (Bornstein et al., 2016; section 21.6).

- **Secondary adrenal insufficiency:** pituitary or hypothalamic disease, including pituitary tumours and surgery (section 23.5), lowers ACTH. Aldosterone is usually preserved because the renin–angiotensin system still works (Bornstein et al., 2016).
- **Glucocorticoid-induced adrenal insufficiency:** long-term glucocorticoid medication suppresses the hypothalamic–pituitary–adrenal (HPA) axis, so the adrenals stop making cortisol on their own. At least 1% of the population takes glucocorticoids long term. Risk comes from oral courses of 3 to 4 weeks or longer above the body's normal daily output, high-dose or long-term inhaled or topical products, joint injections in the past 2 months, and several products used together (Beuschlein et al., 2024). Any route can suppress the axis (Society for Endocrinology, n.d.).

Manifestations develop slowly and are easy to dismiss: fatigue, weight loss, poor appetite, dizziness on standing, abdominal discomfort, and back or leg cramps. Salt craving is the most specific symptom. Blood pressure is low, with a larger than usual drop on standing. Hyponatremia occurs in primary and secondary disease, but hyperkalemia only in primary disease, which removes aldosterone (Arlt & Society for Endocrinology Clinical Committee, 2016; Bornstein et al., 2016). More than half of patients first come to diagnosis through a crisis (Arlt & Society for Endocrinology Clinical Committee, 2016).

In primary disease, high ACTH causes **hyperpigmentation**, most noticeable on sun-exposed skin, skin creases such as the palms, the gums and inner cheeks, scars and the areolae (Bornstein et al., 2016). On darker skin, a general deepening of colour is easy to miss. The nurse asks whether the skin has darkened, compares creases, gums and scars with the person's usual colour, and inspects in natural light, because visual assessment alone is unreliable (Pusey-Reid et al., 2023). In secondary disease the skin may instead look unusually pale (Arlt & Society for Endocrinology Clinical Committee, 2016).

Diagnosis starts with cortisol and ACTH measured together (section 23.1). In the confirmatory corticotropin stimulation test, a cortisol peak below 500 nmol/L (assay dependent) after IV synthetic ACTH indicates adrenal insufficiency; if that test is not possible, an early-morning cortisol below 140 nmol/L, measured with ACTH, suggests adrenal insufficiency until it can be confirmed; a very high ACTH points to primary disease (Bornstein et al., 2016). During a glucocorticoid taper, a morning cortisol above 300 nmol/L suggests recovery (Beuschlein et al., 2024). Ranges vary by laboratory.

Treatment is lifelong replacement, usually hydrocortisone in two or three daily doses with the largest on waking. Dexamethasone is not suggested for replacement because it causes Cushing-like effects. People with primary disease who lack aldosterone also take fludrocortisone and should not restrict salt. Doses are adjusted by weight, lying and standing blood pressure, energy and signs of excess, not by blood levels (Bornstein et al., 2016).

Never stopping abruptly is the central safety rule. Sudden withdrawal after long-term use can cause fatal acute adrenal insufficiency, and suppression can last for months after therapy ends (Pfizer Canada ULC, 2025). Courses shorter than 3 to 4 weeks can usually stop without a taper; longer courses are tapered by the prescriber (Beuschlein et al., 2024).

In hospital, the nurse:

- asks about every glucocorticoid, including inhalers, creams and recent joint injections, during medication reconciliation;
- gives replacement doses on time and reports any missed dose;
- tells the prescriber at once when a patient cannot take oral doses or has prolonged vomiting or diarrhea, because parenteral glucocorticoids are then recommended, as they are for procedures under general or regional anesthesia (Beuschlein et al., 2024; Chapter 7);
- knows that thyroid hormone started before glucocorticoid replacement in untreated adrenal insufficiency can precipitate a crisis (BGP Pharma ULC, 2024; section 23.2).

Adrenal Crisis

Adrenal crisis is a life-threatening emergency: during illness or other stress, the adrenal glands cannot supply the extra cortisol the body needs. Its main features are hypotension and volume depletion. In one study, gastrointestinal illness and other infections were the most common triggers; surgery, procedures, injury, missed doses and abrupt withdrawal are others (Bornstein et al., 2016; Society for Endocrinology, n.d.).

The nurse recognizes a crisis from these cues (Arlt & Society for Endocrinology Clinical Committee, 2016; Bornstein et al., 2016):

- severe weakness, dizziness, fainting, low blood pressure or a drop of 20 mm Hg or more on standing, progressing to shock;

- nausea, vomiting and abdominal pain, which can mimic an acute abdomen;
- fever, confusion, drowsiness, delirium or coma;
- hyponatremia, hyperkalemia in primary disease, rising creatinine and, at times, low glucose.

In an older adult, confusion may be blamed on delirium (Chapter 8) and low blood pressure on sepsis (Chapter 4). Adrenal crisis is considered in anyone who takes or recently took glucocorticoids and has hemodynamic instability, vomiting or diarrhea, whatever the type, route or dose (Beuschlein et al., 2024).

Treatment is immediate, and tests must never delay it (Society for Endocrinology, n.d.). The Endocrine Society and Society for Endocrinology guidelines recommend these steps for adults (Arlt & Society for Endocrinology Clinical Committee, 2016; Bornstein et al., 2016):

- **Hydrocortisone:** 100 mg IV or IM at once, then 200 mg per 24 hours, either as a continuous IV infusion or as 50 mg IV or IM every 6 hours.
- **Fluids:** 1,000 mL of isotonic saline within the first hour, then IV fluid as needed, watching for overload in older adults and people with kidney impairment.
- **Monitoring:** blood pressure, lying and standing when safe; fluid balance; electrolytes, creatinine and glucose.
- **Expert help:** urgent endocrinology input and treatment of the trigger.

The nurse calls for help (the rapid response team in hospital, 9-1-1 in the community; Chapter 6), obtains IV access, gives hydrocortisone under an order or medical directive, and reports using SBAR. Blood for cortisol is drawn first only if it causes no delay (Arlt & Society for Endocrinology Clinical Committee, 2016). As cortisol is replaced, sodium can rise faster than intended (Society for Endocrinology, 2022; Chapter 3).

Prevention rests on teaching: sick-day rules, a steroid emergency card, medical alert identification, and a glucocorticoid emergency injection kit with training for the patient and family (Bornstein et al., 2016). In an international survey, only 12% of patients with primary disease who had a crisis in the previous year had injected themselves (Bornstein et al., 2016). The Practice Story at the end of section 23.5 shows a long-term care nurse recognizing a crisis early.

PATIENT EDUCATION

Steroid Sick-Day Rules and Medical Identification

People who take glucocorticoids for adrenal insufficiency, or who have taken them long term, follow the sick-day plan their prescriber writes (Beuschlein et al., 2024). For people taking hydrocortisone replacement for adrenal insufficiency, the nurse teaches these points from the Endocrine Society guideline (Bornstein et al., 2016):

- **Never stop or skip** your glucocorticoid. Refill your prescription before you run out.
- **Fever or illness:** if you have a fever of 38 °C or higher or an illness that keeps you in bed, or you start antibiotics, double your usual oral dose until you recover, which usually takes 2 to 3 days. For a fever of 39 °C or higher, triple it. Drink extra fluids that contain salt.
- **Vomiting or unable to keep pills down:** use your emergency hydrocortisone injection, or have a family member give it, and then go to hospital. The same applies after a serious injury.
- **Procedures and surgery:** tell the team you take glucocorticoids; you will need extra coverage.
- **Warning signs:** severe weakness, dizziness or fainting, vomiting, abdominal pain or confusion need emergency care. Call 9-1-1.
- **Carry identification:** wear medical alert jewellery and carry a steroid emergency card. Show the card to every health care provider, including paramedics and emergency staff.
- **Practise:** check your kit's expiry date, and practise the injection with the people you live with.

Cushing Syndrome

Cushing syndrome is the group of signs and symptoms caused by prolonged, inappropriately high exposure of tissues to glucocorticoids. The most common cause is prescribed glucocorticoid medication (Nieman et al., 2008). Less often, the body makes

too much cortisol itself, either because a tumour secretes excess ACTH (a pituitary tumour in Cushing disease, section 23.5, or a tumour elsewhere) or because an adrenal tumour overproduces cortisol (Nieman et al., 2008).

The features that best separate Cushing syndrome from common conditions are easy bruising, a full, flushed face (facial plethora), weakness of the proximal muscles (trouble rising from a chair or climbing stairs) and wide **striae**, or stretch marks (Nieman et al., 2008). The guideline highlights reddish-purple striae more than 1 cm wide, which is how new striae look on lighter skin. On darker skin, striae are often brown to black, and in one study they often looked white or skin-coloured in Black women; colour depends on stage and baseline skin tone (Elbuluk et al., 2025). The nurse therefore notes width, number and new appearance rather than colour alone, and compares facial colour with the person's usual appearance (Pusey-Reid et al., 2023; Figure 23.4).

Figure 23.4 Striae in a person with Cushing syndrome. On lighter skin, new striae are often red-purple, as here; on darker skin they are often brown to black, or may look pale. (credit: “Striae” by PanaromicTiger/Wikimedia Commons, CC BY-SA 3.0)

Less specific features include weight gain around the trunk, a fat pad behind the neck, thin skin, acne, excess hair growth, menstrual changes and depression. Hypertension, type 2 diabetes, vertebral osteoporosis, low potassium and unusual infections overlap with Cushing syndrome, which is more likely when they appear at a younger age than expected (Nieman et al., 2008). Glucocorticoids raise glucose (Chapter 22), increase infection risk and can mask its signs, and can cause mood changes from euphoria and insomnia to severe psychiatric reactions (Pfizer Canada ULC, 2025). Bone loss is a lasting concern (Chapter 33).

Diagnosis begins with a thorough drug history to exclude glucocorticoid medication. First-line tests include two 24-hour urine free cortisol collections, two late-night salivary cortisol samples taken between 2300 and 2400 hours, or an overnight dexamethasone suppression test, in which a morning cortisol above 50 nmol/L is abnormal (Nieman et al., 2008). The nurse teaches sample timing and how to complete a 24-hour collection.

Treatment depends on the cause. For medication-induced disease, the prescriber uses the lowest effective dose and tapers when possible, and patients are taught at the start about weight gain, high glucose, high blood pressure and bone loss (Beuschlein et al., 2024). Tumours are often treated with surgery, such as transsphenoidal surgery (section 23.5) or adrenalectomy (Nieman et al., 2008).

Nursing care focuses on fall prevention and gentle handling of thin, easily bruised skin; monitoring of blood pressure, glucose, weight and potassium; early reporting of low-grade fever, a new cough or a subtle wound change; and attention to mood, sleep and body image. Table 23.2 compares adrenal insufficiency with Cushing syndrome.

Table 23.2 Adrenal insufficiency and Cushing syndrome compared (Arlt & Society for Endocrinology Clinical Committee, 2016; Beuschlein et al., 2024; Bornstein et al., 2016; Elbuluk et al., 2025; Nieman et al., 2008)

Feature	Adrenal insufficiency	Cushing syndrome
Problem	Too little cortisol (and aldosterone in primary disease)	Too much glucocorticoid for a prolonged time
Most common causes	Autoimmune adrenal damage; pituitary disease; stopping or reducing long-term glucocorticoids	Prescribed glucocorticoids; pituitary or adrenal tumour

Feature	Adrenal insufficiency	Cushing syndrome
Weight and appetite	Weight loss, poor appetite, salt craving	Weight gain around the trunk, fat pad behind the neck
Blood pressure	Low, with a large drop on standing	High
Skin	Darkening in creases, gums and scars in primary disease (easy to miss on darker skin); pale in secondary disease	Thin skin, easy bruising, wide striae (red-purple on lighter skin, often brown to black on darker skin)
Muscles and energy	Fatigue, weakness, back and leg cramps	Proximal muscle weakness, fatigue
Laboratory pattern	Low sodium; high potassium in primary disease; low cortisol	High glucose; low potassium at times; high cortisol on screening tests
Emergency	Adrenal crisis: shock, vomiting, confusion	Infection masked by glucocorticoids; severe high blood pressure or glucose
Key nursing action	Never miss or stop doses; sick-day rules; emergency kit	Protect skin and bones, monitor glucose and blood pressure, never stop glucocorticoids abruptly

Primary Aldosteronism and Pheochromocytoma in Brief

Both conditions are adrenal causes of hypertension (Chapter 19), and both are easy to miss.

Primary aldosteronism is overproduction of aldosterone by one or both adrenal glands, at least partly independent of renin. Excess aldosterone retains sodium and raises blood pressure, sometimes with low potassium; the condition carries more cardiovascular risk than ordinary hypertension and remains underdiagnosed (Adler et al., 2025). Hypertension Canada advises considering screening when a person with hypertension has unexplained low potassium (below 3.5 mmol/L, or below 3.0 mmol/L on a diuretic), needs three drugs without control, or has an incidental adrenal adenoma (Hypertension Canada, n.d.). The 2025 Endocrine Society guideline, with Canadian authors, suggests screening everyone with hypertension using the aldosterone-to-renin ratio, drawn in the morning with the person seated. One-sided disease is treated by removing the gland; two-sided disease, lifelong with a mineralocorticoid receptor antagonist such as spironolactone (Adler et al., 2025).

A **pheochromocytoma** is a catecholamine-secreting tumour of the adrenal medulla. It is uncommon: these tumours and related paragangliomas occur in 0.2% to 0.6% of people with hypertension in general outpatient clinics (Lenders et al., 2014). Clues include sudden episodes (paroxysms) of high blood pressure or severe, hard-to-control hypertension, with headaches, palpitations, sweating, pallor or panic-like attacks. Beta-blockers, monoamine oxidase inhibitors, urination, changes in abdominal pressure, surgery or anesthesia can trigger episodes (Hypertension Canada, n.d.); the Endocrine Society also lists beta-blockers among drugs that can precipitate a crisis (Lenders et al., 2014). Testing measures plasma free or urine fractionated metanephrines, with plasma preferably drawn supine. Before surgery, alpha-adrenergic blockers are the first choice and are given for 7 to 14 days with a high-sodium diet and extra fluids; afterward, blood pressure, heart rate and glucose are monitored closely (Lenders et al., 2014).

MEDICATIONS

Thyroid and Adrenal Medications

Canadian brand names are given where a current Canadian product monograph was confirmed; doses are individualized by the prescriber.

- **Levothyroxine (Synthroid and others):** take on an empty stomach, 30 to 60 minutes before breakfast, at least 4 hours apart from calcium or iron products; start low in older adults (BGP Pharma ULC, 2024; section 23.2).
- **Liothyronine (Cytomel):** synthetic T3 with a rapid onset within hours and a short duration; not recommended for people with heart disease, including many older adults (Pfizer Canada ULC, 2019).
- **Methimazole (Tapazole):** teach to report fever or sore throat at once, as signs of agranulocytosis (Knight Therapeutics Inc., 2025).
- **Propylthiouracil:** can cause severe liver injury; reserved for people who cannot take methimazole and for early pregnancy; teach to report yellow skin or eyes, dark urine or abdominal pain (Phebra Canada Inc., 2021).

- **Beta-blockers (such as propranolol):** control tremor and fast heart rate in thyrotoxicosis; nonselective agents are avoided in asthma with bronchospasm (Ross et al., 2016).
- **Hydrocortisone (Solu-Cortef injection; oral tablets):** replacement of choice for adrenal insufficiency; the injection is the emergency treatment for adrenal crisis (Bornstein et al., 2016; Pfizer Canada ULC, 2025).
- **Prednisone:** never stop abruptly after long-term use; taper only as the prescriber directs (Beuschlein et al., 2024).
- **Dexamethasone:** long-acting and potent; not suggested for routine replacement because it causes Cushing-like effects (Bornstein et al., 2016).
- **Fludrocortisone (Florinef):** replaces aldosterone; monitor blood pressure, swelling, weight and electrolytes, especially potassium (Knight Therapeutics Inc., 2026).

23.5 Pituitary Disorders and Water Balance

Pituitary Tumours

Most pituitary tumours are benign **pituitary adenomas** (Figure 23.5). They cause problems in two ways: by making too much of a hormone (functioning tumours), and by pressing on nearby structures (mass effects). Nonfunctioning macroadenomas, larger tumours that make no active hormone, are the most common large pituitary tumours. They are usually found because of low pituitary hormones (in about 80% of patients) or vision problems (in about 85%) (Pelsma et al., 2020).

Mass effects include:

- **Visual field loss:** the tumour presses on the optic chiasm, where the nerve fibres from the inner half of each retina cross. Loss usually begins in the upper outer (temporal) fields and typically affects both eyes (**bitemporal visual field loss**). Visual acuity can fall too, and untreated compression can lead to blindness (Pelsma et al., 2020). Patients may bump into door frames or miss cars approaching from the side.
- **Headache** (Petersenn et al., 2023).
- **Low pituitary hormones (hypopituitarism):** low ACTH causes secondary adrenal insufficiency (section 23.4), and low thyroid-stimulating hormone causes central hypothyroidism (section 23.1) (Petersenn et al., 2023).

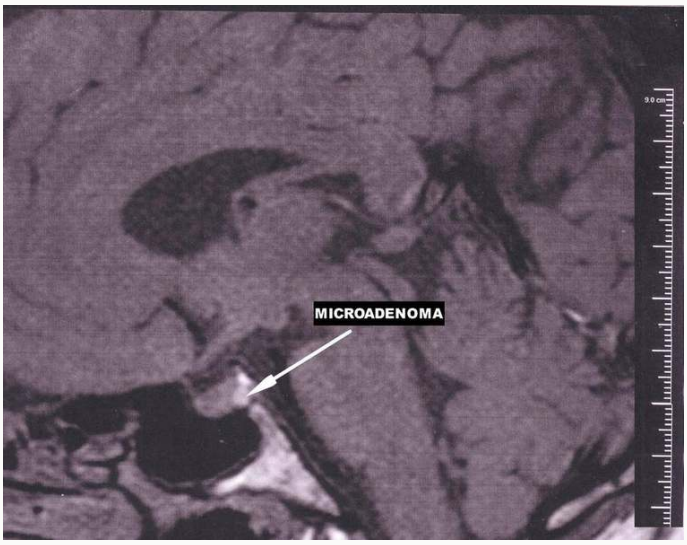

Figure 23.5 MRI of the head from the side, with an arrow marking a pituitary microadenoma, a tumour smaller than 1 cm. MRI is the main imaging test for pituitary tumours. (credit: "Adenome hypophyse esp" by Yakafaucon/Wikimedia Commons, CC BY-SA 4.0)

Sudden severe headache with new vision loss may mean bleeding into the tumour (pituitary apoplexy), which needs urgent imaging (Petersenn et al., 2023); the nurse escalates at once.

Two functioning tumours are worth knowing:

- **Prolactinomas** make up about half of all pituitary adenomas. High prolactin causes menstrual changes, infertility, low libido, breast milk discharge (galactorrhea) and erectile dysfunction. A dopamine agonist medication is usually first-line treatment; patients are taught to report compulsive behaviours such as gambling or shopping (Petersenn et al., 2023).
- **Acromegaly** results from excess growth hormone: enlarged hands and feet, coarse facial features and a protruding jaw, with diabetes, hypertension, heart disease and sleep apnea. Surgery is the usual first treatment (Endocrine Society, 2014).

An ACTH-secreting adenoma causes Cushing disease (section 23.4).

Care After Transsphenoidal Surgery

In **transsphenoidal surgery**, the surgeon reaches the pituitary through the nose and the sphenoid sinus. Most nursing priorities follow from the anatomy.

- **Vision:** the nurse checks visual acuity and fields as ordered and compares them with the preoperative baseline. Most patients' vision improves after decompression. New or worsening vision is reported at once, because it is often linked to bleeding in the surgical site and needs imaging (Pelsma et al., 2020).
- **Nose and cerebrospinal fluid:** nasal congestion, crusting and blood-stained mucus are expected. Clear, watery fluid dripping from the nose, or a salty taste from fluid running down the back of the throat, may be a **cerebrospinal fluid (CSF) leak** and is reported, as is headache with fever and a stiff neck (Cambridge University Hospitals NHS Foundation Trust, 2026).
- **Protecting the repair:** one centre advises no nose blowing for 2 weeks and no heavy lifting, bending or straining on the toilet, because these raise the risk of bleeding or CSF leak (Cambridge University Hospitals NHS Foundation Trust, 2026). Instructions vary, so the nurse follows the surgeon's orders and gives stool softeners as ordered.
- **Water balance:** the nurse measures intake and output closely, often hourly urine volumes at first, and reports a sharp rise in dilute urine. Temporary arginine vasopressin deficiency can follow pituitary surgery (Ferring Inc., 2019). Salt imbalance can also develop after discharge: one centre warns patients that feeling generally unwell and very tired 1 to 2 weeks after surgery may reflect a salt imbalance, and checks a blood test within 5 to 7 days of discharge (Cambridge University Hospitals NHS Foundation Trust, 2026).
- **Cortisol:** surgery can correct pituitary hormone deficiencies or cause new ones, so hormones are retested (Petersenn et al., 2023). The nurse gives glucocorticoids exactly as ordered and watches for signs of adrenal insufficiency (section 23.4). Glucocorticoid replacement can unmask arginine vasopressin deficiency, because cortisol is needed for the kidneys to excrete free water (Baldeweg et al., 2018).

SIADH

The **syndrome of inappropriate antidiuretic hormone secretion (SIADH)** is the release of antidiuretic hormone (ADH; also called arginine vasopressin) even though the plasma is dilute. Chapter 3 explains its mechanism, its diagnostic criteria and the safe limits for correcting sodium; this section adds the endocrine view. The kidneys keep returning water to the blood, so the urine stays concentrated, sodium falls, and the patient looks neither dry nor overloaded (euvolemic). Causes include lung disease such as pneumonia and small cell lung cancer, brain conditions such as stroke, head injury, subarachnoid hemorrhage and meningitis, and drugs such as selective serotonin reuptake inhibitors, carbamazepine and opioids. General anesthesia, nausea, pain and stress are strong triggers, so SIADH is a risk after any surgery (Spasovski et al., 2014).

Nausea, headache and confusion are moderately severe symptoms; vomiting, deep drowsiness, seizures and coma are severe (Spasovski et al., 2014). In an older adult, new confusion or a fall may be the first cue.

Treatment principles are to treat or remove the cause, stop drugs that may be responsible, and restrict fluid as the first-line treatment for moderate or profound hyponatremia from SIADH. Severe or moderately severe symptoms need hypertonic saline in a monitored setting (Society for Endocrinology, 2022; Spasovski et al., 2014). The nurse:

- keeps an accurate intake and output record and weighs the patient daily;
- helps the patient spread a fluid restriction across the day;
- checks neurologic status and keeps the patient safe from falls;
- reports a sudden rise in urine output, which can signal that sodium is rising too fast (Society for Endocrinology, 2022).

Arginine Vasopressin Deficiency and Resistance

In 2022, an international working group renamed diabetes insipidus because the shared word "diabetes" confused patients and staff with diabetes mellitus. In some hospital patients, desmopressin was withheld, with serious outcomes including death (Arima et al., 2022). **Arginine vasopressin deficiency (AVP-D; formerly central diabetes insipidus)** means the pituitary does not release enough vasopressin. **Arginine vasopressin resistance (AVP-R; formerly nephrogenic diabetes insipidus)** means the kidneys do not respond to it (Arima et al., 2022).

In both, the kidneys cannot concentrate urine, so large volumes of dilute urine are passed. Complete AVP deficiency can cause more than 10 L of urine in 24 hours (Baldeweg et al., 2018). A person with a working thirst mechanism and free access to water usually keeps sodium normal by drinking more. Danger comes when the person cannot drink enough: a patient who is confused, drowsy, frail or nothing by mouth, who cannot sense thirst, or whose desmopressin is missed. These patients can develop life-threatening dehydration and **hypernatremia** (Baldeweg et al., 2018). Older adults are at extra risk because thirst weakens with age (Yun et al., 2023).

Causes of AVP deficiency include pituitary and hypothalamic disease, pituitary surgery and head trauma (Baldeweg et al., 2018; Ferring Inc., 2019). Long-term lithium therapy is one cause of AVP resistance: it frequently reduces the kidney's ability to concentrate urine, with thirst and polyuria, and occasionally causes AVP resistance itself (Bausch Health, Canada Inc., 2019).

Desmopressin, a synthetic form of vasopressin, treats AVP deficiency but does not work for AVP resistance (Ferring Inc., 2019). Its most serious adverse effect is hyponatremia from water retention. Patients learn the fluid advice their prescriber gives and report headache, nausea, vomiting, weight gain or confusion. Adults over 65 need closer observation (Ferring Inc., 2019).

The Society for Endocrinology recommends the following inpatient care for known AVP deficiency (Baldeweg et al., 2018):

- **On admission:** identify the patient, alert the endocrine team and flag the need for desmopressin.
- **Every shift:** keep water and desmopressin within reach, and never omit or delay a dose.
- **Monitoring:** check sodium at least every 24 hours while the patient receives IV fluids and regular desmopressin, and at least every 12 hours if consciousness is impaired.
- **Hypernatremia:** treat as a medical emergency in a high-dependency setting.

Table 23.3 compares SIADH with AVP deficiency.

Table 23.3 SIADH and arginine vasopressin deficiency compared (Baldeweg et al., 2018; Ferring Inc., 2019; Spasovski et al., 2014)

Feature	SIADH	AVP deficiency (central diabetes insipidus)
Problem	Too much ADH action for the plasma osmolality	Too little vasopressin released by the pituitary
Urine volume	Not increased	Very high; can exceed 10 L in 24 hours
Urine concentration	Inappropriately concentrated (urine osmolality above 100 mOsm/kg)	Inappropriately dilute
Serum sodium	Low	Normal if the person can drink; high if they cannot
Fluid status	Euvolemic	Dehydration if intake falls behind losses
Common causes	Pneumonia, small cell lung cancer, brain injury or stroke, some drugs, surgery, pain, nausea	Pituitary or hypothalamic disease, pituitary surgery, head trauma
Key nursing actions	Fluid restriction as ordered, daily weight, neurologic checks, report a sudden rise in urine output	Water within reach, desmopressin on time, intake and output, sodium checks, report rising sodium

GOING DEEPER

Osmolality and Urine Tests in Water-Balance Disorders

Required for RN students; optional for PN students.

Serum osmolality is usually about 275 to 295 mOsm/kg, and urine osmolality can range from about 50 to 1,200 mOsm/kg, depending on how much water the kidneys must save or excrete; ranges vary by laboratory (University of Ottawa, 2022). The key is to read the urine against the blood.

- **SIADH:** serum osmolality below 275 mOsm/kg with urine osmolality above 100 mOsm/kg and urine sodium above 30 mmol/L in a euvolemic patient, without adrenal, thyroid, pituitary or kidney failure or recent diuretics (Spasovski et al., 2014). The urine is "too concentrated" for dilute blood.
- **AVP deficiency or resistance:** high-normal or high serum sodium and osmolality with a large volume of dilute urine. A large urine output with a low urine osmolality shows that desmopressin is needed in AVP deficiency (Baldeweg et al., 2018). The urine is "too dilute" for concentrated blood.

- **Very high water intake (as in primary polydipsia):** low serum sodium with very dilute urine, because the kidneys are correctly excreting the extra water. This is the opposite of SIADH, in which urine osmolality stays above 100 mOsm/kg (Spasovski et al., 2014).

Desmopressin given for AVP deficiency should reduce urine volume and raise urine osmolality, and the response is tracked with these measures (Ferring Inc., 2019). During treatment for hypernatremia, sodium is checked every 4 hours at first (Baldeweg et al., 2018).

CLINICAL JUDGMENT

Six Litres of Urine After Pituitary Surgery

Names and details are fictional; this is a composite story.

Daniel Okeke, 54, had transsphenoidal removal of a nonfunctioning pituitary macroadenoma yesterday morning. He is on a neurosurgical unit with hydrocortisone ordered.

- **Recognize cues:** Daniel has passed 6,050 mL of pale urine in the past 18 hours, including 420, 450 and 480 mL in the last three hours. He asks repeatedly for water and says he is "parched." His blood pressure is 118/72 mm Hg and heart rate 96. His vision is unchanged from baseline, and no clear fluid drips from his nose. Laboratory results: sodium 148 mmol/L (142 mmol/L before surgery), serum osmolality 304 mOsm/kg, urine osmolality 130 mOsm/kg.
- **Analyze cues:** Large volumes of dilute urine with a rising sodium and high serum osmolality fit arginine vasopressin deficiency after pituitary surgery (section 23.5). Excreting extra IV fluid would not make his sodium rise.
- **Prioritize hypotheses:** The main risk is dehydration and worsening hypernatremia, especially if he becomes drowsy and cannot drink.
- **Generate solutions:** Report now with SBAR, keep water at the bedside, measure hourly intake and output, recheck sodium as ordered and anticipate desmopressin.
- **Take action:** The nurse reports to the neurosurgical resident. Desmopressin is ordered, hydrocortisone continues on time, and a sodium recheck is ordered for 4 hours later.
- **Evaluate outcomes:** Over 4 hours his urine output falls to 90 mL/h, his sodium is 145 mmol/L, and his thirst eases. The nurse now watches for the opposite problem: water retention and falling sodium in the days ahead.

SCOPE IN PRACTICE

Endocrine Emergencies and the Nurse's Role

Adrenal crisis, severe hyponatremia and severe hypernatremia are life-threatening, so every nurse who notices the cues acts at once: stays with the patient, calls for help and reports using SBAR (Chapter 6). CNO's Scope of Practice standard explains the roles through **authority, competence and context** (College of Nurses of Ontario [CNO], 2025b; Chapter 1, section 1.3):

- **Authority:** administering a substance by injection is a controlled act authorized to RNs and RPNs. It needs an order, either a client-specific order or a medical directive (CNO, 2025a; CNO, n.d.). An emergency hydrocortisone injection is given under such an order. Guidelines also recommend teaching patients and family members to give the emergency injection themselves (Bornstein et al., 2016).
- **Competence:** the nurse must know the drug, route, expected response and what to monitor afterward.
- **Context:** in long-term care, an RPN may be the first nurse at the resident's side, with the physician or nurse practitioner (NP) off site, and calls 9-1-1, the physician or NP and the RN in charge without delay. In hospital, a patient in crisis has complex, changing needs. Employers commonly assign such patients to an RN, but this is employer practice, not a CNO rule. The RPN consults the RN as the patient's needs change and continues to act on what they see.

Employer policy, medical directives and province or territory all shape these roles. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (CNO, 2026).

PRACTICE STORY

The Missed Prednisone

Names and details are fictional; this is a composite story.

Nurse: Mei-Lin Arsenault, RPN. Years in practice: 9. Setting: long-term care home, Ontario.

At 0630, the personal support worker (PSW) told me Mrs. Ruth Halvorsen, 84, had vomited twice overnight. Ruth has taken prednisone every morning for six years for polymyalgia rheumatica. At 0800 she brought her pills back up within minutes, and

again with crackers at 0900. By 1000 something had changed. Ruth, who usually teases me about my coffee, stared past me and could not tell me where she was. Her blood pressure was 86/50 mm Hg, which for Ruth, whose usual is about 140/80, was a big drop. Her heart rate was 112, her temperature 37.8 °C and her glucose 4.6 mmol/L. She was holding her stomach.

The night nurse had written "gastro, push fluids." I could see why. But I kept thinking about that missed prednisone. After six years, her own adrenal glands could not make the cortisol she needed for this illness. Vomiting, falling pressure, confusion: that was adrenal crisis until proven otherwise.

Six months earlier, after a hospital stay, her geriatrician had ordered an emergency hydrocortisone injection kit, with an order to give it IM if she could not keep her prednisone down. I asked our PSW to call 9-1-1 and page our RN supervisor while I checked the order, drew it up and gave it. While we waited, I phoned the NP and used SBAR: "Long-term prednisone, two missed doses from vomiting, BP 86/50 from a baseline of 140/80, new confusion. I've given the emergency hydrocortisone under her standing order and called 9-1-1." She agreed and called the emergency department.

I sent the steroid card, her medication list and the time of the injection with the paramedics. Ruth came back four days later, alert and joking again. Since then, our home's sick-day teaching covers residents on long-term steroids, not only those with diabetes.

Reflect: Which part of my response depended on an existing order, and what would I have done without one? How do authority, competence and context shape an RPN's actions when they are the first nurse at the resident's side?

Chapter 23 Summary

23.1 Endocrine Feedback and Testing

- Most endocrine glands are controlled by negative feedback through hypothalamic–pituitary–target gland axes.
- TSH is the most reliable single thyroid test: high in primary hypothyroidism and low in hyperthyroidism. In pituitary disease it is unreliable, and free T4 guides care.
- Ionized calcium is the active form; a low albumin lowers total calcium without changing ionized calcium. PTH is always read with a calcium.
- Reference ranges vary by laboratory. The nurse times samples such as morning cortisol and asks about biotin, which can distort thyroid immunoassays.

23.2 Thyroid Disorders

- Hypothyroidism, most often from Hashimoto thyroiditis, causes fatigue, cold intolerance, dry skin and constipation. It is treated with levothyroxine taken on an empty stomach and apart from calcium and iron, with TSH checked 6 to 8 weeks after dose changes.
- Myxedema coma (hypothermia, bradycardia, hypoventilation, low sodium, drowsiness) is an emergency needing ICU care, IV thyroid hormone, hydrocortisone and passive rewarming.
- Hyperthyroidism, most often from Graves disease or toxic nodular goitre, is treated with beta-blockers, methimazole (PTU in special cases), radioactive iodine or surgery. Fever or sore throat on an antithyroid drug needs urgent assessment for agranulocytosis.
- Thyroid storm causes fever, marked tachycardia, delirium and organ failure; the nurse calls a rapid response, and the antithyroid drug is given before iodine.
- Older adults often have subtle thyroid symptoms; new atrial fibrillation or weight loss may be the only sign of hyperthyroidism.
- Thyroid cancer incidence in Canada rose until 2013, likely from overdiagnosis, and has since declined.

23.3 Thyroid and Parathyroid Surgery

- After thyroid surgery, the nurse observes at least hourly for the first 6 hours. Neck swelling, tightness, voice change or breathing difficulty may be a hematoma: the nurse calls for help at once, sits the patient up and gives oxygen.
- Who may open the wound at the bedside depends on employer policy, orders or medical directives, and competence.
- Low calcium from parathyroid injury causes perioral and fingertip tingling and cramps; the nurse asks about tingling at every assessment and reports it.

- Primary hyperparathyroidism, usually from a single adenoma, is often found on routine tests; parathyroidectomy is the only cure.
- Hypoparathyroidism is treated with calcium and calcitriol, aiming for a low-normal calcium, with checks after treatment changes to prevent kidney harm.

23.4 Adrenal Disorders

- The adrenal cortex makes cortisol and aldosterone; the medulla releases catecholamines. Illness, surgery and injury raise cortisol needs.
- Adrenal insufficiency may be primary (Addison disease), secondary (pituitary or hypothalamic) or glucocorticoid-induced; hyperkalemia and hyperpigmentation point to primary disease, and darkening is easy to miss on darker skin.
- Long-term glucocorticoids are never stopped abruptly; inhaled, topical and injected products count too.
- Adrenal crisis causes shock, vomiting, abdominal pain and confusion; treatment is immediate: hydrocortisone 100 mg IV or IM, then 200 mg over 24 hours, with 1 L of isotonic saline in the first hour.
- Sick-day rules, a steroid emergency card, medical alert identification and an emergency injection kit prevent crises.
- Cushing syndrome is most often caused by prescribed glucocorticoids; easy bruising, proximal weakness and wide striae are the most telling signs. Primary aldosteronism and pheochromocytoma are adrenal causes of hypertension.

23.5 Pituitary Disorders and Water Balance

- Pituitary adenomas cause hormone excess, hormone deficiency or mass effects such as headache and bitemporal visual field loss; sudden headache with vision loss needs urgent escalation.
- After transsphenoidal surgery, the nurse checks vision, reports clear nasal drainage, protects the repair, measures intake and output, and gives glucocorticoids as ordered.
- SIADH causes euvolemic hyponatremia with concentrated urine; fluid restriction is first-line, and sodium is corrected within the limits in Chapter 3.
- Arginine vasopressin deficiency and resistance (formerly central and nephrogenic diabetes insipidus) cause large volumes of dilute urine; hypernatremia follows when the person cannot drink.
- Desmopressin treats AVP deficiency, must never be omitted in hospital, and can cause hyponatremia.
- Every nurse recognizes and escalates endocrine emergencies; injections are given under an order or directive, and the RPN consults the RN as needs change.

Key Terms (53)

acromegaly: a condition caused by excess growth hormone in adults, usually from a pituitary adenoma, with enlarged hands, feet and facial features.

Addison disease: primary adrenal insufficiency, in which the adrenal cortex is damaged, most often by autoimmune disease, so cortisol and usually aldosterone are low.

adrenal cortex: the outer part of the adrenal gland, which makes the steroid hormones cortisol and aldosterone.

adrenal crisis: a life-threatening emergency in which cortisol supply cannot meet the body's needs, causing hypotension, volume depletion, vomiting and confusion; treated at once with parenteral hydrocortisone and isotonic saline.

adrenal insufficiency: a condition in which the adrenal glands do not supply enough cortisol, with or without enough aldosterone.

adrenal medulla: the inner part of the adrenal gland, which releases the catecholamines epinephrine and norepinephrine.

agranulocytosis: A severe drop in neutrophils, a rare but life-threatening adverse effect of antithyroid drugs.

aldosterone: the main mineralocorticoid hormone; it makes the kidneys retain sodium and water and excrete potassium.

arginine vasopressin deficiency (AVP-D): the current name for central diabetes insipidus, in which too little vasopressin is released, so large volumes of dilute urine are passed.

arginine vasopressin resistance (AVP-R): the current name for nephrogenic diabetes insipidus, in which the kidneys do not respond to vasopressin.

axis: A chain of control in which the hypothalamus and pituitary stimulate a target gland, such as the thyroid or adrenal cortex.

bitemporal visual field loss: loss of the outer (temporal) visual fields of both eyes, caused by pressure on the optic chiasm.

cerebrospinal fluid (CSF) leak: escape of the fluid around the brain, seen after transsphenoidal surgery as clear, watery nasal drainage or salty fluid in the throat.

cortisol: the main glucocorticoid hormone; released under ACTH control, it helps maintain blood pressure and blood glucose and rises during stress.

Cushing disease: Cushing syndrome caused by an ACTH-secreting pituitary adenoma.

Cushing syndrome: the signs and symptoms of prolonged, inappropriately high glucocorticoid exposure, most often from prescribed glucocorticoids.

desmopressin: a synthetic form of vasopressin used to treat arginine vasopressin deficiency; its most serious adverse effect is hyponatremia.

fine-needle aspiration (FNA): A procedure in which cells are drawn from a thyroid nodule through a thin needle for examination.

free T4: The small unbound fraction of thyroxine in the blood that is available to cells.

glucocorticoid-induced adrenal insufficiency: adrenal insufficiency caused by long-term glucocorticoid medication suppressing the hypothalamic–pituitary–adrenal axis; it appears when the drug is stopped, reduced or not absorbed, or when stress raises cortisol needs.

goitre: An enlarged thyroid gland, seen or felt as fullness at the front of the neck.

Graves disease: An autoimmune disorder in which antibodies stimulate the TSH receptor and cause hyperthyroidism.

Hashimoto thyroiditis: Chronic autoimmune thyroiditis, the most common cause of hypothyroidism where diets contain enough iodine.

hormone: A chemical messenger released into the blood by a gland that acts on target cells elsewhere in the body.

hypernatremia: a serum sodium above the reference range, usually from water loss greater than sodium loss.

hyperpigmentation: darkening of the skin and mucous membranes caused by high ACTH in primary adrenal insufficiency, most visible in creases, gums, scars and sun-exposed skin.

hyperthyroidism: Thyrotoxicosis caused by a thyroid gland that makes too much hormone.

hypoparathyroidism: Too little PTH, causing low calcium; most often caused by neck surgery.

hypothyroidism: A deficiency of thyroid hormone that slows metabolism throughout the body.

ionized calcium: The free, physiologically active form of calcium in the blood, not bound to albumin.

myxedema coma: The most severe form of hypothyroidism, an emergency with a falling level of consciousness, hypothermia, bradycardia, hypoventilation and low sodium.

neck hematoma: A collection of blood under a neck incision that can compress the airway; an emergency after thyroid or parathyroid surgery.

negative feedback: The control loop in which a rising level of a final hormone reduces release of the hormones that stimulate it, and a falling level increases their release.

parathyroid hormone (PTH): The hormone from the parathyroid glands that raises blood calcium through bone, the kidneys and activated vitamin D.

parathyroidectomy: Surgical removal of one or more overactive parathyroid glands.

pheochromocytoma: a catecholamine-secreting tumour of the adrenal medulla that can cause episodes of high blood pressure, headache, palpitations and sweating.

pituitary adenoma: a benign tumour of the pituitary gland that may secrete a hormone, press on nearby structures, or both.

primary aldosteronism: overproduction of aldosterone by one or both adrenal glands, independent of renin, causing hypertension and sometimes low potassium.

primary hyperparathyroidism: Excess PTH from one or more parathyroid glands, most often a single benign adenoma, causing high calcium.

prolactinoma: a prolactin-secreting pituitary adenoma, the most common type, usually treated first with a dopamine agonist.

radioactive iodine therapy (RAI): An oral dose of radioactive iodine that destroys overactive thyroid tissue.

recurrent laryngeal nerve: A nerve running close behind the thyroid that controls the vocal cords; injury can cause hoarseness.

sick-day rules: instructions for people who take glucocorticoids to increase the dose during illness and to use an emergency injection when tablets cannot be taken.

steroid emergency card: a card carried by a person who depends on glucocorticoids, telling health care providers how to recognize and treat adrenal crisis.

striae: stretch marks; in Cushing syndrome they may be wide, appearing red to purple on lighter skin and often brown to black on darker skin.

subclinical hypothyroidism: A TSH above the reference range with a normal free T4.

syndrome of inappropriate antidiuretic hormone secretion (SIADH): continued ADH release despite dilute plasma, causing water retention, euvolemic hyponatremia and concentrated urine.

thyroid eye disease: An autoimmune disorder of the tissues around the eyes, closely linked to Graves disease, that causes eyelid retraction, proptosis, swelling and double vision.

thyroid storm: Life-threatening thyrotoxicosis with failure of one or more organs, usually triggered by another illness.

thyroid-stimulating hormone (TSH): The pituitary hormone that drives the thyroid to make thyroid hormone; the most reliable single test of thyroid function in most people.

thyroidectomy: Surgical removal of all (total) or part of the thyroid gland.

thyrotoxicosis: The state caused by too much thyroid hormone acting on the tissues, whatever the cause.

transsphenoidal surgery: removal of a pituitary tumour through the nose and sphenoid sinus.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Ms. Amira Haddad (Questions 1–6): Ms. Amira Haddad, 41, had a total thyroidectomy this morning for Graves disease and arrived on the surgical unit at 1100. At 1500, she tells the registered nurse (RN) that her neck "feels tight." The RN notes the front of her neck is visibly fuller than at the 1400 check, and her voice is hoarse and quieter than earlier. Vital signs: blood pressure 142/88 mm Hg, heart rate 108 beats per minute, respiratory rate 24 breaths per minute, oxygen saturation 93% on room air (97% at 1400), temperature 37.2 °C. The dressing has a small, unchanged spot of dried blood.

1. [CORE] Which findings at 1500 require urgent follow-up? Select all that apply.

a. The visibly increased fullness of the front of the neck since 1400
b. The new hoarse, quieter voice compared with earlier in the day
c. The small, unchanged spot of dried blood on the dressing
d. The feeling of tightness in her neck that she describes
e. The fall in oxygen saturation from 97% to 93% with a respiratory rate of 24
f. A temperature of 37.2 °C on the afternoon of surgery

Answer: a, b, d, e — Recognize cues (section 23.3). New neck swelling (a), a voice change (b), a sense of tightness (d) and rising respiratory rate with falling oxygen saturation (e) are cues of an expanding neck hematoma that can obstruct the airway. A small, unchanged dried stain (c) is expected; a nearly dry dressing does not rule out deep bleeding, but it is not itself a warning sign. A temperature of 37.2 °C (f) is within normal limits.

2. [CORE] Which explanation best accounts for Ms. Haddad's findings at 1500?

a. Low calcium from parathyroid injury causing laryngeal muscle spasm
b. Blood collecting under the incision and pressing on the airway
c. Thyroid storm triggered by handling of the gland during surgery
d. Expected throat irritation from the breathing tube used during anesthesia

Answer: b — Analyze cues (section 23.3). Increasing swelling, tightness, voice change and falling oxygen saturation a few hours after surgery point to a neck hematoma (b). Low calcium (a) begins with tingling around the mouth and in the fingers, and usually appears later; she reports none. Thyroid storm (c) causes high fever, marked tachycardia and agitation; her temperature is normal and she was prepared for surgery. Throat irritation from intubation (d) does not cause visible neck swelling or falling oxygen saturation.

3. [CORE] What is the RN's priority action?

a. Call for immediate help from the rapid response team and the surgeon, sit Ms. Haddad up and give oxygen
b. Reinforce the dressing with a firm pressure bandage over the incision and recheck her neck and breathing in 30 minutes
c. Give the ordered analgesic and reassess her voice and swallowing once the pain eases
d. Draw an ionized calcium and check for a positive Trousseau sign before calling the surgeon

Answer: a — Take action (section 23.3; Clinical Safety box). A suspected hematoma is an airway emergency: the nurse calls for help at once, stays with the patient, sits her up and gives oxygen (a). A tight pressure bandage (b) could worsen airway compression and delays help. Analgesia (c) treats a symptom while the airway is threatened. Calcium testing (d) addresses a different, later problem and delays escalation.

4. [CORE] Ms. Haddad returns to the operating room, the hematoma is evacuated, and she recovers. At 0700 the next day, she says her lips and fingertips are "tingling and numb" and her hands feel crampy. Her ionized calcium is 0.98 mmol/L (laboratory range 1.14 to 1.28 mmol/L). What is the most likely cause?

a. Recurrent laryngeal nerve injury affecting sensation in the face
b. A second, smaller hematoma pressing on nerves in the neck
c. Low PTH from parathyroid gland injury during surgery
d. Anxiety and fast breathing after a frightening night

Answer: c — Analyze cues (section 23.3). Perioral and fingertip tingling with cramps and a low ionized calcium after total thyroidectomy fit hypocalcemia from parathyroid injury and low PTH (c). The recurrent laryngeal nerve (a) controls the vocal cords and does not cause facial tingling. A hematoma (b) causes swelling, voice change and breathing difficulty, not a low calcium. Anxiety with overbreathing (d) can cause tingling, but it would not explain a measured ionized calcium well below the range.

5. [RN] Ms. Haddad's tingling is spreading, and she now has cramping in both hands. Which order does the RN anticipate first?

a. Oral levothyroxine given now instead of tomorrow morning
b. A fluid restriction and a repeat ionized calcium in 24 hours
c. IV magnesium sulfate alone, since magnesium often falls after surgery
d. IV calcium gluconate given with ECG monitoring

Answer: d — Generate solutions (section 23.3; Chapter 3, section 3.6). Symptomatic, worsening hypocalcemia is treated with IV calcium gluconate under ECG monitoring, followed by oral calcium and calcitriol as ordered (d). Levothyroxine (a) replaces thyroid hormone and does not raise calcium. Restricting fluids and waiting 24 hours (b) delays treatment of a progressing emergency. Magnesium is checked and corrected because low magnesium blocks PTH, but magnesium alone (c) does not treat symptomatic hypocalcemia.

6. [CORE] Before discharge, which statement by Ms. Haddad shows that teaching has been effective?

a. "I'll take my calcium and calcitriol as prescribed and call if the tingling comes back."
b. "I'll only need levothyroxine until the swelling in my neck goes down completely."
c. "If my lips tingle at home, I can double my levothyroxine that day to help."
d. "My calcium will be back to normal once I leave hospital, so I won't need blood tests."

Answer: a — Evaluate outcomes (section 23.3). She understands to take calcium and calcitriol as prescribed and to report returning symptoms (a). After total thyroidectomy, levothyroxine is lifelong (b). Levothyroxine does not treat low calcium, and the dose is never changed without advice (c). Most people recover parathyroid function within a month, but calcium is followed with blood tests, and some develop permanent hypoparathyroidism (d).

7. [CORE] A 58-year-old man reports tiredness, feeling cold and constipation. His TSH is high and his free T4 is low. How does the nurse interpret these results?

a. Primary hyperthyroidism, because the high TSH is pushing the thyroid to overproduce

b. Central hypothyroidism, because the pituitary is not making enough TSH

c. Primary hypothyroidism, because the pituitary is responding to low thyroid hormone

d. Normal thyroid function, because the TSH and free T4 balance each other out

Answer: c — Through negative feedback, a failing thyroid makes too little T4 and the pituitary raises TSH: high TSH with low free T4 is primary hypothyroidism (c) (section 23.1). In hyperthyroidism (a), TSH is low. In central disease (b), TSH is low, normal or mildly raised, not clearly high. The results are both abnormal and do not cancel each other out (d).

8. [CORE] A patient is scheduled for thyroid blood tests tomorrow morning. Which question by the nurse is most important to ask today?

a. "Do you take any vitamin or hair, skin and nail supplement that contains biotin?"

b. "Have you had any iodine-containing foods such as seafood in the last month?"

c. "Will you be able to fast from all food and fluids, including water, from midnight tonight until the test?"

d. "Did you have a cold or a sore throat at any time in the past year?"

Answer: a — Biotin can interfere with immunoassays used for thyroid tests and give false results; the Canadian levothyroxine monograph advises stopping biotin at least 2 days before sampling when possible (a) (section 23.1). Dietary seafood (b) is not a routine concern before thyroid tests. TSH and free T4 do not require a complete fluid fast (c). A remote cold (d) does not affect results.

9. [CORE] The nurse reviews levothyroxine teaching with a patient. Which statement shows a need for further teaching?

a. "I take my pill with a glass of water about 45 minutes before I eat breakfast."

b. "I take it every morning with my calcium supplement so I don't forget either one."

c. "I won't switch to a different brand unless my doctor knows and orders a blood test."

d. "I'll have a blood test about 6 to 8 weeks after my dose is changed."

Answer: b — Calcium reduces levothyroxine absorption; the Canadian monograph advises at least 4 hours between them (b) (section 23.2, Patient Education box). Taking it with water 30 to 60 minutes before breakfast (a), not switching products without retesting (c) and a TSH 6 to 8 weeks after a dose change (d) are correct.

10. [CORE] An 82-year-old woman with hypothyroidism is brought from home in January. She has been drowsy for 2 days and stopped taking her medications a week ago. Temperature 34.8 °C, heart rate 46 beats per minute, respiratory rate 8 breaths per minute, sodium 124 mmol/L. Which action is the priority?

a. Encourage her to drink warm fluids to raise her temperature and her sodium

b. Apply an electric warming blanket set to high to restore her temperature quickly

c. Give her usual oral levothyroxine dose now with a sip of water

d. Call for immediate help, support her breathing and prepare for ICU transfer

Answer: d — Hypothermia, bradycardia, slow breathing, low sodium and drowsiness after stopping thyroid medication suggest myxedema coma, an emergency needing ICU care; breathing comes first (d) (section 23.2). A drowsy patient with slow breathing should not be given oral fluids or pills, because of aspiration risk (a, c); oral fluids also lower sodium further, and IV thyroid hormone is used. Rapid active warming (b) can cause vasodilation and shock; rewarming is passive.

11. [CORE] A patient taking methimazole calls the clinic reporting a sore throat and a temperature of 38.6 °C that started today. What is the nurse's best advice?

a. "Take acetaminophen and continue methimazole; call back if you still have a fever in 3 days."

b. "Come in today for a white blood cell count, and hold your methimazole until we have the result."

c. "Gargle with salt water and take your methimazole with food to avoid stomach upset."

d. "Double your methimazole dose, since infections can make your thyroid more overactive."

Answer: b — Fever and sore throat in a patient taking an antithyroid drug may signal agranulocytosis, a rare but life-threatening complication. The Canadian monographs tell patients to report these symptoms right away; a white blood cell count with differential is checked, and the drug is stopped while agranulocytosis is suspected or once it is found (b) (section 23.2). Waiting 3 days (a) or treating it as a minor infection (c) delays diagnosis. Increasing the dose (d) would add to the risk.

12. [CORE] A patient with Graves disease is scheduled for radioactive iodine therapy. Which statement by the patient shows correct understanding?

a. "I may become hypothyroid within a few months and need thyroid hormone for life."

b. "This treatment works right away, so I can stop my beta-blocker after the dose."

c. "I can start trying to get pregnant as soon as the radioactive iodine is out of my body."

d. "The radiation safety instructions are only for patients who receive a second treatment."

Answer: a — Most patients become hypothyroid after radioactive iodine, usually within 2 to 6 months, and need lifelong levothyroxine (a) (section 23.2). The effect is not immediate, so symptom control continues (b). Conception is delayed until thyroid function is stable (c). Written radiation safety instructions apply to every patient who receives a treatment dose (d).

13. [CORE] An 84-year-old man has lost 5 kg over 4 months and has a new irregular pulse of 112 beats per minute. He denies anxiety, tremor or feeling hot. Which test result would the nurse expect to see in his chart?

a. A high TSH, because hypothyroidism is the usual cause of weight loss in older adults

b. A normal TSH, because thyroid disease is unlikely without classic symptoms

c. A high free T4 with a high TSH, the usual pattern in nodular goitre

d. A low TSH, because hyperthyroidism in older adults may cause few adrenergic symptoms

Answer: d — Older adults with hyperthyroidism may have few classic symptoms; weight loss or new atrial fibrillation may be the only clues, and TSH is low (d) (section 23.2, Lifespan box). Hypothyroidism (a) is more likely to cause weight gain and a slower heart rate. The absence of classic symptoms does not rule out thyroid disease (b). A toxic nodular goitre suppresses TSH; a high TSH with high free T4 (c) is not its pattern.

14. [CORE] A registered practical nurse (RPN) is caring for a patient 3 hours after a thyroidectomy. The patient's voice has become hoarse and the patient says swallowing feels harder. What is the most appropriate action by the RPN?

a. Document the hoarseness as an expected effect of surgery and recheck the voice at the end of the shift

b. Ask the patient to rest the voice and sip cold water, and report the change to the RN at the next break

c. Stay with the patient, call for immediate help according to policy, notify the RN and sit the patient up

d. Ask the RN to assume care of the patient and return to the other assigned patients

Answer: c — Voice change and difficulty swallowing soon after thyroid surgery may signal a neck hematoma. Every nurse who recognizes deterioration acts at once and escalates, and the RPN consults the RN as needs change (c) (section 23.3; Chapter 1, section 1.3). Documenting and waiting (a), delaying the report (b) or handing off and leaving the bedside (d) delay help for a threatened airway.

15. [CORE] A patient with known Graves disease is admitted with pneumonia and has missed her methimazole for a week. Her temperature is 39.8 °C, heart rate 154 beats per minute and irregular, and she is newly confused and agitated. What is the nurse's priority?

a. Give acetaminophen and reassess the temperature in 1 hour before calling anyone

b. Restart her oral methimazole and recheck her heart rate in 4 hours

c. Activate the rapid response team, because these cues suggest thyroid storm

d. Apply a cooling blanket and give a sedative ordered as needed for the agitation

Answer: c — High fever, marked tachycardia, AF and new confusion in a patient with Graves disease who has stopped her antithyroid drug and has an infection suggest thyroid storm, which needs ICU-level care without delay (c) (section 23.2; Chapter 6). Fever control alone (a), restarting oral medication and waiting (b) and sedation with cooling (d) delay escalation of a life-threatening emergency.

16. [CORE] A patient with primary hyperparathyroidism asks what the condition might do to the body. Which effects does the nurse include? Select all that apply.

a. Kidney stones, sometimes without symptoms

b. Thinning of the bones with a higher risk of fractures

c. Thirst and passing large amounts of urine

d. Tingling around the mouth and in the fingertips

e. Constipation and nausea

f. Muscle twitching when the cheek is tapped

Answer: a, b, c, e — Primary hyperparathyroidism raises calcium, causing kidney stones (a), bone loss and fractures (b), and symptoms of high calcium such as thirst and frequent urination (c) and constipation and nausea (e) (section 23.3; Chapter 3). Perioral tingling (d) and facial twitching on tapping (f) are signs of low calcium, as in hypoparathyroidism.

17. [CORE] A patient with chronic hypoparathyroidism after thyroid surgery takes calcium and calcitriol. Which teaching point is most important?

a. "Take a calcium supplement only when your lips or fingers tingle, then stop."

b. "Your calcium will need checking within days of any major change in your treatment."

c. "Avoid all dairy products, because the calcium in them could cause stones."

d. "Once you have taken these medicines for a year, they can be stopped for good."

Answer: b — Both too little and too much calcium cause harm; overtreatment can cause kidney stones and kidney damage, so calcium is checked within several days of any significant treatment change (b) (section 23.3). Treatment is regular, not only when symptoms occur (a). Avoiding all dairy (c) is not part of the plan. Hypoparathyroidism lasting more than 12 months is considered permanent, so the medicines usually continue (d).

18. [RN] A patient has a pituitary tumour. TSH is 0.6 mIU/L and free T4 is 6.1 pmol/L (laboratory ranges: TSH 0.4 to 5.0 mIU/L; free T4 8.5 to 15.2 pmol/L). How does the RN interpret these results?

a. Normal thyroid function, because the TSH is within the reference range

b. Central hypothyroidism, because the pituitary is not raising TSH in response to a low free T4

c. Subclinical hypothyroidism, because only one of the two results is abnormal

d. Early hyperthyroidism, because the TSH is near the lower limit of the range

Answer: b — With a low free T4, an intact axis should produce a high TSH. A TSH that is normal or low in the face of low free T4 points to central (pituitary or hypothalamic) disease, and free T4 guides treatment (b) (section 23.1, Going Deeper box). TSH alone is misleading in pituitary disease (a). Subclinical hypothyroidism (c) is a high TSH with a normal free T4. Hyperthyroidism (d) causes a high free T4.

19. [RN] A patient in thyroid storm has orders for propylthiouracil, an iodine solution, propranolol, hydrocortisone and acetaminophen. Which plan for timing is correct?

a. Give the iodine solution first, then the propylthiouracil once the heart rate falls below 100 beats per minute

b. Hold the propranolol until the propylthiouracil has been given for 24 hours

c. Give acetaminophen with ASA for fever, since both lower the temperature quickly

d. Give the propylthiouracil first, then the iodine solution at least 30 to 60 minutes later

Answer: d — The antithyroid drug is given first to block new hormone synthesis; iodine is given at least 30 to 60 minutes later, because iodine given first can worsen storm (d) (section 23.2). Giving iodine first (a) reverses the safe order. Beta-blockade controls the heart rate early and is not delayed (b). Aspirin (ASA) is avoided because it raises free thyroid hormone (c).

20. [RN] A patient on a medical unit has a total calcium of 1.98 mmol/L (range 2.12 to 2.52 mmol/L), an albumin of 22 g/L (range 35 to 50 g/L) and an ionized calcium of 1.20 mmol/L (range 1.14 to 1.28 mmol/L). She has no tingling or cramps. How does the RN interpret these results?

a. True hypocalcemia, which needs IV calcium gluconate before the next assessment

b. Hypercalcemia hidden by low albumin, so her ionized calcium will soon rise

c. Primary hypoparathyroidism, which needs an urgent PTH level drawn

d. A low total calcium explained by low albumin, with a normal active calcium

Answer: d — Because much of the calcium in plasma travels on albumin, a low albumin lowers total calcium while the ionized (active) calcium stays normal, as here; she needs no calcium treatment (d) (section 23.1; Chapter 3, section 3.6). Her normal ionized calcium and lack of symptoms rule out true hypocalcemia (a) and hypoparathyroidism (c). Nothing suggests high calcium (b).

Case: Harold Nakamura (Questions 21–24): Harold Nakamura, 81, lives at home and has taken prednisone every day for 2 years for polymyalgia rheumatica. For 2 days he has had vomiting and diarrhea, and he has not kept down a prednisone dose since yesterday morning. His daughter brings him to the emergency department because he is confused. Vital signs: temperature 37.9 °C, heart rate 116, respiratory rate 22, blood pressure 82/50 mm Hg lying (his usual is about 135/80 mm Hg), oxygen saturation (SpO_2) 95% on room air. Capillary glucose 4.4 mmol/L. Laboratory results: sodium 129 mmol/L, potassium 4.6 mmol/L, creatinine 148 µmol/L (90 µmol/L six months ago).

21. [CORE] Which explanation best accounts for Mr. Nakamura's condition?

a. Septic shock from an intestinal infection, with fever as the main driver of his low blood pressure

b. Adrenal crisis, because vomiting kept him from taking the prednisone his body now depends on

c. Fluid loss from diarrhea alone, which a large oral fluid intake at home would have prevented

d. Delirium from mild dehydration that should clear once he drinks enough oral fluids

Answer: b — After 2 years of daily prednisone, his HPA axis is suppressed, so missed doses during a gastrointestinal illness can trigger adrenal crisis, with hypotension, confusion and hyponatremia (section 23.4). Sepsis (a) remains possible, but his temperature is only mildly raised and the missed glucocorticoid explains the picture better; both are treated urgently. Fluid loss alone (c) ignores the missed prednisone, the most dangerous cue. Delirium (d) does not explain a systolic pressure of 82 mm Hg, and an older adult's new confusion must not be dismissed (Chapter 8).

22. [CORE] Which order should the nurse expect to carry out first?

a. Give hydrocortisone IV or IM without waiting for the cortisol result to return

b. Hold all glucocorticoids until a morning cortisol level confirms the diagnosis tomorrow

c. Give his usual oral prednisone dose with crackers and recheck in one hour

d. Send a 24-hour urine collection for free cortisol before giving any medication

Answer: a — Treatment of a suspected adrenal crisis must never wait for tests; hydrocortisone is given IV or IM at once, with isotonic saline (section 23.4). Holding glucocorticoids (b) could be fatal. Oral prednisone (c) is unreliable when he is vomiting, and parenteral glucocorticoid is recommended. A 24-hour urine collection (d) is a screening test for Cushing syndrome, not an emergency test.

23. [CORE] A practical nurse (PN) is helping with Mr. Nakamura's care and must report his status to the RN. Which information is most important to include?

a. He lives at home with support, and his daughter visits most days to help with meals and errands

b. His oxygen saturation is 95% on room air and his respiratory rate is 22

c. Daily prednisone with missed doses, blood pressure 82/50 mm Hg and new confusion

d. His last bowel movement was this morning, and he says his abdomen has felt sore since yesterday

Answer: c — An SBAR report leads with the cues that show danger and point to the cause: long-term glucocorticoid use, missed doses, hypotension and new confusion (section 23.4; Chapter 6). His home situation (a) matters for discharge planning, not now. His oxygenation (b) is acceptable. Bowel and abdominal details (d) are relevant but less urgent than shock.

24. [CORE] Before discharge, the nurse teaches Mr. Nakamura and his daughter about preventing another crisis. Which statement by the daughter shows understanding?

a. "If he feels unwell, he should skip his prednisone until his stomach settles."

b. "He can stop the prednisone on his own once his muscle pain has been gone for about a month."

c. "We only need his medical alert bracelet when he travels away from home."

d. "If he can't keep his prednisone down, he needs his emergency injection, then hospital."

Answer: d — Sick-day rules call for an emergency glucocorticoid injection when tablets cannot be kept down, followed by hospital care (section 23.4, Patient Education box). Skipping doses during illness (a) is what caused this crisis. Long-term prednisone is never stopped without a supervised taper (b). Medical alert identification and a steroid emergency card are worn and carried at all times (c).

25. [CORE] A patient has adrenal insufficiency. Which finding suggests primary disease (Addison disease) rather than insufficiency caused by long-term glucocorticoid use?

a. Fatigue, poor appetite and weight loss over several months

b. Dizziness and light-headedness when standing up from a chair

c. Potassium of 5.8 mmol/L with darkening of the palm creases

d. Sodium of 131 mmol/L on routine blood work done last week

Answer: c — In primary disease, aldosterone is lost, causing hyperkalemia, and high ACTH darkens creases, gums and scars; neither occurs when the HPA axis is suppressed by glucocorticoids (section 23.4). Fatigue and weight loss (a), postural dizziness (b) and hyponatremia (d) occur in both primary and secondary disease.

26. [CORE] A patient with deeply pigmented skin is being assessed for possible Addison disease. Which approach should the nurse use to look for hyperpigmentation?

a. Inspect gums, palm creases and scars in natural light and ask if the skin has darkened

b. Compare the colour of the patient's face with the nurse's own forearm under the room lights

c. Rely on the absence of visible darkening on the face to rule out hyperpigmentation

d. Inspect the abdomen under the room's fluorescent lights for wide purple stretch marks

Answer: a — Hyperpigmentation shows most in creases, mucous membranes and scars, and on darker skin it is best judged against the person's own usual colour, in natural light, with the patient's or family's report (section 23.4). Comparing with another person's skin (b) is not meaningful. General darkening is easy to miss on darker skin, so absence on the face (c) does not rule it out. Fluorescent light distorts colour, and wide striae (d) suggest Cushing syndrome, not Addison disease.

27. [CORE] A patient has taken prednisone for 8 months for an inflammatory condition and tells the nurse, "I feel great now, so I'm going to stop the pills this weekend." What is the nurse's best response?

a. "That's reasonable, as long as you taper off over the weekend by halving the dose each day."

b. "Stopping suddenly could cause a dangerous drop in cortisol; ask your prescriber about a taper."

c. "You can stop safely now, because your symptoms show that your adrenal glands are working again."

d. "Keep taking it, but switch to taking it every other day so your body can start making its own cortisol."

Answer: b — After long-term use, abrupt withdrawal can cause fatal adrenal insufficiency, and the HPA axis may stay suppressed for months; tapering is planned by the prescriber (section 23.4). A self-designed rapid taper (a) or an every-other-day schedule (d) is not something the nurse can direct. Feeling well (c) says nothing about adrenal recovery.

28. [CORE] During medication reconciliation, which products should the nurse identify as possible causes of glucocorticoid-induced adrenal insufficiency? Select all that apply.

a. Fluticasone inhaler used twice daily for 3 years

b. High-potency corticosteroid cream applied daily for 18 months

c. Corticosteroid injection into the knee 6 weeks ago

d. Acetaminophen taken as needed for knee pain

e. Levothyroxine taken every morning for 10 years

f. Calcium carbonate taken with supper

Answer: a, b, c — Glucocorticoids by any route can suppress the HPA axis, including inhaled or topical products used for more than a year and joint injections in the past 2 months (section 23.4). Acetaminophen (d), levothyroxine (e) and calcium (f) do not suppress the axis.

29. [CORE] Which finding in a patient with weight gain most suggests Cushing syndrome rather than common obesity?

a. Weight gain mainly around the abdomen and waist

b. Fatigue, low energy and difficulty sleeping at night

c. A blood pressure of 142/88 mm Hg at two visits

d. Difficulty rising from a chair and easy bruising

Answer: d — Proximal muscle weakness and easy bruising are among the features that best separate Cushing syndrome from common conditions (section 23.4). Central weight gain (a), fatigue and poor sleep (b) and high blood pressure (c) are common in many people and are less specific.

30. [CORE] A patient with hypertension takes three antihypertensive drugs, and their blood pressure is still not controlled. Their potassium is 3.2 mmol/L, and they do not take a diuretic. Which test should the nurse anticipate?

a. Plasma free metanephrines with the patient supine

b. Overnight dexamethasone suppression test

c. Aldosterone-to-renin ratio drawn in the morning with the patient seated

d. Corticotropin stimulation test with cortisol levels at 30 and 60 minutes

Answer: c — Hypertension resistant to three drugs and unexplained low potassium are Hypertension Canada's reasons to screen for primary aldosteronism with the aldosterone-to-renin ratio (section 23.4). Metanephrines (a) screen for pheochromocytoma, the dexamethasone test (b) for Cushing syndrome, and the stimulation test (d) for adrenal insufficiency.

31. [CORE] A patient with a large pituitary adenoma reports bumping into door frames on both sides. Which finding should the nurse expect on visual field testing?

a. Loss of the outer (temporal) fields of both eyes
b. Loss of all vision in one eye only
c. A blind spot in the centre of both visual fields
d. Loss of the lower fields of both eyes, starting at the bottom

Answer: a — A pituitary tumour pressing on the optic chiasm typically causes bitemporal visual field loss, often beginning in the upper outer quadrants (section 23.5). Loss in one eye only (b), central blind spots (c) and loss starting in the lower fields (d) are not the typical pattern.

32. [CORE] On the second day after transsphenoidal surgery, a patient tells the nurse that clear, watery fluid drips from their nose when they lean forward. What should the nurse do?

a. Encourage the patient to blow their nose gently to clear the drainage
b. Document the finding as expected nasal congestion and reassess at the end of the shift
c. Give a decongestant nasal spray from the patient's own supply
d. Report the finding promptly as a possible cerebrospinal fluid leak

Answer: d — Clear, watery nasal drainage after transsphenoidal surgery may be a CSF leak and is reported promptly (section 23.5). Nose blowing (a) is avoided after surgery. Congestion with crusting is expected, but clear watery fluid is not (b). Using a patient's own medication without an order (c) is unsafe.

33. [CORE] Twelve hours after pituitary surgery, a patient's urine output is 400 mL/h of pale urine, and the patient is very thirsty. What should the nurse do first?

a. Restrict the patient's oral fluids to slow the urine output
b. Report the output and request a serum sodium and urine osmolality
c. Encourage the patient to drink only when the next meal tray arrives
d. Increase the IV fluid rate to match the urine output without an order

Answer: b — Large volumes of dilute urine with thirst after pituitary surgery suggest arginine vasopressin deficiency; the nurse reports and expects sodium and osmolality checks to guide treatment (section 23.5). Restricting fluid (a) or delaying drinking (c) risks dehydration and hypernatremia. Changing IV fluids without an order (d) is outside the nurse's authority.

34. [CORE] A patient with small cell lung cancer has a sodium of 128 mmol/L, moist mucous membranes, no edema and concentrated urine. The patient has no symptoms. Which treatment should the nurse anticipate first?

a. A large IV bolus of 0.9% sodium chloride
b. Oral desmopressin at bedtime
c. Fluid restriction with daily weights and intake and output
d. Rapid hypertonic saline infusion given on the general medical unit

Answer: c — This picture fits SIADH, and fluid restriction is the first-line treatment for moderate or profound hyponatremia from SIADH when there are no severe symptoms (section 23.5). Isotonic saline (a) treats low volume, but this patient is euvolemic. Desmopressin (b) would cause more water retention. Hypertonic saline (d) is reserved for severe or moderately severe symptoms and is given in a monitored setting within safe limits (Chapter 3).

35. [CORE] A patient with arginine vasopressin deficiency is starting desmopressin at home. Which statement shows the patient understands the teaching?

a. "I'll call my clinic if I get a bad headache, nausea or sudden weight gain."
b. "I should drink as much water as I possibly can every day to keep my kidneys well flushed."
c. "This medicine will also work if my kidney problem from the lithium I take gets any worse."
d. "I can skip doses whenever I'm busy, because missing one is never a problem."

Answer: a — Hyponatremia from water retention is desmopressin's most serious adverse effect, and headache, nausea, vomiting, weight gain or confusion are warning signs (section 23.5). Drinking as much as possible (b) increases that risk. Desmopressin does not work for arginine vasopressin resistance, such as that caused by lithium (c). Missed doses can cause dangerous dehydration, especially when the patient cannot drink (d).

36. [CORE] An RPN in a long-term care home finds a resident with Addison disease vomiting, confused and hypotensive. The resident has an emergency hydrocortisone injection kit with a written order for IM use when vomiting. Which action is appropriate?

a. Wait for the physician's next scheduled visit before giving any medication
b. Give the resident's oral hydrocortisone with sips of water and recheck in 2 hours
c. Ask the personal support worker to give the injection while the RPN calls the NP
d. Give the IM hydrocortisone under the order, call 9-1-1 and report to the NP

Answer: d — Administering a substance by injection is a controlled act authorized to RPNs with an order; this resident's order covers the situation, and adrenal crisis needs immediate treatment and transfer (section 23.5, Scope in Practice box). Waiting (a) delays life-saving treatment. Oral medication (b) will not stay down. Asking the personal support worker to inject (c) is not appropriate: an emergency injection for an unstable resident is not a routine activity of living, no delegation is in place, and the RPN holds the order and the competence to act.

37. [CORE] An RPN on a surgical unit is caring for a patient after pituitary surgery. Over 2 hours, the patient's urine output rises sharply and the patient becomes drowsy and difficult to rouse. What should the RPN do?

a. Continue the assessment plan and document the change at the end of the shift
b. Report to the RN at once and stay with the patient, whose needs have changed
c. Encourage the patient to drink a full jug of water before reassessing
d. Hold the next dose of hydrocortisone until the patient is more alert

Answer: b — A deteriorating patient needs immediate escalation, and the RPN consults the RN when a patient's needs change; drowsiness may prevent the patient from drinking and lead to hypernatremia (section 23.5). Delaying (a) is unsafe. A drowsy patient may not swallow safely (c). Holding hydrocortisone (d) risks adrenal insufficiency.

38. [RN] A patient 2 days after pituitary surgery has passed 5 L of urine in 24 hours. Results: sodium 151 mmol/L, serum osmolality 310 mOsm/kg, urine osmolality 120 mOsm/kg. Which interpretation is correct?

a. SIADH, because the urine is too concentrated for the patient's serum osmolality

b. Very high water intake, because the serum sodium is low and the urine maximally dilute

c. Arginine vasopressin deficiency, because the urine is dilute despite high serum osmolality

d. Normal postoperative diuresis of IV fluids, because the results are within expected ranges

Answer: c — Dilute urine with a high serum sodium and osmolality means the kidneys are not conserving water as they should, which fits arginine vasopressin deficiency (section 23.5, Going Deeper box). SIADH (a) shows concentrated urine with low serum osmolality. Very high water intake (b) lowers sodium, but this sodium is high. Diuresis of IV fluids (d) would not raise sodium to 151 mmol/L.

39. [RN] A patient with known Addison disease arrives with blood pressure 78/44 mm Hg, sodium 126 mmol/L, potassium 5.9 mmol/L and glucose 3.2 mmol/L. Which set of orders should the RN carry out first?

a. Fludrocortisone by mouth and a low-sodium diet

b. Cortisol and ACTH levels, then a corticotropin stimulation test before starting any treatment

c. Oral potassium binder and repeat electrolytes in 6 hours

d. Hydrocortisone 100 mg IV, 1 L isotonic saline in the first hour, and glucose treatment

Answer: d — Adrenal crisis is treated at once with hydrocortisone 100 mg IV or IM and rapid isotonic saline, with monitoring of glucose and electrolytes; the low glucose also needs treatment (section 23.4). Fludrocortisone (a) is not emergency treatment, and salt is never restricted in primary disease. Tests (b) must not delay treatment. A potassium binder alone (c) ignores shock, the immediate threat; potassium is monitored while hydrocortisone and fluids are given.

40. [RN] A patient is scheduled for adrenalectomy for a pheochromocytoma in 2 weeks. Which preoperative plan should the RN expect?

a. An alpha-adrenergic blocker for 7 to 14 days with a high-sodium diet and extra fluids

b. A beta-blocker alone, started today, to control the heart rate before surgery

c. Fluid restriction and a low-sodium diet to keep blood pressure down

d. No medications before surgery, because removing the tumour will correct the blood pressure

Answer: a — The Endocrine Society guideline makes alpha-adrenergic blockers the first choice and recommends 7 to 14 days of preoperative treatment, with a high-sodium diet and fluids, to bring blood pressure and heart rate to normal (section 23.4). Beta-blockers are among the drugs that can precipitate a pheochromocytoma crisis, so a beta-blocker alone (b) is unsafe. Restricting fluid and sodium (c) works against restoring volume before surgery. Going without blockade (d) risks severe blood pressure swings during surgery.

VI Gastrointestinal, Hepatic, Biliary & Pancreatic Care

UNIT CLINICAL SCOPE & INTEGRATION

Presents evidence-informed nursing care for upper and lower gastrointestinal disorders, enteral and parenteral nutrition, bariatric surgery, peptic ulcer disease, gastrointestinal bleeding, inflammatory bowel disease, bowel obstruction, ostomy care, cirrhosis, portal hypertension, viral and autoimmune hepatitis, cholelithiasis, and acute and chronic pancreatitis.

Contents of UNIT VI

Chapter	Chapter Title	Visual Assets	Page
Chapter 24	Upper Gastrointestinal Disorders and Nutrition	6 Figs • 4 Tbls	p. 696
Chapter 25	Lower Gastrointestinal Disorders	6 Figs • 4 Tbls	p. 727
Chapter 26	Liver, Biliary and Pancreatic Disorders	9 Figs • 4 Tbls	p. 759

24 Upper Gastrointestinal Disorders and Nutrition

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Screen adults for malnutrition and refeeding risk using Canadian tools, and recognize the signs and causes of malnutrition.
2. Give enteral and parenteral nutrition safely, including feeding tube placement verification and medications by tube.
3. Recognize dysphagia, support screening and assessment, and apply texture-modified diets using the IDDSI framework.
4. Care for adults with GERD, gastritis and peptic ulcer disease, including H. pylori treatment and safe use and deprescribing of acid-suppressing drugs.
5. Recognize an upper GI bleed early on a range of skin tones, escalate it, and support resuscitation and endoscopy using the CJMM.
6. Provide respectful, weight-inclusive care for people living with obesity, and care for patients before and after bariatric surgery.
7. Distinguish RN and RPN roles in feeding tube and nutrition care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5	Clinician; Scholar	Foundations of Practice
4, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Illness often takes away eating first. Pain, nausea, a sore mouth, trouble swallowing, fasting for tests and the hospital routine can all cut what a patient takes in, and many adults are already undernourished when they arrive. Nurses are often the first to notice. They see the half-eaten tray, the loose denture, the cough during a drink of water and the weight that has dropped since the last admission. Nurses also give most of the nutrition that does not come on a plate, through feeding tubes and intravenous lines, and they are the ones who check that a tube is in the right place before anything goes down it.

This chapter is the book's home for nutrition and for disorders of the upper gastrointestinal (GI) tract in adults. Section 24.1 reviews digestion and explains how to screen for and recognize malnutrition with Canadian tools. Section 24.2 covers enteral nutrition through feeding tubes, including how placement is confirmed and how medications are given by tube, and parenteral nutrition given into a vein. Section 24.3 deals with dysphagia and texture-modified diets. The second half of the chapter turns to gastroesophageal reflux disease, gastritis and peptic ulcer disease (24.4), upper GI bleeding (24.5), and obesity and bariatric surgery (24.6).

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1 (sections 1.3 to 1.5), and weight stigma, food insecurity and cultural safety in Chapter 2. Phosphate, potassium and magnesium are explained in Chapter 3, infection prevention and control in Chapter 4, and early warning scores and rapid response in Chapter 6. Older adults and deprescribing are covered in Chapter 8, palliative nutrition and hydration in Chapter 10 and aspiration pneumonia in Chapter 13. Lower GI disorders are in Chapter 25, and swallowing screening after stroke is taught in Chapter 31.

24.1 Digestion and Nutrition Assessment

The Upper GI Tract in Brief

The upper GI tract runs from the mouth to the duodenum, the first part of the small intestine (Figure 24.1). Chewing and saliva soften food and begin digestion. The tongue gathers the food into a soft, cohesive mass called a **bolus** and pushes it to the back of the mouth. Swallowing then becomes a fast reflex. The soft palate rises to close off the nose, the larynx lifts, the epiglottis folds over the airway and breathing pauses for a moment while the bolus passes into the esophagus. Waves of muscle contraction, called **peristalsis**, carry it down to the stomach. The lower esophageal sphincter relaxes to let the bolus in and then closes to keep stomach contents from flowing back up (section 24.4).

The stomach stores and mixes food. Its lining secretes hydrochloric acid, which kills many microbes and starts protein digestion, along with the enzyme pepsin and intrinsic factor, which is needed to absorb vitamin B12 (section 20.2). Because acid can injure tissue, the stomach protects itself with a layer of mucus and bicarbonate, a rich blood supply and rapid repair of its lining, and prostaglandins support these defences. When the balance tips toward injury, as with *Helicobacter pylori* infection or nonsteroidal anti-inflammatory drugs (NSAIDs), gastritis and ulcers can follow (section 24.4).

The stomach releases its contents a little at a time into the duodenum, where bile and pancreatic enzymes continue digestion and bicarbonate neutralizes the acid. Most nutrients are absorbed farther along the small intestine (Chapter 25). This layout matters for tube feeding: the stomach acts as a reservoir, while the small intestine does not, so where a feeding tube ends shapes how feeds can be given (section 24.2).

Screening for Malnutrition

In this chapter, **malnutrition** means undernutrition: the body is not taking in or not using enough energy and nutrients, so it loses muscle and fat and its function declines. In a Canadian Malnutrition Task Force study of 1,015 adults admitted to medical and surgical units in 18 hospitals for at least 2 days between 2010 and 2013, 45% were malnourished at admission when assessed with Subjective Global Assessment (SGA; described below) (Allard et al., 2016; Eckert & Cahill, 2018).

Every adult admitted to hospital is screened. The **Canadian Nutrition Screening Tool (CNST)** is a two-question screen from the Canadian Malnutrition Task Force. It asks:

- Over the last six months, has the person lost weight without meaning to?
- For more than a week, has the person been eating less than they usually do?

Answering yes to both questions means the person is at nutrition risk. If the patient cannot answer, a family member or someone else who knows them well may answer for them. Weight that was lost and then regained does not count as weight loss (Eckert & Cahill, 2018). Any hospital staff member can ask the questions (Eckert & Cahill, 2018), and each hospital or unit decides whose job it is (Keller et al., 2018).

The CNST is the first step of the **Integrated Nutrition Pathway for Acute Care (INPAC)**, a Canadian pathway that hospitals adapt to their own routines (Keller et al., 2018). In brief:

- **Screen:** every patient is screened with the CNST on admission.
- **Classify:** patients at risk are assessed with **Subjective Global Assessment (SGA)**, a structured bedside assessment that sorts nutrition status by weight change, intake, symptoms, function and physical signs of muscle and fat loss.
- **Standard care for all:** the team removes barriers to eating and monitors intake. Eating half a meal or less is treated as low intake that needs action.
- **Advanced care:** patients who are eating poorly or are malnourished receive diet changes and other measures to boost intake, and move back to standard care once intake improves.
- **Specialized care:** patients with more severe malnutrition, or who do not improve, receive a comprehensive assessment and an individual plan overseen by the dietitian.
- **Weigh and plan ahead:** a weight on admission and at least weekly is the minimum, and nutrition is part of discharge planning (Keller et al., 2018).

Nurses carry much of this pathway. They remove barriers at mealtimes, such as an unopened container, a missing denture or pain, estimate how much of each tray was eaten and refer to the registered dietitian when screening or intake shows risk. Screening also starts a conversation about home: a person who cannot afford, reach or prepare enough food will lose ground after discharge (Chapter 2).

Signs and Causes of Malnutrition

Screening flags risk; it does not make a diagnosis. The **Global Leadership Initiative on Malnutrition (GLIM)** criteria, an international consensus, use two steps: screen with a validated tool such as the CNST, then confirm malnutrition when the person meets at least one phenotypic criterion (what the body shows) and at least one etiologic criterion (the cause). Severity is then graded as moderate or severe (Cederholm et al., 2019).

- **Phenotypic criteria:** unintended weight loss of more than 5% within six months or more than 10% over a longer period; a low body mass index (BMI), below 20 kg/m² under age 70 or below 22 kg/m² over age 70; or reduced muscle mass measured with a validated method.
- **Etiologic criteria:** reduced intake or absorption, such as eating half or less of energy needs for more than a week, any reduction for more than two weeks, or a chronic GI condition that limits absorption; or inflammation from acute illness, injury or chronic disease (Cederholm et al., 2019).

Most malnutrition in hospital has more than one cause. Illness and inflammation raise the body's needs and break down muscle, while appetite falls. Intake drops with nausea, pain, low mood, confusion, fatigue and missed meals around tests. Oral health matters: missing teeth, poorly fitting dentures and mouth pain make chewing hard (Alberta Health Services [AHS], 2022). Medications can add nausea, dry mouth or drowsiness. Swallowing problems (section 24.3) and conditions that limit absorption deepen the deficit, and social factors such as living alone shape what happens at home (Allard et al., 2016).

The nurse also looks for muscle loss: wasting at the temples, shoulders and thighs, a weak grip and slower walking. In the Canadian study, weaker handgrip was linked with a longer stay (Allard et al., 2016).

Weight history tells more than BMI alone. A single BMI says nothing about recent change, and a person in a larger body can lose a great deal of weight and muscle while their BMI stays in or above the usual range. This is why GLIM counts weight loss and muscle mass as well as low BMI (Cederholm et al., 2019). The nurse asks about usual weight and recent change and weighs the patient on admission and weekly.

Blood tests have a limited role. Serum albumin and prealbumin were long used as nutrition markers, but the American Society for Parenteral and Enteral Nutrition (ASPEN) now states that they mainly reflect inflammation. During illness the liver makes less of them and they shift out of the bloodstream, so levels fall whether or not the person is malnourished. They predict the risk of poor outcomes, but they should not be used to diagnose malnutrition or to stand in for muscle mass (Evans et al., 2021).

CANADIAN CONTEXT

Malnutrition in Canadian Hospitals

Much of what is known about malnutrition in Canadian hospitals comes from the Canadian Malnutrition Task Force. Its cohort study followed 1,015 adults admitted to medical and surgical units in 18 Canadian hospitals for at least 2 days, from 2010 to 2013. Assessed with SGA, 45% were malnourished on arrival (Allard et al., 2016).

- **Who:** malnutrition at admission was linked with having many chronic conditions, living alone and relying on grown children to buy groceries (Allard et al., 2016).
- **Length of stay:** malnutrition at admission was linked with a longer stay, independent of other factors. A weaker handgrip and eating less than half of meals in hospital were also linked with longer stays (Allard et al., 2016).
- **Cost:** a CMAJ summary of this Canadian work reports stays 34% to 53% longer and costs 31% to 55% higher for malnourished patients than for well-nourished ones (Eckert & Cahill, 2018).
- **Response:** the task force built INPAC, a pathway that hospitals tailor to their own routines. Who screens, how meal intake is recorded and when weights are taken are decided locally (Keller et al., 2018).

For nurses, the message is that malnutrition is common, is often present before the first hospital meal, and can be found early with two screening questions, a look at the meal tray and a weekly weight.

GOING DEEPER

Refeeding Syndrome

Required for RN students; optional for PN students.

Refeeding syndrome is a fall in blood phosphate, potassium or magnesium, sometimes with thiamine deficiency, after nutrition is started or sharply increased in an undernourished person. ASPEN's consensus defines it as a fall of 10% or more in any of these electrolytes within five days, graded mild, moderate or severe by the size of the fall and any organ dysfunction (da Silva et al., 2020).

- **Mechanism:** carbohydrate triggers insulin release, which moves phosphate and potassium into cells; magnesium also falls, and thiamine demand rises. Body stores are already low, so levels can drop quickly even if normal before feeding (Chapter 3).
- **Who is at risk:** very low BMI, recent unintended weight loss, little or no intake for days, low electrolytes before feeding, loss of fat and muscle, and conditions such as eating disorders, long-term heavy alcohol or other drug use, malabsorption, cancer, previous bariatric surgery, and food insecurity or homelessness.
- **Why it matters:** low phosphate weakens the breathing muscles and the heart; thiamine deficiency can cause neurologic signs and heart dysfunction.
- **Prevention and monitoring:** check potassium, magnesium and phosphate before feeding; give thiamine before feeding or dextrose-containing IV fluids; start calories low and increase them gradually; in high-risk patients, check electrolytes every 12 hours for 3 days; take vital signs every 4 hours for the first 24 hours; and record daily weight and intake and output (da Silva et al., 2020). The nurse reports falling electrolytes promptly.

24.2 Enteral and Parenteral Nutrition

Feeding Tubes

Enteral nutrition means feeding into the GI tract. In this chapter, it refers to liquid formula given through a feeding tube to a person whose gut can digest and absorb but who cannot take enough by mouth, or cannot swallow safely. Common reasons include dysphagia after stroke (section 24.3), head and neck cancer, and critical illness. **Parenteral nutrition**, given into a vein, is used when the gut cannot be used or cannot meet the person's needs (see Parenteral Nutrition, below).

Feeding tubes are named by where they enter and where their tip ends (Table 24.1). A **nasogastric (NG) tube** passes through the nose and esophagus into the stomach (Figure 24.2). Nasal tubes, including those that end in the small intestine, are meant for short-term feeding. When tube feeding is expected to last longer, the team discusses a tube placed through the abdominal wall with the patient and family. A **gastrostomy tube** enters the stomach this way; a **percutaneous endoscopic gastrostomy (PEG)** is a gastrostomy placed with the help of an endoscope passed through the mouth (Figure 24.3). A **jejunostomy tube** enters the jejunum,

the middle part of the small intestine. Because the stomach acts as a reservoir, gastric tubes can take continuous, intermittent or bolus feeds; tubes that end in the small intestine usually need a slow, continuous feed by pump.

Choosing a tube, and deciding whether to feed by tube at all, is a shared decision. It weighs the person's goals, prognosis and wishes (Chapter 1, section 1.5; Chapter 10 for palliative nutrition). After a stroke, for example, the decision to start tube feeding is made as early as possible, usually within the first three days of admission, with the patient, family and team (Heart and Stroke Foundation of Canada, 2019).

Figure 24.2 Supplies gathered for nasogastric tube insertion, including the tube, lubricant, a securement device, pH strips, a large syringe and water for the patient to sip. Placement is confirmed before the tube is first used, as described later in this section. (credit: “Gather supplies” by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Figure 24.3 Equipment for placing a percutaneous endoscopic gastrostomy (PEG) tube: the tube with its internal disc (bumper), which holds it inside the stomach, an introducer needle and a guidewire. (credit: “PEG tube kit” by Gilo1969/Wikimedia Commons, CC BY-SA 3.0)

Table 24.1 Enteral feeding tubes compared (ASPEN, 2014; Lemyze, 2010; Nova Scotia Health Library, 2026)

Tube	Route and tip position	Usual use	Nursing points
Nasogastric (NG)	Through the nose and esophagus; tip in the stomach	Short-term feeding, medications and fluids	Radiograph before first use of a blindly placed tube; check the external length mark and other bedside checks before each use; protect the nostril from pressure
Nasojejunal (NJ)	Through the nose, past the stomach; tip in the jejunum	Short-term feeding when gastric feeding is not tolerated or aspiration risk is high	Placement confirmed by imaging; usually a continuous feed by pump; check medications with the pharmacist

Tube	Route and tip position	Usual use	Nursing points
Gastrostomy, including PEG	Through the abdominal wall into the stomach	Longer-term feeding; may be a low-profile "button"	Inspect and clean the site daily; watch for leakage, redness, pain or a tube that has moved; report a dislodged tube at once per policy
Jejunostomy (or gastrojejunostomy)	Through the abdominal wall; tip in the jejunum	Longer-term feeding when the stomach cannot be used	Continuous feed by pump; small bore blocks easily, so flush carefully; site care as for a gastrostomy

Confirming Placement

A tube passed blindly at the bedside can slip into the trachea instead of the esophagus. A tube in the airway can pierce the lung and cause a collapsed lung (pneumothorax), and formula or medication given through it can cause aspiration pneumonia; these complications can be life-threatening. Risk is highest in patients with a weak cough or gag reflex or reduced consciousness, and the absence of coughing during insertion does not prove the tube is in the stomach (Lemyze, 2010; Lortie & Charbonney, 2016).

First use. Canadian sources describe a radiograph as the reference standard. A tube placed blindly is confirmed by radiograph before any feed or medication is given, with no exceptions (Lortie & Charbonney, 2016). The nurse waits for confirmation that the tip is in the intended position before using the tube.

Every use after that. Tubes can move with coughing, vomiting, suctioning or a confused patient's pulling. After radiograph confirmation, the nurse records the centimetre mark at the nostril and compares it with the documented mark every 12 hours, as needed and before use (Nova Scotia Health Library, 2026). Tube position is checked at each initial assessment and before each feed or medication (ASPEN, 2014). Employer policy may add a pH test of fluid drawn back from the tube. Gastric fluid is usually acidic, often pH 5 or below, and is typically green or colourless (Lemyze, 2010). One Canadian provincial guide calls for pH testing before intermittent feeds, every 4 to 6 hours when a continuous feed can be paused, and at least 1 hour after medications (Nova Scotia Health Library, 2026).

pH has limits. Acid-suppressing drugs (section 24.4) raise gastric pH, so the test is of little use in patients taking them, and pH alone cannot always tell the stomach from the airway (Lemyze, 2010). Listening over the stomach while injecting air is not a valid check: similar sounds can be heard when the tube lies in the airway, the pleural space or the esophagus (Lemyze, 2010; Lortie & Charbonney, 2016).

When anything suggests the tube has moved, the nurse stops and does not use it. Warning signs include a mark that has changed, vomiting or retching, new coughing or breathing difficulty, or a pH that does not fit gastric placement. The nurse keeps the tube in place, secures it and reports to the prescriber; repeat imaging may be ordered. Employer policy sets which bedside checks are used, how often, and who may reinsert a tube (Scope in Practice box, this section).

CLINICAL SAFETY

Is the Tube in the Right Place?

A misplaced tube turns a routine feed into an emergency. Before anything goes down a nasal feeding tube, the nurse asks these questions.

- **Was placement confirmed after insertion?** A blindly placed tube needs radiograph confirmation before first use (Lortie & Charbonney, 2016). If the report is not back, the tube is not used.
- **Is the external mark where it should be?** The nurse compares the centimetre mark at the nostril with the documented mark (Nova Scotia Health Library, 2026).
- **Do the bedside checks fit gastric placement?** The nurse uses the checks that employer policy names, such as aspirate pH and appearance, and remembers that acid-suppressing drugs raise pH (Lemyze, 2010).
- **Has anything changed?** Vomiting, coughing fits, new breathing difficulty or falling oxygen saturation after insertion or during a feed are red flags.
- **Am I relying on a check that does not work?** Listening for air injected into the tube does not show where the tip lies and is never used to confirm placement (Lemyze, 2010).

If any answer is uncertain, the nurse holds the feed and medications, keeps the tube secured and reports to the prescriber. A patient with new respiratory distress needs urgent assessment and escalation (Chapter 6).

Giving Tube Feeds Safely

Formula can be given in three main ways. A **continuous feed** runs by pump over all or part of the day (Figure 24.4). An **intermittent feed** gives a set volume several times a day over a period of time. A **bolus feed** gives a volume by syringe over a short time, into the stomach only. Closed, ready-to-hang systems may hang for up to 24 hours, while formula poured into an open container may hang for up to 8 hours (ASPEN, 2014); employer policy may set shorter times.

Position is the simplest protection against aspiration, and lying flat is a known risk factor (Lemyze, 2010). The nurse keeps the head of the bed at 30 to 45 degrees during continuous feeds unless this is contraindicated, and for at least an hour after an intermittent feed (Nova Scotia Health Library, 2026). If the patient must lie flat for care, the feed is paused.

The nurse checks tolerance at each assessment. Abdominal distension or discomfort, nausea, vomiting, diarrhea and constipation are reported, along with stool pattern and intake and output. **Gastric residual volume (GRV)**, the volume of fluid drawn back from a gastric tube, was once checked routinely. In one Canadian provincial guide, routine GRV checks are no longer done unless ordered, and GRV is kept for patients who have other signs of intolerance (Nova Scotia Health Library, 2026). If a patient vomits, the nurse stops the feed, turns or sits the patient up and assesses breathing.

Water flushes keep the tube open and add to fluid intake. For adults who are not on a fluid restriction, ASPEN's nursing guidance calls for at least 30 mL of water before and after each intermittent feed (ASPEN, 2014). The prescriber or dietitian may order other flush volumes, especially for patients on fluid restrictions.

Figure 24.4 An enteral feeding pump with its feeding set. Enteral equipment is kept apart from IV lines, and ENFit connectors are designed so the two cannot be joined. (credit: "Enteral feeding pumps" by Ahmed Shawky Mohammedin, MD (Ashashyou)/Wikimedia Commons, CC BY-SA 3.0)

Formula belongs only in the GI tract. **ENFit** is a connector design for enteral equipment that does not fit IV or other non-enteral ports, to prevent misconnections (ASPEN, 2014). The nurse still traces every line from the patient to its source before connecting anything.

Skin care prevents harm. A nasal tube is secured without pressure on the nostril, and the skin is checked and the securement changed as policy directs. A gastrostomy or jejunostomy site is inspected daily for redness, swelling, drainage, leakage, pain or a tube that has moved. A tube that comes out is reported at once, as policy directs.

Medications by Feeding Tube

Medications are a common cause of blocked tubes. In about 15% of patients fed by tube, medications given through the tube block it (Institute for Safe Medication Practices Canada [ISMP Canada], 2013). Safe practice starts with the pharmacist.

- **Ask first.** Product monographs may say nothing about giving a drug by tube, so the nurse consults the pharmacist or another drug information source when unsure (ISMP Canada, 2013).
- **Do not assume a liquid is best.** Some liquid medications are thick or granular and block tubes readily (ISMP Canada, 2013).

Figure 24.5 A three-chamber parenteral nutrition bag. Amino acids, dextrose and lipid are kept in separate compartments until the seals between them are opened and the contents mixed, just before use. (credit: "Smofkabiven Zentral Bag" by Ibrahim Husain Meraj/Wikimedia Commons, CC BY-SA 4.0)

- **Never crush modified-release or enteric-coated drugs.** Extended-release, delayed-release and enteric-coated products, and drugs that irritate the mucosa, are not crushed (ISMP Canada, 2013). Beaded capsule contents are not given by tube (Nova Scotia Health Library, 2026). The prescriber and pharmacist choose another form or drug.
- **One at a time.** Each medication is prepared and given separately, never mixed with others and never added to the formula or flush bag (Nova Scotia Health Library, 2026).
- **Flush.** The nurse flushes with at least 15 mL of water before, between and after each medication (ASPEN, 2014).

Parenteral Nutrition

Parenteral nutrition provides dextrose, amino acids, lipid, electrolytes, vitamins, trace elements and water into a vein (Figure 24.5). It is a high-risk therapy. The patient should have a documented indication based on published guidelines (Ayers et al., 2014). Typical indications are a gut that does not work, such as with prolonged obstruction or severe malabsorption, or enteral feeding that cannot meet needs.

Most parenteral nutrition is concentrated. It is given through a **central venous access device**, such as a peripherally inserted central catheter (PICC), whose tip lies in a large central vein where blood flow dilutes the solution. A less concentrated formula can be given peripherally for a short time. The solution's osmolarity must suit the route (Ayers et al., 2014).

Safe administration includes these steps:

- **Check the bag against the order.** This includes the patient, the contents, the rate and the in-line filter named on the label (Ayers et al., 2014).
- **Give it safely.** It runs by infusion pump, through the line and filter that policy names. Employer policy usually reserves one lumen of the central line for parenteral nutrition and limits what else may run with it.
- **Prevent infection.** Line care, dressing changes and tubing changes follow infection-prevention policy (Chapter 4). A new fever or chills in a patient with a central line is reported at once.
- **Monitor.** Capillary glucose, electrolytes, weight and intake and output are monitored as ordered, because the dextrose load can cause hyperglycemia and the electrolyte shifts described in the Going Deeper box in section 24.1. ASPEN counts IV dextrose toward the calorie limits for patients at refeeding risk (da Silva et al., 2020).
- **Change only by order.** The nurse does not stop the infusion, change its rate or speed it up to make up lost time. Rate changes, interruptions and stopping follow the prescriber's order and employer policy, including any glucose checks the policy requires when the infusion is interrupted or stopped.

SCOPE IN PRACTICE

Feeding Tubes and the Nurse

In Ontario, putting an instrument "beyond the point in the nasal passages where they normally narrow" and putting an instrument "into an artificial opening into the body" are controlled acts authorized to nursing (College of Nurses of Ontario [CNO], 2025). Inserting a nasogastric tube is the first; reinserting a gastrostomy tube through an established stoma is the second.

- **Authority:** RNs and RPNs may perform these acts with an order from an authorized prescriber or a directive. Nurses cannot initiate controlled acts in public hospitals (Chapter 1, section 1.3). Starting, changing or stopping tube feeds also follows an order, and the dietitian usually recommends the formula and rate.
- **Competence:** the nurse must have the knowledge, skill and judgment to perform the act safely and to manage what follows (CNO, 2025). This includes confirming tube placement as section 24.2 describes and recognizing a misplaced tube.
- **Context:** employer policy decides who may replace a dislodged gastrostomy tube, after how long the stoma has healed, and with which equipment. Employers can limit a nurse's scope but cannot expand it (CNO, 2025). Policies often direct a dislodged tube in a new stoma, or in an unstable patient, to the surgical or interventional team.

Any nurse who finds a dislodged tube, coughing or breathing changes during a feed, or new abdominal pain stops the feed and escalates. Rules differ by province or territory and by employer, so nurses outside Ontario check their own regulator's standards.

24.3 Dysphagia and Texture-Modified Diets

Recognizing Dysphagia

Dysphagia is a swallowing disorder that can involve the mouth, the throat (pharynx), the esophagus or the junction with the stomach (American Speech-Language-Hearing Association [ASHA], n.d.). It is common after stroke and in other neurologic diseases, in head and neck cancer, and in frail older adults. Its consequences are serious: malnutrition, dehydration, aspiration pneumonia, choking and death (ASHA, n.d.).

Aspiration is the entry of food, fluid, saliva or stomach contents into the airway below the vocal folds. Nurses see patients eat and drink more often than anyone else on the team, so they are often first to notice the signs of dysphagia (ASHA, n.d.):

- coughing or clearing the throat while eating or drinking, or soon after;
- a voice that sounds wet or gurgly with or after meals and drinks;
- drooling or trouble controlling saliva or food in the mouth, such as food left in the cheeks;
- needing extra time to chew or swallow, so meals take much longer;
- weight loss, malnutrition or dehydration because the person cannot eat enough;
- repeated chest infections or aspiration pneumonia, sometimes with fever.

A cough is not a reliable alarm. In **silent aspiration**, material enters the airway with no cough or other obvious sign (ASHA, n.d.). Coughing can also occur without aspiration, so neither its presence nor its absence settles the question. For this reason, the nurse watches for later clues: a wet voice, a rising respiratory rate, new crackles, a falling oxygen saturation or a low-grade fever. These findings are reported promptly, because aspiration pneumonia can follow (Chapter 13).

Screening, Assessment and Diets

A **swallowing screen** is a brief pass-or-fail check that finds people who need a full assessment. Any trained member of the team, often the nurse, can do it with a validated protocol (ASHA, n.d.). After a stroke, people are screened before any oral intake, including medications, by a trained professional using a valid tool (Heart and Stroke Foundation of Canada, 2019; Chapter 31). A failed screen leads to a referral to the **speech-language pathologist (SLP)** (Heart and Stroke Foundation of Canada, 2019), and the person usually stays nothing by mouth, including oral medications, until assessed, as the plan directs. A passed screen does not remove all risk: no bedside screen has been shown to predict aspiration reliably (ASHA, n.d.).

The SLP leads the full assessment. It includes a clinical swallowing assessment and, for people at high risk, an instrumental study. These studies are a **videofluoroscopic swallowing study**, an X-ray of swallowing, or a **flexible endoscopic evaluation of swallowing**, which views the throat through a thin scope (ASHA, n.d.; Heart and Stroke Foundation of Canada, 2019). The SLP recommends food textures, drink thickness and swallowing strategies; the dietitian makes sure the diet meets nutritional needs.

A **texture-modified diet** changes the texture of food, the thickness of drinks, or both, to make swallowing safer. The **International Dysphagia Diet Standardisation Initiative (IDDSI)** framework gives these diets standard names and tests (Cichero et al., 2017). Some Canadian health authorities still use older diet names alongside it; Alberta Health Services, for example, has not fully moved

to IDDSI and maps its diet names onto IDDSI levels (AHS, 2022). The framework is a continuum of eight levels numbered 0 to 7, with drinks at levels 0 to 4 and foods at levels 3 to 7, each with a colour code and simple tests, such as a 10 mL syringe flow test for drinks and fork and spoon tests for foods (Cichero et al., 2017; International Dysphagia Diet Standardisation Initiative [IDDSI], 2026). Older names map onto it: "nectar-thick" fluids correspond to Level 2 and "honey-thick" to Level 3 (AHS, 2022). The levels are summarized here in this book's own words (Table 24.2); the framework and its detailed definitions belong to IDDSI and are released under a Creative Commons Attribution-ShareAlike licence (IDDSI, 2026).

Table 24.2 IDDSI drink and food levels in brief (IDDSI, 2026; Cichero et al., 2017)

Level	Name	What it is like	Example of who may need it
0	Thin (drinks)	Flows quickly, like water	A person who can manage all drinks safely
1	Slightly thick (drinks)	A little thicker than water; still flows through a straw	An adult who finds thin drinks move slightly too fast to control
2	Mildly thick (drinks)	Pours off a spoon and can be sipped, but flows more slowly than water	A person with mildly reduced tongue control
3	Moderately thick (drinks); liquidised (foods)	Can be drunk from a cup; smooth with no lumps; drips slowly through a fork	A person who needs more time to control a drink or food in the mouth
4	Extremely thick (drinks); pureed (foods)	Holds its shape on a spoon; cannot be poured, sipped or sucked through a straw; no chewing needed	A person with much reduced tongue control or who cannot chew
5	Minced and moist (foods)	Soft, moist food with small lumps (in adults, no wider than 4 mm) that the tongue can squash	A person who cannot bite and can chew only a little
6	Soft and bite-sized (foods)	Tender, moist pieces no larger than 1.5 cm; needs chewing but not biting	A person who can chew but not bite safely, or who tires with harder foods
7	Easy to chew; regular (foods)	Everyday soft foods (easy to chew) or foods of all textures (regular)	A person who can bite and chew soft foods, or all foods, safely

The framework also names **transitional foods**, which start firm but change texture with moisture or heat, such as some wafers (IDDSI, 2026).

Thickened drinks and modified textures lower risk but do not remove it (ASHA, n.d.). The nurse puts the plan into practice at each meal:

- **Position and pace:** the person sits upright, ideally in a chair, and eats at a steady pace with small mouthfuls, using the strategies the SLP recommends, under supervision if the plan calls for it.
- **Avoid hidden thin fluids:** foods that combine thin liquid and solids, such as cereal with milk, are avoided unless the plan allows them. Ice cream and jelly melt into thin fluid in the mouth (AHS, 2022).
- **Check the mouth:** after meals, the nurse checks for food left in the mouth and gives careful mouth care, which lowers pneumonia risk (Heart and Stroke Foundation of Canada, 2019).
- **Watch intake:** thick drinks and pureed food are less appealing, and a person eating pureed meals may not get enough energy and protein (AHS, 2022). The nurse tracks food and fluid intake closely and involves the dietitian.
- **Medications:** pills are not given with thin fluids when thin fluids are restricted (AHS, 2022). The nurse asks the pharmacist about a suitable form. Modified-release and enteric-coated products are never crushed (ISMP Canada, 2013).

A capable person may choose foods outside the plan. The nurse explains the risks and benefits and involves the SLP and team. Some sites use a documented managed-risk agreement (AHS, 2022). Consent and capacity are taught in Chapter 1, section 1.5.

LIFESPAN CONSIDERATIONS

Nutrition and Swallowing in Older Adults

Older adults in hospital are at high risk of both malnutrition and dysphagia, and the two problems feed each other.

- **Thresholds shift with age:** GLIM uses a higher BMI cut-off for low BMI over age 70 (below 22 kg/m² rather than below 20 kg/m²), so a BMI that seems acceptable in a younger adult may signal risk in an older one (Cederholm et al., 2019).
- **The mouth matters:** missing teeth, loose dentures and mouth pain make chewing hard (AHS, 2022). The nurse checks that dentures are in, fit well and are cleaned, and refers for dental care.
- **Life at home:** living alone and relying on adult children for groceries were linked with malnutrition on admission in the Canadian study (Allard et al., 2016). Discharge planning asks who shops and cooks and whether there is enough money for food (Chapter 2).
- **Texture and intake:** pureed meals and thick drinks can lower intake (AHS, 2022). Familiar foods, help with set-up and time to eat, company at meals and frequent small snacks help.
- **Watch for silence:** an older adult with dementia or after a stroke may aspirate without coughing (ASHA, n.d.). A new fever, confusion or fast breathing after meals is reported.
- **Medications:** reviewing medications that dry the mouth or reduce alertness, and deprescribing where possible, supports eating and swallowing (Chapter 8).

24.4 GERD, Gastritis and Peptic Ulcer Disease

Acid helps digestion, but the same acid can injure tissue when it reaches the esophagus or when the stomach's protective lining fails (section 24.1). This section covers the three most common acid-related disorders and the drugs used to treat them, including when and how to stop those drugs.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is present when stomach contents flow back into the esophagus and cause troublesome symptoms, complications or both (Katz et al., 2022). The main barrier to reflux is the lower esophageal sphincter, supported by the crural diaphragm that surrounds it. When this barrier works poorly, acid reaches the esophageal lining. Slow clearing of acid from the esophagus and a weakened lining make the injury worse (Katz et al., 2022).

The two classic symptoms are:

- **Heartburn:** a burning feeling behind the sternum that rises from the upper abdomen toward the neck.
- **Regurgitation:** stomach contents coming back up into the throat or mouth without effort, often with a sour or bitter taste (Katz et al., 2022).

Some symptoms are **alarm features** that suggest a more serious cause, such as cancer, a stricture or bleeding. Canadian and American gastroenterology guidance names difficulty swallowing (dysphagia), unintended weight loss, signs of gastrointestinal bleeding, anemia and persistent vomiting (Katz et al., 2022; Moayyedi et al., 2017). A person with an alarm feature needs prompt assessment by the prescriber, and endoscopy is usually the first test (Katz et al., 2022). The joint Canadian and American dyspepsia guideline also suggests endoscopy for people aged 60 or older whose main symptom is epigastric pain (Moayyedi et al., 2017). The nurse who hears about an alarm feature documents it and reports it rather than accepting "just heartburn" as the explanation.

Lifestyle measures are part of every plan (Farrell et al., 2017; Katz et al., 2022):

- Avoid eating within 2 to 3 hours of bedtime.
- Raise the head of the bed for night-time symptoms.
- Avoid tobacco and any foods the person finds trigger symptoms.
- Offer weight-loss support to people with a higher body weight who want it, using respectful, weight-inclusive language (section 24.6; Chapter 2).

Barrett esophagus is a precancerous change in the lining of the lower esophagus. GERD raises the risk of Barrett esophagus. Barrett esophagus is not cancer, but it can progress to esophageal cancer if it is not treated (Canadian Cancer Society, n.d.).

Gastritis and Peptic Ulcer Disease

Gastritis is inflammation of the stomach lining. **Peptic ulcer disease (PUD)** is a break through the lining of the stomach (gastric ulcer) or the first part of the duodenum (duodenal ulcer). The two leading causes are infection with **Helicobacter pylori (H. pylori)**, a bacterium that lives in the stomach, and NSAIDs, including acetylsalicylic acid (ASA). Each is an independent risk factor for ulcers and their complications (Malfertheiner et al., 2022; Tarasconi et al., 2020). Low-dose ASA for heart disease is discussed in Chapter 17; patients should not stop it without talking to the prescriber.

H. pylori infection is not spread evenly across Canada. In a multicentre Canadian study of people with dyspepsia, about 30% had the infection. Rates of 50% or more have been reported only in Indigenous communities. In Aklavik, Northwest Territories, 58% of residents tested had active infection, and gastric cancer was the second most common cancer among Inuit men in the territory (Cheung et al., 2014). The researchers worked with a community planning committee because residents had asked for the study. They pointed to structural causes, including crowded housing, challenges with water and sanitation, and distance from health care, rather than to individual behaviour (Cheung et al., 2014).

Manifestations. Dyspepsia, defined as epigastric pain as the main symptom for at least 1 month, is the usual complaint (Moayyedi et al., 2017). Nausea, early fullness and bloating may accompany it.

Complications. The nurse watches for three serious complications:

- **Bleeding:** by far the most common complication, covered in section 24.5 (Tarasconi et al., 2020).
- **Perforation:** the ulcer erodes through the wall of the stomach or duodenum, and contents leak into the abdomen. It usually begins with sudden abdominal pain. Signs of **peritonitis** (inflammation of the lining of the abdominal cavity), such as a tender, rigid abdomen, are typical, but they are absent in some patients (Tarasconi et al., 2020). Perforation is a surgical emergency: in pooled studies, 30-day mortality averaged 23.5%, and every hour's delay before surgery raises the risk of death (Tarasconi et al., 2020). The nurse keeps the patient NPO, assesses vital signs and escalates at once (Chapter 6).
- **Obstruction:** scarring near the outlet of the stomach can block emptying and cause repeated vomiting. Better medical treatment has made this complication rare (Tarasconi et al., 2020).

Diagnostics. H. pylori can be found with a non-invasive urea breath test or stool antigen test, or with biopsies taken during endoscopy. Guidance recommends non-invasive testing, and treatment if positive, for people under 60 with dyspepsia (Moayyedi et al., 2017). Some drugs suppress the bacteria and cause false-negative results. The European consensus that Canadian specialists contributed to advises stopping proton pump inhibitors 2 weeks before testing, stopping bismuth at least 4 weeks before, and avoiding any other drug that suppresses the bacteria, such as antibiotics. Antacids or H2-receptor antagonists may be used for symptoms in the meantime (Malfertheiner et al., 2022). The nurse checks the medication list when the test is booked and tells the prescriber if a recent drug could affect the result.

Treatment of H. pylori. The Toronto Consensus, the Canadian Association of Gastroenterology's guidance, recommends that every regimen last 14 days (Fallone et al., 2016). It names two first-line options:

- **Bismuth quadruple therapy:** a proton pump inhibitor, bismuth, metronidazole and tetracycline. It is the preferred first choice for people with a penicillin allergy.
- **Concomitant non-bismuth quadruple therapy:** a proton pump inhibitor, amoxicillin, metronidazole and clarithromycin.

Older three-drug regimens are restricted to areas where clarithromycin resistance is known to be low. A failed clarithromycin regimen is not repeated (Fallone et al., 2016). Success is confirmed with a breath or stool test at least 4 weeks after treatment ends; a blood antibody test cannot show eradication (Malfertheiner et al., 2022).

Patient education. The regimens involve many tablets several times a day, and missed doses lower the cure rate. The nurse teaches the patient to take every dose for the full 14 days, even when symptoms settle, and to ask the pharmacist which side effects to expect. Pharmacy blister packs can help (Fallone et al., 2016). The patient should report severe diarrhea (Chapter 4) or a rash, and should return for the confirmation test.

Acid-Suppressing Medications and Deprescribing

Three groups of drugs reduce or neutralize stomach acid (Table 24.3). **Proton pump inhibitors (PPIs)** block the final step of acid production in the stomach's acid-secreting cells and are the strongest of the three (Sun Pharma Canada, 2025). They are widely prescribed in Canada: in 2012, pantoprazole was the fifth most commonly prescribed drug in the country. Many people keep taking a PPI without a documented ongoing reason (Farrell et al., 2017).

Long-term PPI use has been linked with vitamin B12 deficiency, low magnesium, fractures, Clostridioides difficile infection and community-acquired pneumonia (Farrell et al., 2017; Sun Pharma Canada, 2025). These risks are small for any one person, but older adults may be more vulnerable (Farrell et al., 2017; Chapter 8). The goal is the lowest dose that controls symptoms, for no longer than needed.

Deprescribing is the planned, supervised reduction or stopping of a drug whose harms may now outweigh its benefits. The Canadian PPI deprescribing guideline applies to adults who have taken a PPI for more than 4 weeks for heartburn or esophagitis and whose symptoms have resolved (Farrell et al., 2017). In the book's own words, the process has five steps:

1. **Confirm the reason.** If no ongoing reason is documented, the risks may outweigh the benefit.

2. **Check for reasons to continue.** People with Barrett esophagus, severe esophagitis or a past bleeding ulcer, and those who take NSAIDs regularly and are at high risk of bleeding, usually stay on a PPI (Bruyère Research Institute, 2018; Farrell et al., 2017).

3. **Choose a plan with the patient.** Either lower the daily dose, or stop and switch to on-demand use, taking the drug daily only when symptoms return until they settle. An H2-receptor antagonist is a weaker alternative. No tapering method has been shown to be best (Farrell et al., 2017).

4. **Follow up** at about 4 and 12 weeks for heartburn, regurgitation and epigastric pain (Farrell et al., 2017).

5. **Manage symptoms that return** with lifestyle measures, an occasional antacid or alginate product, or on-demand use. If symptoms persist, the prescriber confirms H. pylori has been tested and treated (Bruyère Research Institute, 2018).

A PPI started in an intensive care unit to prevent stress ulcers and continued after the patient leaves the unit is one situation the Canadian algorithm lists for review (Bruyère Research Institute, 2018). Nurses notice these drugs during medication reconciliation and raise them with the prescriber or pharmacist.

Table 24.3 Drugs for acid-related disorders (Bruyère Research Institute, 2018; Fallone et al., 2016; Farrell et al., 2017; Malfertheiner et al., 2022; Pharmascience Inc., 2026; Sun Pharma Canada, 2025)

Class	Canadian examples	How it works	Nursing points
Proton pump inhibitors	Omeprazole, esomeprazole, lansoprazole, dexlansoprazole, pantoprazole, rabeprazole; pantoprazole is also given IV in hospital	Block the proton pump, the last step in acid secretion by stomach cells	Many work best 30 to 60 minutes before a meal; check each product's directions. Swallow delayed-release tablets whole. Review the need at every transition. Stop 2 weeks before H. pylori testing if the prescriber agrees.
H2-receptor antagonists	Famotidine	Block histamine-2 receptors on acid-secreting cells, lowering acid output	Weaker than PPIs. Used as a step-down option or for occasional symptoms. Can be used for symptoms in the weeks before H. pylori testing.
Antacids and alginates	Calcium carbonate; other antacid combinations; alginate products	Neutralize acid already in the stomach (antacids); form a barrier layer on top of stomach contents (alginates)	For occasional symptoms and during PPI deprescribing. Ask a pharmacist about spacing them from other medicines.
H. pylori regimens	Bismuth quadruple therapy; concomitant non-bismuth quadruple therapy	Combine acid suppression with antibiotics, plus bismuth in one option, to clear the infection	Every regimen runs 14 days. Teach adherence and side effects. Confirm cure at least 4 weeks after treatment with a breath or stool test.

PATIENT EDUCATION

Taking and Stopping a Proton Pump Inhibitor

- **Take it at the right time.** Many PPIs work best 30 to 60 minutes before a meal, usually breakfast (Katz et al., 2022). Some products can be taken with food, so follow the label or the pharmacist's directions.
- **Swallow it whole.** Do not crush or chew delayed-release tablets or capsules unless the pharmacist says that product allows it (Sun Pharma Canada, 2025).
- **Know why you take it.** Ask at each visit whether you still need it and for how long.
- **Do not stop on your own.** If your symptoms have settled, ask about lowering the dose or using it only when needed. Some heartburn may come back for a few days; this does not always mean you need the full dose again (Farrell et al., 2017).
- **Help yourself without pills.** Avoid eating 2 to 3 hours before bed, raise the head of your bed, avoid foods that trigger your symptoms and avoid tobacco (Katz et al., 2022).
- **Use rescue products wisely.** An antacid or alginate product can help with an occasional flare (Bruyère Research Institute, 2018).
- **Get help quickly** for trouble swallowing, weight loss you did not plan, vomiting that will not stop, vomit that looks like blood or coffee grounds, or black stools. Call 9-1-1 for heavy bleeding or fainting.

24.5 Upper Gastrointestinal Bleeding

Upper gastrointestinal bleeding (UGIB) is bleeding from the esophagus, stomach or duodenum. In one survey its yearly incidence fell from 78 to 61 cases per 100,000 people between 2001 and 2009. Even so, up to 11% of patients die within 30 days (Barkun et al., 2019). This section covers non-variceal bleeding; bleeding from esophageal varices in liver disease is covered in Chapter 26.

Causes and Risk

Peptic ulcer is the leading cause of non-variceal UGIB (Tarasconi et al., 2020). Other causes include:

- **Erosive disease:** severe esophagitis or erosive gastritis (section 24.4).
- **Mallory–Weiss tear:** a tear in the lining where the esophagus joins the stomach, typically after forceful retching or vomiting.
- **Cancer** of the esophagus or stomach.

The main risk factors are NSAIDs, ASA and H. pylori infection (Tarasconi et al., 2020). Anticoagulants and antiplatelet drugs do not cause ulcers but make any bleeding heavier and harder to stop (Barkun et al., 2019; Chapter 19). Older adults often take several of these drugs together, so the nurse reviews over-the-counter products such as naproxen and ibuprofen during every medication history.

Recognizing a Bleed

Blood can leave the body from either end of the gut:

- **Hematemesis:** vomiting bright red blood or clots, which usually means brisk bleeding.
- **Coffee-ground emesis:** dark, granular vomit; the blood has been altered by stomach acid.
- **Melena:** black, sticky, tar-like stool with a strong odour, formed when blood is digested on its way through the bowel.
- **Hematochezia:** red or maroon blood from the rectum. This usually signals a lower bleed, but a brisk upper bleed can cause it too. In a British guideline, 11% to 15% of patients first thought to have a lower bleed had an upper source, and red rectal bleeding with unstable vital signs suggests one (Oakland et al., 2019).

Blood loss produces the signs of hypovolemic shock described in Chapter 6. Early on, heart rate rises and blood vessels constrict to hold blood pressure steady. Low blood pressure is a late sign that compensation is failing (Schiller et al., 2017). Other cues are dizziness or fainting on standing, cool skin, slow capillary refill, restlessness or new confusion, and falling urine output.

Pallor can be hard to see on darker skin. Brown skin may look yellow-brown, and very dark skin may look ash grey. The nurse inspects the conjunctivae, lips, oral mucosa and nail beds in natural light and compares with the person's usual colour. A visual check alone is unreliable, so the nurse pairs it with vital signs and laboratory results (Pusey-Reid et al., 2023).

Two groups may not show the expected rise in heart rate. Beta-blockers blunt the heart-rate response that helps the body tolerate blood loss (Schiller et al., 2017), and guidance warns that shock measures based on heart rate must be read with care in people taking them (Oakland et al., 2019). Older adults may also mount a weaker response (Chapter 8). In these patients a modest rise in heart rate, new dizziness or a falling hemoglobin deserves the same urgency as frank tachycardia. The Clinical Judgment box "Melena on Day 2" shows these cues in a real-world sequence.

Care and Escalation

The nurse who suspects UGIB acts at once and does not wait for the next routine assessment. Every nurse who notices deterioration escalates, using SBAR and the rapid response team when criteria are met (Chapter 6). In Ontario, an RPN who finds melena or coffee-ground emesis assesses the patient, reports at once to the RN and the prescriber, and consults the RN as the patient's needs change. Many employers assign patients who are becoming unstable to an RN; this is a common employer practice, not a CNO rule, and employer policy shapes who does what (Chapter 1, section 1.3). Care proceeds in parallel:

- **Airway and position:** a patient who is vomiting blood or is drowsy is turned on their side, with suction ready.
- **Vital signs and early warning score:** repeated often, with intake and output.
- **IV access:** large-bore access, often two lines, as ordered or per policy, for fluids and blood.
- **Blood work:** complete blood count, group and screen (Chapter 20), coagulation tests, urea and creatinine.
- **Fluids:** fluid resuscitation begins for a patient whose circulation is unstable (Barkun et al., 2019).
- **Transfusion:** the international consensus, reviewed by the Canadian Association of Gastroenterology, suggests red cell transfusion when hemoglobin is below 80 g/L in a patient without cardiovascular disease. A higher threshold is suggested for people with cardiovascular disease. Neither threshold applies to massive bleeding (Barkun et al., 2019; section 20.6).
- **NPO:** in preparation for endoscopy (Chapter 7).
- **Medications:** an IV PPI may be ordered before endoscopy, but it must not delay the procedure. H2-receptor antagonists are not recommended for acute ulcer bleeding, and drugs that speed stomach emptying are not given routinely before endoscopy (Barkun et al., 2019).
- **Anticoagulants and antiplatelets:** held as the prescriber directs. Endoscopy is not delayed because a patient takes an anticoagulant (Barkun et al., 2019; Chapter 19).

Endoscopy both finds and treats the source. The consensus suggests it within 24 hours of presentation for patients admitted with UGIB (Barkun et al., 2019). An ulcer with active bleeding or a visible vessel has high-risk features. These lesions are treated during endoscopy, followed by high-dose IV PPI for 3 days and then an oral PPI twice daily until day 14 (Barkun et al., 2019). Patients with a clean-based ulcer may go home soon after the procedure. In rural and remote hospitals without endoscopy on site, meeting the 24-hour window can mean an early transfer, so a prompt report from the nurse starts that process sooner.

Monitoring for rebleeding. After endoscopy, the nurse watches for fresh hematemesis, new melena, a rising heart rate, a falling blood pressure or a drop in hemoglobin, and reports any of them at once. Melena may continue for a while as old blood passes, so the nurse looks at the trend in vital signs and hemoglobin as well as the stool.

Preventing a second bleed. Patients with an ulcer are tested for H. pylori and treated if positive (Tarasconi et al., 2020; section 24.4). NSAIDs are stopped where possible. Low-dose ASA for heart disease is restarted once the prescriber judges that the heart risk outweighs the bleeding risk. People with a past ulcer bleed who need an antiplatelet or anticoagulant usually take a PPI as well (Barkun et al., 2019). Before discharge, the nurse teaches the patient to avoid over-the-counter NSAIDs, including combination cold and pain products, and to seek help for black stools, vomiting of blood or fainting. The discharge summary lists which drugs were stopped or held and who will decide when to restart them, so the family physician, the community pharmacist and home care nurses share one plan. Iron deficiency after a bleed is followed up as section 20.2 describes.

> GOING DEEPER
>
> **Risk Scores in Upper GI Bleeding**
>
> *Required for RN students; optional for PN students.*

Risk scores help teams decide who needs admission and urgent endoscopy and who can safely be managed as an outpatient. The **Glasgow-Blatchford score** was built to predict which patients will need treatment, such as transfusion, endoscopic therapy or surgery, rather than only who will die (Blatchford et al., 2000). It uses information available before endoscopy:

- blood urea and hemoglobin;
- heart rate and systolic blood pressure;
- melena or fainting at presentation;
- a history of liver disease or heart failure.

Each item adds points, and higher totals mean greater need for treatment.

The international consensus suggests that a score of 1 or less identifies patients at very low risk of rebleeding or death. Such patients may not need admission or inpatient endoscopy. The consensus prefers this score because it is very sensitive: it wrongly labels as low risk 1% or fewer of patients who are truly at high risk (Barkun et al., 2019). It advises against another pre-endoscopy score, AIMS65, for this purpose.

A score supports the team's judgment; it never replaces it. A patient with a low score whose vital signs change, who faints or who keeps passing melena is reassessed and escalated. Nurses supply much of the score's data, so accurate, timely vital signs and a complete history of liver disease, heart failure and fainting matter.

CLINICAL JUDGMENT

Melena on Day 2

Names and details are fictional; this is a composite story.

Rosa Delgado, 81, was admitted for pneumonia. She takes apixaban for atrial fibrillation and metoprolol, and her daughter mentions she has taken naproxen for knee pain for 3 weeks. On day 2 the RPN caring for her reports two black, tarry stools since morning. Mrs. Delgado says she feels light-headed when she stands.

Recognize cues: Heart rate 92 (her usual 70s), blood pressure 108/64 mm Hg (usual 135/80 mm Hg), respiratory rate 20, SpO_2 95% on room air. Conjunctivae and lips are pale compared with her usual colour. Hemoglobin is 98 g/L, down from 121 g/L on admission.

Analyze cues: Melena, a falling hemoglobin, postural dizziness and a drop in blood pressure together point to an upper GI bleed. Naproxen and apixaban explain the risk. Metoprolol can hide how fast her heart would otherwise beat (section 24.5).

Prioritize hypotheses: Ongoing blood loss leading to shock is the most urgent concern. A fall from dizziness is a related risk.

Generate solutions: Report to the physician now using SBAR. Anticipate IV access, repeat blood work with group and screen, NPO, an IV PPI, holding apixaban and naproxen, and endoscopy within 24 hours. Keep her in bed with help to stand.

Take action: The RN and RPN stay with her, raise the early warning score and page the physician, who comes within 15 minutes. The RN starts IV access as ordered, sends blood and keeps her NPO.

Evaluate outcomes: One hour later her heart rate is 104 and her blood pressure is 96/58 mm Hg. Because her vital signs are worsening, the RN calls the rapid response team. After resuscitation and an endoscopy that treats a bleeding gastric ulcer, her vital signs settle and her hemoglobin holds steady. She is tested for H. pylori before discharge, and naproxen is stopped.

PRACTICE STORY

Coffee Grounds at Midnight

Names and details are fictional; this is a composite story.

Nurse: Jasleen Brar, RN. Years in practice: 4. Setting: medical unit, Ontario.

Just before midnight, the RPN on my team, Kwame, asked me to look at Mr. Leblanc. He was 76 and had been admitted with heart failure. Kwame had found a small amount of dark, gritty vomit in his basin. "It looks like coffee grounds," Kwame said, "and he says his stools were black yesterday. I didn't want to wait until morning."

Mr. Leblanc said he felt "washed out." His heart rate was 96, a little higher than earlier, but he takes bisoprolol, so I did not trust that number to tell me everything. His blood pressure had dropped from 128/74 to 106/62 mm Hg since the evening check. His skin is deep brown, so I checked his conjunctivae and gums under the bright exam light, and they looked pale. His chart showed he takes apixaban, and his wife had brought in ibuprofen for his back.

I asked Kwame to stay with him and keep him on his side in case he vomited again, and I called the physician on call with an SBAR report. I said "I am concerned about an upper GI bleed" in my first sentence. She ordered a stat hemoglobin, group and

> screen, two IV lines, NPO and an IV PPI, and she held his apixaban. His hemoglobin came back at 89 g/L; it had been 117 g/L two days earlier.
>
> At 0200 his heart rate was 108 and his pressure was 94/56 mm Hg. That met our rapid response criteria, so I called the team. He went for endoscopy in the morning, where a bleeding duodenal ulcer was treated.
>
> Kwame noticed the cue, and he was right not to wait. What I added was putting the cues together: the black stools, the beta-blocker, the drug list and the trend.
>
> Reflect: What cues allowed this bleed to be recognized before Mr. Leblanc's blood pressure fell sharply? How do the RPN's and the RN's roles in assessment and escalation differ here, and where do they overlap?

24.6 Obesity and Bariatric Surgery

Obesity as a Chronic Disease

The Canadian Adult Obesity Clinical Practice Guideline defines **obesity** as "a complex chronic disease in which abnormal or excess body fat (adiposity) impairs health" (Wharton et al., 2020). Like other chronic diseases, it has many causes, including biology, environment, income, stress and medications, and it needs long-term care rather than blame.

Body mass index (BMI), weight in kilograms divided by height in metres squared, is used to define obesity in practice: a BMI over 30 kg/m², divided into class 1 (30 to 34.9), class 2 (35 to 39.9) and class 3 (40 or more) (Wharton et al., 2020). BMI is useful for screening and for population statistics. It does not show where fat is stored or whether it is harming health (Statistics Canada, 2024; Wharton et al., 2020). Clinicians therefore add waist circumference, ethnicity-specific BMI cut-offs and an assessment of complications (Pedersen et al., 2025). The **Edmonton Obesity Staging System** is a five-stage tool that rates metabolic, physical and mental health effects. It predicted death better than BMI or waist size alone (Wharton et al., 2020).

Canadian data. In the 2022 Canadian Community Health Survey, about 30% of adults aged 18 and older had obesity, up from 21% in 2003. Rates were about equal in women and men and peaked at ages 50 to 64. They varied by province, from 26% in British Columbia to 43% in New Brunswick (Statistics Canada, 2024). These figures come from self-reported height and weight. People tend to under-report weight and over-report height, so Statistics Canada adjusts the data using measured surveys. Without that adjustment, obesity would be underestimated by about 6 to 7 percentage points (Statistics Canada, 2024).

Respectful care. Weight bias in health care lowers the quality of care for people living with obesity (Wharton et al., 2020). Chapter 2 covers weight stigma in depth. At the bedside, the nurse:

- uses person-first language ("a person living with obesity");
- asks permission before talking about weight or measuring the person;
- does not assume a new complaint is caused by body weight (Wharton et al., 2020);
- has right-sized equipment ready before it is needed, including blood pressure cuffs, gowns, chairs, beds, lifts and scales, and weighs people in private (Chapter 2).

Medications for Obesity

The guideline supports medication, added to nutrition, activity and psychological support, for adults with a BMI of 30 or more, or 27 or more with an obesity-related complication (Wharton et al., 2020). The 2025 update lists six drugs with Health Canada approval for chronic weight management (Pedersen et al., 2025). Five of them are:

- **Glucagon-like peptide-1 (GLP-1) receptor agonists:** semaglutide (Wegovy) and liraglutide (Saxenda).
- **Dual glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 receptor agonist:** tirzepatide (Zepbound).
- **Naltrexone–bupropion** (Contrave).
- **Orlistat** (Xenical), which blocks fat absorption in the gut.

The sixth is limited to certain rare genetic forms of obesity. These drugs are meant for long-term use. People who stop them tend to regain weight and lose the health benefits they gained (Pedersen et al., 2025). Nausea, vomiting, diarrhea and constipation are common with the injectable drugs, especially as the dose is increased. Orlistat can cause oily stools and urgency. The guideline

recommends against compounded products and against drugs not approved for weight loss (Pedersen et al., 2025). Treatment goals are set with the patient before starting, based on their values and preferences. Semaglutide is also approved to reduce the risk of non-fatal heart attack in adults with established cardiovascular disease and a BMI of 27 or more (Pedersen et al., 2025). Cost can limit access, in part because some payers do not recognize obesity as a chronic disease (Pedersen et al., 2025). Diabetes use of GLP-1 receptor agonists is covered in Chapter 22, and holding them before procedures in Chapter 7.

Bariatric Surgery

Bariatric surgery changes the stomach, the intestine or both to support long-term weight loss and improve obesity-related disease. The Canadian guideline says surgery can be considered for adults with a BMI of 40 or more, or 35 or more with one or more obesity-related diseases. It should also be considered for people with a BMI of 30 to 35 whose type 2 diabetes stays poorly controlled despite the best medical care (Obesity Canada, 2020b). With behaviour change, surgery leads to a long-term loss of about 20% to 40% of body weight. Laparoscopic surgery is the standard approach. For most patients the death rate is under 0.1% and the serious complication rate is under 5%, and surgery improves life expectancy (Obesity Canada, 2020b). The choice of operation is a shared decision, made with an experienced interprofessional team after the patient has heard the risks, benefits and side effects of each option.

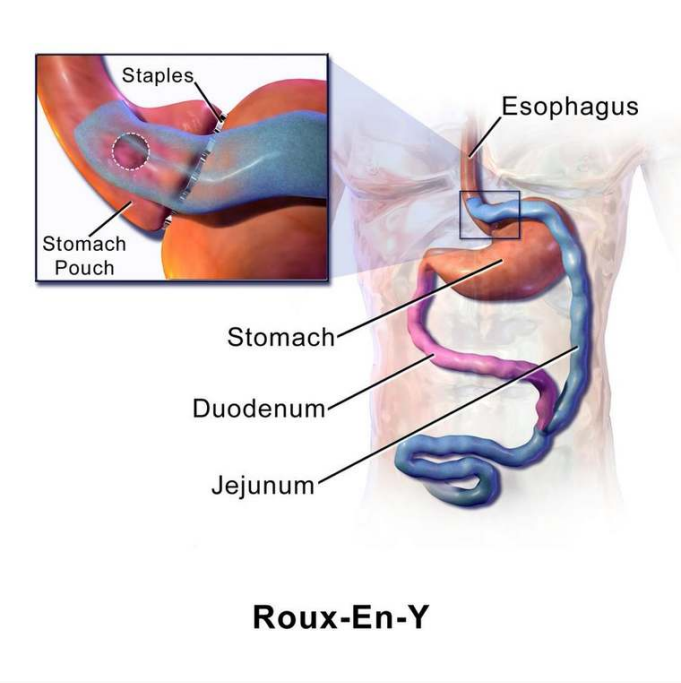

Figure 24.6 Roux-en-Y gastric bypass anatomy: a small proximal stomach pouch is created with surgical staples and anastomosed directly to a Roux limb of the jejunum, bypassing the distal stomach and duodenum. (credit: "Blausen 0776 Roux-En-Y 01" by BruceBlaus/Wikimedia Commons, CC BY 3.0)

Two widely used operations, sleeve gastrectomy and Roux-en-Y gastric bypass, are compared in Table 24.4. Adjustable gastric banding should no longer be offered because of its complications and long-term failure (Obesity Canada, 2020b; Figure 24.6).

Table 24.4 Sleeve gastrectomy and Roux-en-Y gastric bypass compared (Kim et al., 2015; Mechanick et al., 2020; Obesity Canada, 2020b; The Ottawa Hospital, 2023)

Feature	Sleeve gastrectomy	Roux-en-Y gastric bypass
What is done	A large part of the stomach is removed, leaving a narrow tube	A small new stomach pouch is made and joined to the small intestine; the rest of the stomach is bypassed
Leak rates in published series	0% to 7%	0.1% to 8.3%
Timing of leaks	Often appear later, sometimes after discharge	Signs may be subtle or delayed
Dumping syndrome	Can occur; sweets and high-fat foods are limited	Concentrated sweets are removed from the diet to limit symptoms
Diet progression	Pureed stage may last up to 2 weeks	Pureed stage usually about 1 week
NSAIDs	Avoided after surgery	Stopped before surgery and avoided after
Alcohol	Avoided because of changed alcohol metabolism and risk of alcohol use disorder	Avoided for the same reasons
Vitamins and minerals	Lifelong supplements and regular blood tests	Lifelong supplements and regular blood tests

Care After Bariatric Surgery

Early care follows the perioperative principles in Chapter 7, including VTE prevention. Early walking lowers the risk of clots (Mechanick et al., 2020). The nurse encourages calf and ankle exercises and short walks several times a day from the day of surgery (The Ottawa Hospital, 2023).

Anastomotic leak. An **anastomotic leak** is escape of stomach or intestinal contents through a staple or suture line. It is among the most dangerous early complications. After sleeve gastrectomy, the most common signs are tachycardia, fever and abdominal pain, and the pain often spreads to the left shoulder (Kim et al., 2015). Blood tests rarely help, and imaging can be normal even when a leak is present. A persistently high heart rate is therefore never explained away as pain or anxiety. Leaks after sleeve gastrectomy often show up after discharge (Kim et al., 2015), so discharge teaching names these signs. The nurse who finds them escalates at once (Chapter 6).

Staged diet. Eating restarts in stages: clear fluids, full fluids, pureed foods, soft foods, then regular textures over several weeks, as the surgical team's protocol directs (Mechanick et al., 2020). The nurse teaches the patient to:

- sip small amounts often;
- meet a protein target of at least 60 g a day (Mechanick et al., 2020);
- eat slowly and chew well;
- separate drinks from solid food by about 30 minutes (The Ottawa Hospital, 2023).

Dumping syndrome. In **dumping syndrome**, food moves too quickly into the small intestine and draws water in. It causes cramping, bloating, nausea, diarrhea, faintness and a fast heart rate, usually 10 to 90 minutes after eating (The Ottawa Hospital, 2023). Avoiding concentrated sweets and high-fat foods, eating small meals and separating liquids from solids reduce symptoms (Mechanick et al., 2020; The Ottawa Hospital, 2023).

Lifelong supplements. Surgery reduces absorption of several nutrients. Patients take supplements every day for life, usually including (Mechanick et al., 2020; Obesity Canada, 2020b; The Ottawa Hospital, 2023):

- a multivitamin with minerals;
- vitamin B12;
- calcium citrate and vitamin D;
- iron as blood work shows it is needed.

Calcium and iron are taken at least 2 hours apart. Blood tests check iron, vitamin B12, vitamin D and other nutrients at set intervals, then at least yearly (Obesity Canada, 2020a; The Ottawa Hospital, 2023). Deficiencies such as iron and B12 deficiency are discussed in section 20.2.

Medications and alcohol. Early after surgery, crushed or liquid immediate-release forms replace extended-release drugs (Mechanick et al., 2020). Only crush a tablet the pharmacist confirms can be crushed. NSAIDs are avoided, and acetaminophen is the usual pain reliever (Mechanick et al., 2020; The Ottawa Hospital, 2023). Diabetes and blood pressure medications often need adjustment as weight falls (Chapter 22). Surgery changes how the body handles alcohol and raises the risk of alcohol use disorder, so patients are advised to avoid alcohol (Mechanick et al., 2020; Chapter 11).

Mental health and follow-up. Mood, relationships and body image can all be affected after surgery. The risks include depression, thoughts of suicide, disordered eating and substance use (Obesity Canada, 2020a; The Ottawa Hospital, 2023). The nurse screens for these concerns and connects patients with the team's mental health supports. Pregnancy is avoided for 12 to 18 months after surgery, so contraception is discussed (Mechanick et al., 2020). Follow-up is shared among the surgical centre, primary care and the patient, with an annual review of nutrition, supplements, medications and blood work (Obesity Canada, 2020a). Weight is usually lowest 12 to 18 months after surgery and then rises somewhat. This is expected, but large regain is a reason to return to the bariatric team, not a personal failure (Obesity Canada, 2020a).

Chapter 24 Summary

24.1 Digestion and Nutrition Assessment

- The upper GI tract runs from the mouth to the duodenum; the stomach's acid is balanced by mucosal defences, and the stomach acts as a reservoir that shapes how tube feeds can be given.
- In a Canadian Malnutrition Task Force study, 45% of adults admitted to medical and surgical units in 18 hospitals were malnourished at admission, and malnutrition was linked with longer stays.
- Every adult admitted is screened with the two-question Canadian Nutrition Screening Tool, the first step of INPAC, which then guides assessment, levels of nutrition care, weekly weights and discharge planning.
- GLIM diagnoses malnutrition when a person meets at least one phenotypic and one etiologic criterion; weight history and muscle tell more than BMI alone, and albumin reflects inflammation rather than nutrition.
- Refeeding syndrome is a fall in phosphate, potassium or magnesium after nutrition starts in an undernourished person; at-risk patients need electrolytes checked, thiamine, a slow start and close monitoring.

24.2 Enteral and Parenteral Nutrition

- Feeding tubes are named by entry and tip position; nasal tubes are for short-term use, and gastrostomy or jejunostomy tubes for longer-term feeding.
- A blindly placed nasal tube is confirmed by radiograph before first use; afterwards, the nurse checks the external mark and does the bedside checks policy names before each use, and never relies on listening for injected air.
- Feeds are given with the head of the bed at 30 to 45 degrees unless contraindicated; routine gastric residual checks are no longer done unless ordered; ENFit connectors help prevent misconnections.
- Medications go through the tube one at a time with water flushes, after checking with the pharmacist; modified-release and enteric-coated products are never crushed, and nothing is added to the formula.
- Parenteral nutrition is a high-risk IV therapy, usually given through a central line; the nurse checks the bag against the order, prevents infection, monitors glucose and electrolytes, and changes or stops the infusion only by order.

24.3 Dysphagia and Texture-Modified Diets

- Signs of dysphagia include coughing or a wet voice with eating or drinking, trouble controlling food in the mouth, slow meals, weight loss and repeated chest infections; aspiration can be silent.
- A swallowing screen identifies who needs assessment; after a stroke, no food, drink or oral medication is given until the person is screened, and a failed screen usually means nothing by mouth until the speech-language pathologist assesses the person.
- The IDDSI framework describes drinks (levels 0 to 4) and foods (levels 3 to 7) on one continuum with standard tests.
- At meals, the nurse positions the person upright, follows the SLP's strategies, avoids hidden thin fluids, gives mouth care and watches food and fluid intake.
- Pills are not given with thin fluids when these are restricted, and a capable person's choices outside the plan are respected after an informed discussion.

24.4 GERD, Gastritis and Peptic Ulcer Disease

- GERD causes heartburn and regurgitation. Dysphagia, unplanned weight loss, bleeding, anemia and persistent vomiting are alarm features that need prompt assessment.
- Lifestyle measures include no meals 2 to 3 hours before bed, raising the head of the bed, and avoiding tobacco and personal trigger foods.
- H. pylori and NSAIDs, including ASA, are the main causes of peptic ulcers. H. pylori is much more common in some northern Indigenous communities, for structural reasons.
- Sudden severe abdominal pain with a rigid abdomen suggests perforation, a surgical emergency: keep the patient NPO and escalate.

- H. pylori treatment lasts 14 days (Toronto Consensus). PPIs are stopped 2 weeks before testing, and cure is confirmed at least 4 weeks after treatment.
- Long-term PPIs carry small risks. Adults whose symptoms have resolved can lower the dose or switch to on-demand use, with follow-up at 4 and 12 weeks.

24.5 Upper Gastrointestinal Bleeding

- Peptic ulcer is the leading cause of non-variceal UGIB. NSAIDs, ASA, H. pylori, anticoagulants and antiplatelets raise risk.
- Hematemesis, coffee-ground emesis and melena point to an upper bleed. A brisk upper bleed can also cause red rectal bleeding.
- Beta-blockers and older age can blunt tachycardia. Pallor on darker skin is assessed in the conjunctivae and oral mucosa in natural light.
- Care includes airway protection, IV access, group and screen, NPO, an IV PPI that does not delay endoscopy, and endoscopy within 24 hours.
- Transfusion is suggested below 80 g/L without cardiovascular disease, and at a higher threshold with it.
- A Glasgow-Blatchford score of 1 or less marks very low risk, but the score never replaces judgment.

24.6 Obesity and Bariatric Surgery

- Obesity is a chronic disease. BMI is a screening tool with limits; self-reported data underestimate prevalence (about 30% of Canadian adults in 2022, adjusted).
- Respectful care means asking permission before talking about weight or measuring, using person-first language and having right-sized equipment ready.
- Six drugs are approved in Canada for chronic weight management. They are meant for long-term use, and weight returns when they are stopped.
- Surgery can be considered at a BMI of 40 or more, or 35 or more with an obesity-related disease. Sleeve gastrectomy and Roux-en-Y gastric bypass are two widely used operations.
- Tachycardia, fever and abdominal pain after surgery suggest an anastomotic leak. Escalate even if imaging is normal.
- After surgery: staged diet, dumping prevention, lifelong vitamin and mineral supplements, no NSAIDs, no alcohol, and attention to mental health.

Key Terms (49)

alarm features: symptoms such as dysphagia, unplanned weight loss, bleeding, anemia or persistent vomiting that suggest a serious cause and call for prompt assessment.

anastomotic leak: escape of stomach or intestinal contents through a surgical staple or suture line.

aspiration: The entry of food, fluid, saliva or stomach contents into the airway below the vocal folds.

bariatric surgery: surgery on the stomach, intestine or both to support long-term weight loss and improve obesity-related disease.

Barrett esophagus: a precancerous change in the lining of the lower esophagus, linked with long-term reflux, that raises the risk of esophageal cancer.

bolus: A soft, cohesive mass of chewed food or fluid that the tongue shapes and moves to the back of the mouth for swallowing.

Canadian Nutrition Screening Tool (CNST): A two-question screen asking about unintended weight loss over the last six months and eating less than usual for over a week; a yes to both shows nutrition risk.

central venous access device: An IV catheter whose tip lies in a large central vein, such as a peripherally inserted central catheter (PICC), used for concentrated solutions such as most parenteral nutrition.

coffee-ground emesis: dark, granular vomit containing blood that has been altered by stomach acid.

deprescribing: the planned, supervised reduction or stopping of a drug whose harms may now outweigh its benefits.

dumping syndrome: cramping, nausea, diarrhea, faintness and fast heart rate after eating, caused by food moving too quickly into the small intestine.

dyspepsia: epigastric pain as the main symptom for at least 1 month.

dysphagia: A swallowing disorder involving the mouth, pharynx, esophagus or the junction of the esophagus and stomach.

Edmonton Obesity Staging System: a five-stage tool that rates the metabolic, physical and mental health effects of obesity.

ENFit: A connector design for enteral feeding equipment that does not fit IV or other non-enteral ports, used to prevent tubing misconnections.

enteral nutrition: Feeding into the GI tract; in this chapter, liquid formula given through a feeding tube.

gastric residual volume (GRV): The volume of fluid drawn back from a gastric feeding tube; no longer checked routinely unless ordered or when signs of intolerance appear.

gastritis: inflammation of the stomach lining.

gastroesophageal reflux disease (GERD): a condition in which stomach contents flow back into the esophagus and cause troublesome symptoms, complications or both.

gastrostomy tube: A feeding tube that passes through the abdominal wall into the stomach, used for longer-term feeding.

Glasgow-Blatchford score: a pre-endoscopy risk score for upper GI bleeding that predicts the need for treatment; a score of 1 or less marks very low risk.

Global Leadership Initiative on Malnutrition (GLIM) criteria: International criteria that diagnose malnutrition when a person at risk meets at least one phenotypic criterion (weight loss, low BMI or reduced muscle mass) and at least one etiologic criterion (reduced intake or absorption, or inflammation).

Helicobacter pylori (H. pylori): a bacterium that lives in the stomach and causes gastritis, peptic ulcers and some stomach cancers.

hematemesis: vomiting of bright red blood or clots.

hematochezia: red or maroon blood passed from the rectum.

Integrated Nutrition Pathway for Acute Care (INPAC): A Canadian pathway for hospital nutrition care that moves from screening with the CNST to assessment, standard, advanced and specialized nutrition care, and discharge planning.

International Dysphagia Diet Standardisation Initiative (IDDSI): The international framework that describes drink thickness and food texture on a continuum of eight levels numbered 0 to 7.

jejunostomy tube: A feeding tube that passes through the abdominal wall into the jejunum, usually used with a continuous feed by pump.

malnutrition: In this chapter, undernutrition: a state in which the body does not take in or use enough energy and nutrients, so muscle and fat are lost and function declines.

melena: black, sticky, tar-like stool containing digested blood.

nasogastric (NG) tube: A tube passed through the nose and esophagus into the stomach, used for short-term feeding, medications or drainage.

obesity: a chronic, complex disease in which excess or abnormal body fat harms health.

parenteral nutrition: Nutrition given into a vein, used when the gut cannot be used or cannot meet the person's needs.

peptic ulcer disease (PUD): a break through the lining of the stomach or duodenum, most often caused by H. pylori or NSAIDs.

percutaneous endoscopic gastrostomy (PEG): A gastrostomy tube placed with the help of an endoscope passed through the mouth into the stomach.

perforation: erosion of an ulcer through the wall of the stomach or duodenum, letting contents leak into the abdomen; a surgical emergency.

peristalsis: Waves of muscle contraction that move food along the GI tract.

peritonitis: inflammation of the lining of the abdominal cavity.

proton pump inhibitor (PPI): a drug that blocks the final step of acid production in the stomach.

refeeding syndrome: A fall in blood phosphate, potassium or magnesium, sometimes with thiamine deficiency, within days of starting or increasing nutrition in a person who has been undernourished.

Roux-en-Y gastric bypass: bariatric surgery that creates a small stomach pouch joined to the small intestine, bypassing the rest of the stomach.

silent aspiration: Aspiration that occurs without coughing or other obvious signs.

sleeve gastrectomy: bariatric surgery that removes a large part of the stomach, leaving a narrow tube.

speech-language pathologist (SLP): A regulated health professional who assesses swallowing and recommends food textures, drink thickness and swallowing strategies.

Subjective Global Assessment (SGA): A structured bedside assessment that classifies nutrition status using weight change, intake, symptoms, function and physical signs of muscle and fat loss.

swallowing screen: A brief pass-or-fail check, done by a trained team member with a validated protocol, that identifies people who need a full swallowing assessment.

texture-modified diet: A diet that changes food texture, drink thickness or both to make swallowing safer.

upper gastrointestinal bleeding (UGIB): bleeding from the esophagus, stomach or duodenum.

weight bias: negative attitudes, beliefs or actions toward people because of their body weight.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Gurdev Sandhu (Questions 1–4): Gurdev Sandhu, 82, was admitted 4 days ago with an ischemic stroke; he failed his bedside swallowing screen, the speech-language pathologist found that he aspirates thin fluids, a small-bore nasogastric tube was inserted yesterday with its tip confirmed in the stomach by radiograph and the 60 cm mark documented at the nostril, and he now receives continuous enteral formula by pump and his medications by tube, with nothing by mouth.

1. [CORE] Before giving Mr. Sandhu's 0900 medications through the tube, which action should the nurse take first?

a. Inject 20 mL of air into the tube while listening over the upper abdomen for a gurgling sound

b. Compare the mark at the nostril with the 60 cm documented and do the bedside checks policy requires

c. Ask the prescriber for a repeat radiograph of the tube before each medication pass for the rest of the day

d. Withdraw and discard about 60 mL of stomach contents to prove that the tube is open and working

Answer: b — After radiograph confirmation, the nurse checks that the tube has not moved before each use by comparing the external centimetre mark with the documented mark and doing the bedside checks policy names, such as aspirate pH (section 24.2, Confirming Placement). Listening for injected air is not a valid check, because similar sounds occur when the tube is in the airway or esophagus. A radiograph is needed for first use and when the tube may have moved, not before every medication pass. Withdrawing and discarding a large volume does not confirm the tip position and removes gastric fluid and formula.

2. [CORE] At 1400, the nurse finds Mr. Sandhu lying almost flat after a care aide repositioned him. The feed is running. What is the nurse's best action?

a. Stop the feed for the rest of the shift and report the flat position to the prescriber and dietitian

b. Leave him flat for now, because repositioning him again so soon could cause a pressure injury on his sacrum

c. Raise the head of the bed only during medication passes and flushes, when aspiration risk is highest

d. Raise the head of the bed to 30 to 45 degrees unless contraindicated, and keep it raised during the feed

Answer: d — Lying flat during a feed is a risk factor for aspiration; the head of the bed is kept at 30 to 45 degrees during continuous feeds unless contraindicated (section 24.2, Giving Tube Feeds Safely). Stopping the feed for the whole shift is not needed once he is repositioned and has no signs of aspiration. Pressure injury prevention is done with turning and support surfaces while the head stays raised, not by leaving him flat. Aspiration risk is present throughout a continuous feed, not only during medication passes.

3. [CORE] Mr. Sandhu's medication record lists an extended-release tablet once daily for blood pressure. What should the nurse do?

a. Crush the tablet into a fine powder, mix it into the formula in the feeding bag and restart the pump

b. Crush the tablet into a fine powder, dissolve it in warm water, give it and then flush with water

c. Hold the dose and contact the pharmacist and prescriber about a form that can go through the tube

d. Give the tablet whole by mouth with a small sip of water, because a single tablet carries little risk

Answer: c — Extended-release, delayed-release and enteric-coated products are never crushed; the pharmacist and prescriber choose another form or drug (section 24.2, Medications by Feeding Tube). Crushing alters the release and can cause a dangerous dose. Medications are never added to the formula. Mr. Sandhu aspirates thin fluids and is nothing by mouth, so oral medication with water is unsafe.

4. [CORE] On day 6, Mr. Sandhu becomes restless. His respiratory rate has risen from 18 to 28 breaths/min, his oxygen saturation has fallen from 96% to 89% on room air, his temperature is 38.2 °C and there are new coarse crackles at the right lung base. He has not coughed. What is the nurse's priority?

a. Stop the feed, keep the head of the bed up, assess the airway and escalate at once to the prescriber or rapid response team

b. Continue the feed, because he has not coughed and silent aspiration is rare, then recheck his vital signs in 4 hours

c. Give acetaminophen for the fever and record the new findings so that the day team can review them on morning rounds

d. Flush the tube with 30 mL of water and recheck the mark at the nostril before deciding whether anyone needs to be called

Answer: a — The findings suggest aspiration, possibly from a displaced tube or reflux of formula, and the patient is deteriorating; the nurse stops the feed, protects the airway and escalates at once (section 24.2, Confirming Placement; section 24.3, Recognizing Dysphagia; Chapter 6). Aspiration can be silent, so the lack of a cough is not reassuring. Treating the fever and waiting delays care for a patient with falling oxygen saturation. Flushing a tube that may be in the airway is dangerous, and the tube is not used until its position is confirmed.

5. [CORE] A nurse screens a newly admitted 70-year-old man with the Canadian Nutrition Screening Tool. Which pair of answers shows that he is at nutrition risk?

a. He lost 4 kg over the winter but has since regained it, and he has eaten less than usual for 3 days

b. He lost weight on purpose following a meal plan, and he has eaten normally over the past month

c. He has lost weight in the past 6 months without trying, and has eaten less than usual for over a week

d. He has not lost any weight, but he has eaten noticeably less than usual for more than 2 weeks in a row

Answer: c — The CNST asks about unintended weight loss over the last six months and eating less than usual for over a week; a yes to both shows nutrition risk (section 24.1, Screening for Malnutrition). Weight that was regained does not count as weight loss, and 3 days of lower intake does not meet the time frame. Planned weight loss with normal intake gives two "no" answers. One "yes" alone does not meet the CNST's definition of risk, although the nurse still watches intake.

6. [CORE] A patient admitted with pneumonia has a serum albumin of 26 g/L. A nursing student says this proves the patient is malnourished. Which response by the nurse is most accurate?

a. "Albumin falls with inflammation, so it can't diagnose malnutrition; weight change, intake and muscle tell us more."

b. "Low albumin confirms protein malnutrition, so the patient should start a high-protein supplement right away."

c. "Albumin is the best measure of muscle mass, so this result shows how much muscle the patient has lost."

d. "Albumin rises quickly once a patient eats well, so a repeat level in 2 days will show whether feeding works."

Answer: a — ASPEN states that albumin and prealbumin mainly reflect inflammation and should not be used to diagnose malnutrition or stand in for muscle mass (section 24.1, Signs and Causes of Malnutrition). Low albumin in pneumonia does not confirm malnutrition. Albumin is not a measure of muscle. Because inflammation drives the level, a short-term change does not show whether feeding is working.

7. [CORE] A 58-year-old woman with a BMI of 31 kg/m² has lost 10 kg in 4 months without trying and says food has "not tasted right" since chemotherapy began. Which conclusion is correct?

a. Her BMI is above the usual range, so her nutrition is adequate and no further screening is needed now

b. Losing weight in a larger body is a health benefit, so the team should encourage her to keep it up

c. Malnutrition can only be diagnosed once the BMI falls below 20 kg/m², so she should be rechecked later

d. She is at nutrition risk despite her BMI, so she needs screening and a referral to the dietitian

Answer: d — Unintended weight loss and reduced intake signal risk whatever the BMI; a person in a larger body can lose a great deal of muscle while the BMI stays high (section 24.1, Signs and Causes of Malnutrition). A high BMI does not show adequate nutrition. Unintended weight loss during cancer treatment is not a benefit, and framing it that way is weight bias (Chapter 2). GLIM counts weight loss and muscle loss as well as low BMI, so a low BMI is not required.

8. [CORE] Meal records show that a patient has eaten about one quarter of each meal for 2 days. Under the Integrated Nutrition Pathway for Acute Care (INPAC), what does this finding mean?

a. Intake is acceptable for a patient who is ill in hospital, so the nurse simply continues routine meal monitoring

b. Intake of half a meal or less is low, so the team acts on barriers to eating and considers more nutrition care

c. Intake has failed by mouth, so the nurse should request that parenteral nutrition be started today

d. Intake is reviewed only at the weekly weight, so the nurse waits until then before acting on it

Answer: b — INPAC treats eating half a meal or less as low intake that needs action, such as removing barriers to eating and moving to advanced care with dietitian involvement as needed (section 24.1, Screening for Malnutrition). Low intake is not acceptable to watch without acting. Parenteral nutrition is for a gut that cannot be used or cannot meet needs, not a first step for low oral intake. Waiting a week delays action.

9. [CORE] An RPN on a medical unit is about to restart a patient's intermittent tube feed and finds the 52 cm mark at the nostril. The mark was documented at 60 cm after radiograph confirmation. What should the RPN do?

a. Hold the feed, secure the tube without using it, and report to the RN or prescriber as employer policy directs

b. Push the tube in 8 cm until the 60 cm mark is back at the nostril, retape it and then start the feed as ordered

c. Inject air into the tube while listening over the stomach, and start the feed if a clear gurgle can be heard

d. Start the feed at half the ordered rate for now and recheck the mark at the nostril at the end of the shift

Answer: a — A changed external mark suggests the tube has moved, so the tube is not used until its position is confirmed; the RPN reports to the RN or prescriber, and repeat imaging may be ordered (section 24.2, Confirming Placement). Pushing a tube back in blindly can place it in the airway, and reinsertion follows an order or directive and employer policy. Listening for injected air does not confirm placement. A slower feed into a misplaced tube is still dangerous.

10. [CORE] A patient on an IDDSI Level 5 (minced and moist) diet with Level 2 (mildly thick) drinks asks the RPN for toast and coffee with no thickener. The patient is alert and capable. What is the best response?

a. Bring the toast and plain coffee right away, because a capable patient's wishes always override the diet plan

b. Decline the request and document in the chart that the patient is not complying with the diet order

c. Explain the reasons for the plan, offer safe choices and involve the SLP and team in a discussion of the risks

d. Soften the toast in milk and thicken the coffee to Level 4, so that both items fit the minced and moist level

Answer: c — A capable person may make choices that carry risk, but the choice must be informed; the nurse explains, offers safe options and involves the SLP and team, and some sites use a managed-risk agreement (section 24.3, Screening, Assessment and Diets; Chapter 1, section 1.5). Giving the food without discussion skips informed choice. Labelling the patient noncompliant without discussion is neither respectful nor safe. Toast soaked in milk mixes thin liquid with solids, and the nurse does not change texture levels without the SLP's plan.

11. [CORE] A patient receiving continuous gastric feeds has a soft, non-distended abdomen, no nausea and regular bowel movements. A new graduate asks whether to check gastric residual volume every 4 hours. Which reply fits the Canadian provincial guidance described in this chapter?

a. "Yes; residuals are checked every 4 hours in every adult who is receiving a continuous gastric feed."

b. "Not routinely; residuals are checked when they are ordered or when signs of intolerance appear."

c. "Yes; any fluid that returns is a sign of intolerance, so the feed is stopped whenever it occurs."

d. "Never; residuals are no longer measured for any reason, even if the abdomen becomes distended."

Answer: b — In one Canadian provincial guide, routine gastric residual checks are not done unless ordered and are reserved for patients with other signs of intolerance (section 24.2, Giving Tube Feeds Safely). Routine checks every 4 hours are no longer standard. Some fluid normally returns from the stomach and does not by itself mean intolerance. Residuals may still be checked when ordered or when signs such as distension appear.

12. [CORE] Why are hospitals using ENFit connectors on enteral feeding equipment?

a. They allow enteral syringes to fit IV lines too, so one syringe can be used for every route

b. They hold the tube firmly in place, so the nurse no longer needs to check the mark at the nostril

c. They allow formula to flow faster, so continuous feeds can be finished in fewer hours each day

d. They are designed so enteral equipment cannot connect to IV or other non-enteral ports

Answer: d — ENFit connectors are designed so enteral equipment cannot connect to IV or other non-enteral ports, to prevent misconnections (section 24.2, Giving Tube Feeds Safely). Allowing one syringe to fit every route is exactly the error they prevent. Connectors do not secure the tube or replace placement checks. They do not change the flow rate.

13. [CORE] A patient receiving parenteral nutrition through a peripherally inserted central catheter has a capillary glucose of 14.6 mmol/L. What should the nurse do?

a. Report the result to the prescriber, follow the glucose orders and keep monitoring as ordered

b. Stop the parenteral nutrition at once and hang normal saline until the next bag is delivered from pharmacy

c. Slow the infusion to half the ordered rate and recheck the glucose at the end of the shift

d. Move the infusion to a peripheral IV line so the dextrose enters the bloodstream more slowly

Answer: a — The dextrose in parenteral nutrition can cause hyperglycemia; the nurse reports, follows orders and keeps monitoring (section 24.2, Parenteral Nutrition). The nurse does not stop the infusion or change its rate without an order. A concentrated central formula is not moved to a peripheral line, and the route does not change the glucose load.

14. [CORE] A nurse watches an older adult with Parkinson disease eat lunch. Which findings suggest dysphagia? Select all that apply.

a. A wet, gurgly voice after sips of water

b. Coughing and throat clearing during the meal

c. Taking much longer than usual to finish meals

d. Asking for a second helping of dessert

e. Two chest infections with fever in the past 3 months

f. A clear, strong voice after eating and drinking

Answer: a, b, c, e — A wet voice, coughing or throat clearing during meals, needing extra time to eat, and repeated chest infections are signs of dysphagia (section 24.3, Recognizing Dysphagia). A good appetite does not suggest a swallowing problem. A clear, strong voice after eating does not point to dysphagia, though it does not rule out silent aspiration.

15. [CORE] After a stroke, a patient who is waiting for a swallowing assessment drinks some water during a family visit and does not cough. His daughter says this proves he swallows safely. What is the nurse's best response?

a. "That is reassuring; a person who swallows without coughing is protecting his airway well."

b. "Not coughing is a good sign, so he can keep having water until the assessment takes place."

c. "Some people aspirate without coughing, so he needs to stay on his plan until he is assessed."

d. "Coughing only matters when people eat solid food, so small sips of water are safe for him today."

Answer: c — Silent aspiration happens without a cough, so the absence of coughing does not show a safe swallow; he stays on his plan until the speech-language pathologist assesses him (section 24.3, Recognizing Dysphagia; Screening, Assessment and Diets). Thin water is often the hardest consistency to control, and a failed or pending screen means nothing by mouth. Coughing with fluids matters as much as coughing with solids.

16. [CORE] A patient's plan calls for IDDSI Level 2 (mildly thick) drinks. Which description fits this level?

a. Flows as quickly as water and can be drunk through any straw or cup

b. Pours off a spoon and can be sipped, but flows more slowly than water

c. Holds its shape on a spoon and cannot be poured, sipped or sucked through a straw

d. Smooth and lump-free, and falls slowly in small blobs between the tines of a fork

Answer: b — Level 2 drinks pour off a spoon and can be sipped but flow more slowly than thin drinks (section 24.3, Screening, Assessment and Diets). Flowing like water describes Level 0. Holding shape on a spoon describes Level 4 (extremely thick). Dripping slowly through a fork describes Level 3.

17. [CORE] A patient on an IDDSI Level 4 (pureed) diet is prescribed an enteric-coated tablet. What should the nurse do?

a. Crush the tablet finely and mix it into a spoonful of pureed fruit so that it fits the diet level

b. Give the tablet whole with a glass of thin water after making sure the patient is sitting upright

c. Split the tablet in half so that each piece is easier to swallow with a spoonful of thick drink

d. Keep the tablet whole and ask the pharmacist about another form that suits the diet level

Answer: d — Enteric-coated and modified-release products are never crushed or split; the pharmacist advises on a suitable form (section 24.3, Screening, Assessment and Diets; ISMP Canada, 2013). Crushing destroys the coating. A person on pureed food may not swallow a whole tablet safely, and pills are not given with thin fluids when thin fluids are restricted. Splitting also damages the coating.

18. [RN] A 34-year-old with a BMI of 15.5 kg/m² who has eaten almost nothing for 10 days started enteral feeds yesterday. Phosphate was 1.05 mmol/L before feeding and is 0.62 mmol/L today. Which interpretation and action are best?

a. The drop of about 40% after feeding began fits refeeding syndrome; report it promptly and expect replacement and a slower feed

b. The new value is most likely a laboratory error, because it changed so much within a single day, so the test should just be repeated

c. Phosphate always dips on the second day of feeding and returns to normal without treatment, so the feed should continue

d. The fall shows that the feed is being used well by the body, so the rate should be increased to reach the goal sooner

Answer: a — A fall of more than 30% in phosphate within 5 days of starting nutrition in an undernourished person fits severe refeeding syndrome by ASPEN's definition; the nurse reports promptly, and the prescriber and dietitian may replace electrolytes and slow the feed (section 24.1, Going Deeper: Refeeding Syndrome). The patient's risk makes a true fall likely, so it should not be dismissed as error. Low phosphate can weaken breathing muscles and the heart and needs treatment. Increasing the feed would worsen the shift.

19. [RN] A patient who has received parenteral nutrition through a central venous catheter for 9 days develops chills and a temperature of 38.7 °C, with no other obvious source. What should the nurse suspect, and what should the nurse do first?

a. Hyperglycemia from the dextrose load; give insulin by sliding scale and continue the infusion at the same rate

b. A reaction to the lipid emulsion; slow the infusion to half the ordered rate and recheck the temperature in an hour

c. A catheter-related bloodstream infection; report at once and prepare for cultures and sepsis screening per orders

d. Refeeding syndrome; hold the next bag and give an oral phosphate supplement from the ward stock right away

Answer: c — Fever and chills in a patient with a central line and parenteral nutrition suggest a catheter-related bloodstream infection; the nurse reports at once and prepares for cultures and sepsis assessment per orders (section 24.2, Parenteral Nutrition; Chapter 4). Hyperglycemia does not cause fever and chills, and insulin is given only by order. The nurse does not change the rate without an order. Refeeding syndrome causes falling electrolytes, not fever, and nurses do not give ward-stock supplements without an order.

20. [RN] Which patient meets the GLIM criteria for malnutrition?

a. A 66-year-old man admitted with pneumonia whose BMI is 24 kg/m², with stable weight and his usual intake

b. A 72-year-old woman who lost 7% of her weight in 3 months and has eaten under half her needs for 2 weeks

c. A 50-year-old man after surgery with a serum albumin of 28 g/L, stable weight and his usual intake

d. A 45-year-old runner who lost 6% of her weight in 4 months while eating as usual, with no illness at all

Answer: b — GLIM requires at least one phenotypic criterion and at least one etiologic criterion (section 24.1, Signs and Causes of Malnutrition). A weight loss of more than 5% within six months is phenotypic, and eating half or less of energy needs for more than a week is etiologic. Pneumonia is an etiologic criterion (inflammation) but there is no phenotypic criterion. Albumin is not a GLIM criterion, and surgery alone supplies only inflammation. Weight loss with usual intake and no illness meets only a phenotypic criterion.

Case: Ernest Kowalczyk (Questions 21–26): Ernest Kowalczyk, 79, was admitted 2 days ago to a medical unit with a urinary tract infection. He takes apixaban for atrial fibrillation and metoprolol for hypertension, and he has taken naproxen bought at a pharmacy for 3 weeks for hip pain. At 1000 he tells the practical nurse (PN) he has had two black, sticky, foul-smelling stools this morning and feels dizzy when he stands. Vital signs at 1000: temperature 37.0 °C, heart rate 94 (88 at 0800 and 72 yesterday), blood pressure 112/66 mm Hg (138/80 mm Hg yesterday), respiratory rate 20, SpO_2 95% on room air. His skin is dark brown; his conjunctivae and lips look paler than at admission. Hemoglobin is 101 g/L (124 g/L on admission). Blood urea has risen from 6.8 to 11.2 mmol/L.

21. [CORE] Which findings require immediate follow-up by the nurse? Select all that apply.

a. Temperature 37.0 °C after 2 days of treatment for a urinary tract infection

b. Two black, sticky stools this morning with a foul smell

c. Hemoglobin of 101 g/L, down from 124 g/L on admission

d. Oxygen saturation of 95% on room air with a respiratory rate of 20

e. Dizziness when he stands up, which is new this morning

f. Blood pressure of 112/66 mm Hg compared with 138/80 mm Hg yesterday

g. Hip pain for which he has been taking naproxen for 3 weeks

Answer: b, c, e, f — Melena (b), a 23 g/L drop in hemoglobin (c), new postural dizziness (e) and a fall in blood pressure (f) are cues of an active upper GI bleed with early hypovolemia (section 24.5). His temperature (a) is normal and shows the infection is responding. An SpO_2 of 95% with a respiratory rate of 20 (d) is acceptable for him and is not the urgent problem. Hip pain (g) explains why he took naproxen, which matters for risk, but the pain itself does not need immediate follow-up.

22. [CORE] The nurse notes that Mr. Kowalczyk's heart rate has risen only to 94. Which explanation best accounts for this?

a. Bleeding from the upper GI tract does not change heart rate until a person has lost more than half of their blood volume

b. Apixaban slows the sinus node, so patients taking it rarely develop a fast heart rate during bleeding

c. Metoprolol blunts the heart-rate rise that normally helps a person compensate for blood loss

d. A heart rate below 100 in an adult older than 75 shows that compensation for blood loss is adequate

Answer: c — Beta-blockers such as metoprolol blunt the sympathetic rise in heart rate that helps people tolerate blood loss, and older adults may also respond less, so a modest rise can hide a serious bleed (section 24.5). Heart rate normally rises early, long before half the blood volume is lost (a). Apixaban is an anticoagulant and does not slow the sinus node (b); it makes bleeding heavier. A heart rate under 100 (d) does not prove adequate compensation, especially with a falling blood pressure and hemoglobin.

23. [CORE] Which problem should the nurse address first?

a. Risk of hypovolemic shock from ongoing upper GI bleeding

b. Risk of falling because of dizziness when he stands up

c. Lack of knowledge about the risks of over-the-counter NSAIDs

d. Risk of acute kidney injury from naproxen and the infection

Answer: a — Ongoing blood loss that leads to shock threatens his life and drives the other problems, so it comes first (section 24.5; Chapter 6). Fall risk (b) is real and is managed at the same time by keeping him in bed with help, but it follows from the bleed. Teaching about NSAIDs (c) belongs to discharge planning once he is stable. Kidney injury (d) is possible and is monitored, but it is not the most urgent problem.

24. [CORE] The physician is notified and comes to assess Mr. Kowalczyk. Which plan should the nurse expect while he waits for endoscopy?

a. Clear fluids by mouth, oral iron three times a day and a repeat hemoglobin tomorrow morning

b. Continue apixaban to prevent stroke, and give naproxen with food to protect his stomach

c. Transfuse two units of red cells at once, because his hemoglobin has fallen below 110 g/L

d. NPO, IV access, group and screen, an IV PPI, holding apixaban and endoscopy within 24 hours

Answer: d — The expected plan is NPO for endoscopy, IV access, blood work with group and screen, an IV PPI that does not delay the procedure, holding the anticoagulant as the prescriber directs and endoscopy within 24 hours (section 24.5). Oral intake and oral iron with a next-day check (a) ignore an active bleed. Continuing apixaban and naproxen (b) would worsen bleeding; naproxen is a cause. A fall below 110 g/L is not a transfusion threshold; the decision depends on his hemoglobin, his cardiovascular history and his clinical status, so he is reassessed as results and vital signs change rather than given two units at once (c; section 20.6).

25. [CORE] At 1130, Mr. Kowalczyk vomits about 200 mL of bright red blood. He is drowsy but answers questions. Heart rate is 112 and blood pressure is 90/54 mm Hg. Which action should the nurse take first?

a. Insert a nasogastric tube to remove blood from his stomach before calling anyone

b. Turn him onto his side, stay with him and call the rapid response team

c. Measure his capillary refill time and document the volume of emesis in the chart

d. Give the next scheduled dose of metoprolol to slow his heart rate

Answer: b — Protecting his airway and getting immediate help come first: turning him on his side lowers the risk of aspiration, and his vital signs meet rapid response criteria (section 24.5; Chapter 6). A nasogastric tube (a) needs an order and is not the first action. Capillary refill and documentation (c) matter but must not delay escalation. Giving metoprolol (d) would lower his blood pressure further and hide his response to bleeding; the nurse holds the dose and discusses it with the prescriber.

26. [CORE] Mr. Kowalczyk has endoscopic treatment of a bleeding gastric ulcer and is receiving a high-dose IV PPI. Which finding the next morning best shows that the treatment is working?

a. He passed one more black stool overnight, and his heart rate is 104

b. His blood pressure is 102/60 mm Hg, and he says he is thirsty

c. Heart rate 80, blood pressure 128/74 mm Hg and hemoglobin steady at 92 g/L on two checks

d. He has had no stool since the procedure, and he is sleeping more than usual

Answer: c — Stable vital signs close to his usual values and a hemoglobin that holds steady on repeated checks show that bleeding has stopped (section 24.5). One more black stool can be old blood, but a heart rate of 104 (a) suggests ongoing loss. A blood pressure of 102/60 mm Hg with thirst (b) suggests he is still volume depleted. No stool (d) does not prove the bleed has stopped, and increased sleepiness in an older adult needs assessment (Chapter 8).

27. [CORE] A 52-year-old with heartburn for 2 years asks for a refill of an over-the-counter antacid. Which additional finding should the nurse report to the prescriber promptly?

a. Food sticking in the chest when swallowing, with 6 kg of weight loss she did not plan

b. Heartburn that is worse after large meals and when she lies down soon after eating

c. A sour taste in the mouth on waking that clears after she brushes her teeth

d. Relief of burning within minutes of chewing an antacid tablet

Answer: a — Dysphagia and unplanned weight loss are alarm features that call for prompt assessment, usually with endoscopy (section 24.4). Symptoms that worsen after large meals and when lying down (b), and a sour taste on waking (c), are typical GERD symptoms. Quick relief with an antacid (d) is expected and is not an alarm feature.

28. [CORE] The nurse teaches a patient with GERD about lifestyle measures. Which statement shows the patient needs more teaching?

a. "I'll put blocks under the head of my bed because my heartburn wakes me at night."

b. "I'll keep a note of which foods seem to bring on my heartburn so I can avoid them."

c. "I'll ask about the smoking cessation program, since tobacco can make reflux worse."

d. "I'll have my main meal later in the evening, right before I go to bed, so I sleep better."

Answer: d — Eating within 2 to 3 hours of bedtime worsens reflux, so a large meal right before bed needs correcting (section 24.4). Raising the head of the bed for night-time symptoms (a), avoiding personal trigger foods (b) and avoiding tobacco (c) are all recommended.

29. [CORE] A patient is booked for a urea breath test for H. pylori in 10 days. She takes pantoprazole every morning for heartburn. Which action should the nurse take?

a. Tell her to take an extra pantoprazole the morning of the test so the result is clearer

b. Contact the prescriber, because a PPI should usually be stopped 2 weeks before testing

c. Tell her the PPI has no effect on the test and she should keep taking it as usual

d. Advise her to switch to a bismuth product for her heartburn until the test is done

Answer: b — PPIs can suppress H. pylori and cause a false-negative result, so guidance advises stopping them 2 weeks before testing; with only 10 days left, the nurse contacts the prescriber about the timing (section 24.4). An extra dose (a) would make a false-negative more likely. Saying the PPI has no effect (c) is wrong. Bismuth (d) should also be avoided for 4 weeks before testing; an antacid or H2-receptor antagonist can be used for symptoms instead.

30. [CORE] A patient starting bismuth quadruple therapy for H. pylori asks why there are so many pills. Which response by the nurse is best?

a. "You can stop the antibiotics once your stomach pain is gone, but keep taking the acid reducer."

b. "Take whichever pills you can manage; even half the doses will usually clear the infection."

c. "Take every dose for the full 14 days. A pharmacy blister pack can help you keep track."

d. "If you miss a day, take a double dose of everything the next day to make up for it."

Answer: c — Canadian guidance recommends 14 days for every regimen, and missed doses lower the cure rate; adherence aids such as blister packs help (section 24.4). Stopping antibiotics when pain settles (a) or taking only some doses (b) risks treatment failure and resistance. Doubling doses (d) is unsafe and is not how missed doses are handled; the patient asks the pharmacist.

31. [CORE] A patient with known peptic ulcer disease suddenly reports severe abdominal pain. The abdomen is rigid and very tender, and heart rate has risen from 84 to 118. Which action should the nurse take first?

a. Keep the patient NPO and notify the physician urgently, using SBAR

b. Give the ordered oral antacid and reassess the pain in 30 minutes

c. Encourage the patient to walk to help relieve gas and bloating

d. Apply a warm compress to the abdomen and give the ordered acetaminophen by mouth

Answer: a — Sudden severe pain with a rigid abdomen and a rising heart rate suggests perforation, a surgical emergency in which delay raises mortality; the nurse keeps the patient NPO and escalates at once (section 24.4; Chapter 6). An oral antacid (b) and oral acetaminophen (d) add to stomach contents and delay escalation; heat can mask findings. Walking (c) treats the cues as gas and delays care.

32. [CORE] A nurse reviews the medication list of an older adult who has taken a proton pump inhibitor for 6 years. Which conditions have been linked with long-term PPI use? Select all that apply.

a. Vitamin B12 deficiency

b. High blood potassium

c. Low blood magnesium

d. Hip and other fractures

e. Clostridioides difficile infection

f. Community-acquired pneumonia

g. Low blood sugar during sleep

Answer: a, c, d, e, f — The Canadian PPI deprescribing guideline and product monographs link long-term PPI use with vitamin B12 deficiency (a), low magnesium (c), fractures (d), C. difficile infection (e) and community-acquired pneumonia (f) (section 24.4). High potassium (b) and nocturnal low blood sugar (g) are not listed harms of PPIs.

33. [CORE] The nurse is assessing a patient with dark brown skin for possible anemia after an upper GI bleed. Which approach is best?

a. Rely on the colour of the palms under the room's overhead fluorescent lighting

b. Ask the patient whether their skin looks paler than usual to them today

c. Check capillary refill alone, because colour cannot be judged on dark skin

d. Inspect the conjunctivae and oral mucosa in natural light against usual colour

Answer: d — Pallor on darker skin may look ash grey or yellow-brown and is best seen in the conjunctivae, lips and oral mucosa in natural light, compared with the person's usual colour, and confirmed with vital signs and hemoglobin (section 24.5). Fluorescent overhead light (a) distorts colour. The patient's own view (b) is useful history but is not an assessment. Colour can be assessed on dark skin with the right technique, and capillary refill alone (c) is not enough.

34. [CORE] In an Ontario hospital, a registered practical nurse (RPN) is asked to insert a nasogastric tube for a patient. Which statement about the RPN's authority is correct?

a. The RPN may insert the tube on their own judgment, because it is a routine nursing activity

b. The RPN may insert the tube with an order or directive if competent and if employer policy allows

c. Only an RN may insert a nasogastric tube, because it is a controlled act

d. The RPN may insert the tube only if a physician is present at the bedside

Answer: b — Putting an instrument beyond the point where the nasal passages normally narrow is a controlled act authorized to both RNs and RPNs; it needs an order or directive, the nurse must be competent and employer policy can limit it (Scope in Practice box, section 24.2). It is not something a nurse may initiate in a public hospital (a). The act is not limited to RNs (c), and the law does not require a physician at the bedside (d).

35. [CORE] A patient living with obesity is admitted for cellulitis. Which nursing action best reflects respectful, weight-inclusive care?

a. Ask the patient's permission before talking about weight or measuring them, and weigh them in private

b. Begin admission teaching by explaining that weight loss will help the cellulitis heal faster

c. Use the standard adult blood pressure cuff for all patients, so readings are consistent across the unit

d. Record "morbidly obese" in the nursing assessment so that other staff can plan equipment needs

Answer: a — The Canadian guideline recommends asking permission before talking about weight or measuring, and privacy protects dignity (section 24.6). Assuming the complaint is about weight (b) is a form of weight bias. A cuff that is too small (c) gives falsely high readings; right-sized equipment is needed. Stigmatizing labels (d) should be avoided; person-first language and a clear equipment plan meet the same need.

36. [CORE] A patient 6 weeks after Roux-en-Y gastric bypass reports cramping, nausea, sweating and a fast heart rate about 20 minutes after eating. Which teaching is most appropriate?

a. "Drink a large glass of fruit juice with each meal to replace the fluid that you are losing."

b. "These symptoms mean the surgery has failed, so you should call 9-1-1 every time they happen."

c. "Avoid concentrated sweets, eat small meals and wait about 30 minutes after eating to drink."

d. "Lie flat for an hour after meals and add an extra dessert to keep up your energy."

Answer: c — These are signs of dumping syndrome, which is reduced by avoiding concentrated sweets and high-fat foods, eating small meals and separating liquids from solids (section 24.6). Fruit juice with meals (a) and extra dessert (d) add sugar and liquid at the wrong time and worsen symptoms. Dumping does not mean surgery has failed (b), although severe or new symptoms should be reported to the bariatric team.

37. [CORE] A patient is preparing for discharge 2 days after sleeve gastrectomy. Which statement shows understanding of medication safety after bariatric surgery?

a. "I'll take ibuprofen for my incision pain because it works better than acetaminophen."

b. "I can stop my multivitamin once I am eating regular food again in a few months."

c. "I'll crush my extended-release blood pressure tablet so it is easier to swallow."

d. "I'll use acetaminophen for pain and ask the pharmacist before I crush any tablet."

Answer: d — Acetaminophen is the usual pain reliever after bariatric surgery, and only tablets the pharmacist confirms can be crushed should be crushed (section 24.6). NSAIDs such as ibuprofen (a) are avoided because of ulcer risk. Supplements are lifelong (b). Crushing an extended-release tablet (c) can release the whole dose at once; early after surgery, immediate-release or liquid forms are used instead.

38. [RN] A 46-year-old arrives in the emergency department after one episode of melena. Vital signs and hemoglobin are normal, and the Glasgow-Blatchford score is 0. How should the nurse interpret this score?

a. The patient has a high risk of rebleeding and needs endoscopy within the next hour

b. The patient is at very low risk and may not need admission or inpatient endoscopy

c. The score rules out a peptic ulcer, so no follow-up or teaching is needed

d. The score cannot be calculated until endoscopy has shown the source of bleeding

Answer: b — The international consensus suggests that a Glasgow-Blatchford score of 1 or less identifies patients at very low risk who may not need admission or inpatient endoscopy, with clinical judgment and follow-up (Going Deeper box, section 24.5). A score of 0 does not mean high risk (a). The score estimates risk; it does not rule out an ulcer, and the patient still needs follow-up and teaching (c). The score uses pre-endoscopy data such as urea, hemoglobin and vital signs (d).

39. [RN] A medication review is done for four adults who have taken a PPI for more than a year. For which patient is deprescribing the PPI most appropriate to discuss?

a. A 64-year-old whose heartburn from mild esophagitis resolved after an 8-week course

b. A 70-year-old with Barrett esophagus who has regular follow-up with a gastroenterologist

c. A 75-year-old with a documented bleeding duodenal ulcer last year who takes ASA daily

d. A 68-year-old with severe (grade D) esophagitis found on endoscopy 2 years ago

Answer: a — The Canadian deprescribing guideline applies to adults with resolved symptoms from GERD or mild to moderate esophagitis, who can lower the dose or switch to on-demand use (section 24.4). Barrett esophagus (b), a history of bleeding ulcer with ongoing ASA (c) and severe esophagitis (d) are reasons to continue a PPI.

40. [RN] On the day of discharge, 2 days after sleeve gastrectomy, a patient has a heart rate of 124 (88 yesterday), a temperature of 38.3 °C and abdominal pain that spreads to the left shoulder. A contrast study yesterday was normal. Which action should the nurse take?

a. Give the ordered hydromorphone and recheck vital signs in 4 hours, because pain explains the tachycardia

b. Proceed with discharge, because yesterday's normal contrast study rules out a leak

c. Encourage fluids by mouth and deep breathing, and report the findings at the next physician round

d. Hold the discharge and notify the surgeon urgently, because these are signs of an anastomotic leak

Answer: d — Tachycardia, fever and abdominal pain that often spreads to the left shoulder are the most common signs of a leak after sleeve gastrectomy, and imaging can be normal even when a leak is present, so the nurse escalates at once (section 24.6). Explaining the heart rate as pain (a) delays treatment of a life-threatening complication. A normal study does not rule out a leak (b). Waiting for rounds (c) delays care, and extra oral fluids may be unsafe if a leak is present.

25 Lower Gastrointestinal Disorders

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Assess bowel function and manage constipation, fecal impaction, diarrhea and fecal incontinence, with attention to older adults.
2. Explain Crohn disease and ulcerative colitis, support their treatment, and recognize a severe flare.
3. Recognize and care for adults with diverticular disease and appendicitis, including signs of perforation and peritonitis.
4. Recognize bowel obstruction and ileus, escalate signs of strangulation, and provide nursing care using the CJMM.
5. Support colorectal cancer screening and care for patients after colorectal surgery.
6. Assess stomas and peristomal skin on a range of skin tones, and teach ostomy care and living well with an ostomy.
7. Distinguish RN and RPN roles in bowel and ostomy care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4	Clinician; Scholar	Foundations of Practice
5, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Collaborator	Legal Practice; Collaborative Practice

Introduction

Bowel habits are private, and many adults find them hard to talk about. Yet changes in bowel function are among the most common problems the nurse meets, in hospital and in the community. Consider four patients: a man who has not passed stool for four days after hip surgery; an older woman whose new "diarrhea" turns out to be liquid stool leaking around a hard mass; a young adult passing bloody stool ten times a day; and a patient whose abdominal pain has suddenly become constant, with a rigid abdomen. Each needs a nurse who asks clear questions, recognizes what is serious and acts early.

This chapter covers disorders of the lower gastrointestinal (GI) tract: the small and large intestines, the rectum and the anus. Section 25.1 explains normal bowel function and assessment, then constipation, fecal impaction, diarrhea and fecal incontinence. Section 25.2 covers inflammatory bowel disease, including how to recognize a severe flare. Section 25.3 covers diverticular disease and appendicitis, with the signs of perforation and peritonitis. Section 25.4 turns to bowel obstruction and ileus, section 25.5 to colorectal cancer screening and surgery, and section 25.6 to ostomy care and teaching.

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1 (sections 1.3 to 1.5), and cultural safety and body image in Chapter 2. Dehydration, potassium and magnesium are in Chapter 3; *Clostridioides difficile* (*C. difficile*) infection and contact precautions in section 4.4; and opioid-induced constipation in Chapter 5. Recognizing deterioration and calling for help are in Chapter 6, perioperative care in Chapter 7 and delirium in section 8.2. Nutrition, feeding tubes and upper GI bleeding are in Chapter 24, and skin care in Chapter 35.

25.1 Bowel Function, Constipation and Diarrhea

Normal Bowel Function and Assessment

The small intestine absorbs most nutrients and much of the water that enters the gut each day. The **colon** (large intestine) absorbs more water and electrolytes, stores waste and moves it toward the rectum with slow waves of muscle contraction. The longer stool stays in the colon, the more water is removed and the harder it becomes. When stool stretches the rectum, the person feels an urge to defecate. The internal anal sphincter relaxes without conscious control, while the external sphincter is under voluntary control, so a person can usually wait until a toilet is available.

"Normal" bowel habits vary widely, so the nurse compares each finding with the person's own usual pattern. A **bowel history** covers:

- usual frequency, consistency and timing, and any recent change;
- straining, urgency, pain, a feeling of incomplete emptying, and leakage;
- blood, mucus or black stool (upper GI bleeding is covered in section 24.5);
- fluid and fibre intake, activity, and toileting habits and privacy;
- medications, including over-the-counter laxatives, iron and calcium supplements, and recent antibiotics;
- past abdominal surgery, and any family history of colorectal cancer or inflammatory bowel disease.

Rectal bleeding, a lasting change in bowel habit, unplanned weight loss, anemia, or diarrhea that wakes the person at night is reported to the prescriber, because these findings need investigation (section 25.5).

By convention, the abdominal examination follows the order inspect, auscultate, percuss, then palpate, so that listening comes before touching. The nurse inspects the contour for distension, scars, hernias and stomas. Percussion sounds hollow (tympanic) over gas and dull over fluid, stool or a mass. Palpation starts lightly, away from any painful area, while the nurse watches the patient's face and feels for guarding or rigidity.

Bowel sounds are less useful than many clinicians believe. In a Danish study, 53 doctors listened to recordings of bowel sounds from 98 patients being assessed for possible obstruction. Their median sensitivity for an abnormal finding was 0.42 and their median specificity 0.78, agreement between listeners was poor, and senior doctors did no better than junior ones (Breum et al., 2015). The authors concluded that decisions should not be based on bowel sounds. The nurse still documents them, but gives more weight to the whole picture: passing of flatus and stool, distension, nausea and vomiting, pain, and tolerance of food and fluids.

The **Bristol Stool Form Scale** is a seven-point picture chart that describes stool form in words patients and nurses share (Lewis & Heaton, 1997). Types 1 and 2 are separate hard lumps or a lumpy sausage, which suggest slow transit and constipation. Types 3 and 4 are formed and smooth or slightly cracked. Types 5 to 7 range from soft blobs to entirely liquid stool, which suggest fast transit. The nurse records the type with the amount, colour, and any blood or mucus.

Constipation and Fecal Impaction

Constipation means stools that are infrequent, hard or difficult to pass, often with straining or a sense of incomplete emptying. Because people define it differently, the nurse asks what the patient means (Larkin et al., 2008). Common causes in hospital include:

- **medications:** opioids (section 5.4), drugs with anticholinergic effects, iron and calcium supplements;
- **immobility** and bed rest;
- **low fluid and fibre intake**, including during fasting for tests or surgery;
- **toileting barriers:** lack of privacy, bedpans, waiting for help, and ignoring the urge (Larkin et al., 2008);
- **neurologic disease**, such as Parkinson disease, stroke, multiple sclerosis and spinal cord injury;
- **metabolic causes**, such as hypothyroidism (Chapter 23) and a high calcium or low potassium (Chapter 3).

Fecal impaction is a mass of hard stool in the rectum or colon that the person cannot pass. Liquid stool from higher in the bowel can seep around the mass. This **overflow diarrhea** is easily mistaken for ordinary diarrhea. An antidiarrheal drug then makes the impaction worse. Impaction may cause abdominal or rectal discomfort, distension, loss of appetite, nausea, urinary retention and, in

older adults, new confusion. A digital rectal examination confirms it; in Ontario this is a controlled act, and who may do it is explained in the Scope in Practice box in section 25.6.

Prevention comes first. Unless fluids are restricted, the nurse encourages regular drinks, adds fibre gradually with enough fluid, helps the patient walk, and offers the toilet at a regular time, ideally after a meal. Sitting upright on a toilet or commode, with the feet supported and the door closed, makes passing stool easier than using a bedpan. When these measures are not enough, a laxative is added (Table 25.1). A joint guideline of two American gastroenterology societies made strong recommendations for polyethylene glycol and sodium picosulfate in chronic constipation, and conditional ones for fibre, lactulose, senna and magnesium oxide (Chang et al., 2023). For impaction, rectal measures such as a suppository or enema, or manual removal by an authorized nurse, clear the rectum; a regular oral plan then prevents recurrence (Larkin et al., 2008).

The nurse reports constipation at once when it comes with severe or worsening pain, vomiting, distension, no passing of gas, fever, or rectal bleeding. These findings may mean bowel obstruction (section 25.4) or another serious cause.

Diarrhea

Diarrhea is an increase in loose or watery stools above the person's usual pattern. Acute diarrhea starts suddenly and usually settles within days; chronic diarrhea lasts for weeks. Causes include:

- **infection**, including *C. difficile* after antibiotics. The nurse follows section 4.4 for testing and contact precautions as soon as it is suspected;
- **medications**, such as antibiotics, magnesium-containing products, laxative overuse and cancer treatment (Chapter 9);
- **enteral feeding** (section 24.2);
- **inflammatory bowel disease** (section 25.2);
- **overflow around an impaction**.

The nurse records the frequency, volume and Bristol type of each stool, and any blood, fever or pain. Large losses cause dehydration and low potassium and magnesium; the nurse watches for thirst, dizziness on standing, a rising heart rate and falling urine output, and monitors intake and output (sections 3.2, 3.5 and 3.6).

Liquid stool damages skin quickly. The nurse cleanses gently and promptly, pats the skin dry and applies a barrier product (Chapter 35). Irritation may look red on lighter skin but purple, grey or darker than surrounding skin on darker skin, so the nurse also feels for warmth and asks about burning and itching (Wounds International, 2023).

Antidiarrheal drugs are used only once infection has been considered. The Canadian monograph for loperamide states that it must not be used in acute dysentery (blood in the stool with fever), acute ulcerative colitis, bacterial enterocolitis from invasive organisms, or pseudomembranous colitis after broad-spectrum antibiotics (Kenvue Canada, 2026). It is stopped at once if the abdomen becomes distended, and in acute diarrhea it is stopped if there is no improvement within 48 hours. Doses above those recommended have caused serious heart rhythm problems. Loperamide never replaces fluid and electrolyte therapy.

Fecal Incontinence in Brief

Fecal incontinence is the involuntary loss of liquid or solid stool. Causes include diarrhea and urgency, overflow from impaction, sphincter injury from childbirth or anal surgery, nerve damage from diabetes, stroke or spinal cord injury, dementia, and limited mobility when help to the toilet is slow. Many people never mention it, so the nurse asks privately and plainly. Care treats the cause: managing diarrhea or impaction, a regular toileting schedule, prompt answers to call bells, and referral to a continence specialist, such as a Nurse Specialized in Wound, Ostomy and Continence (NSWOC). The nurse protects the skin as above (Chapter 35) and protects dignity: calling incontinence products "briefs" rather than "diapers," changing them promptly and keeping the patient covered.

Table 25.1 Laxatives and bowel care products (Chang et al., 2023; Larkin et al., 2008; Canadian product monographs)

Class	Canadian examples	How it works	Nursing points

Class	Canadian examples	How it works	Nursing points
Bulk-forming	Psyllium	Absorbs water and adds bulk, so stool is softer and easier to pass	Give with a full glass of fluid; avoid when fluid intake is poor or obstruction is suspected; bloating is common at first
Osmotic	Polyethylene glycol 3350; lactulose; magnesium hydroxide	Holds or draws water into the bowel to soften stool	Mix polyethylene glycol in fluid; gas and cramps may occur, especially with lactulose; check kidney function before magnesium products
Stimulant	Sennosides; bisacodyl	Stimulates the bowel's nerves and muscle to push stool along	Cramping is common; often paired with an osmotic laxative when opioids are used (Chapter 5)
Rectal suppositories and enemas	Glycerin suppository; bisacodyl suppository; sodium phosphate enema	Softens stool or triggers emptying of the lower bowel	For low impaction or when oral measures fail; position on the left side; stop if pain or resistance; read the product's cautions before using a phosphate enema, especially for an older adult or a person with kidney disease or dehydration
Bowel preparation products	Polyethylene glycol–electrolyte solutions; sodium picosulfate–magnesium oxide–citric acid	Empties the whole colon before colonoscopy or surgery	Follow the specific product's instructions; see section 25.5

LIFESPAN CONSIDERATIONS

Constipation and Impaction in Older Adults

Older adults are at high risk of constipation and impaction. Many take several drugs that slow the bowel, move less, and drink less because thirst is blunted or toileting is difficult. Cognitive impairment may stop them from reporting symptoms, so the first signs may be indirect: new or worse confusion (section 8.2), restlessness, falls, loss of appetite, urinary retention, or loose stool that is really overflow.

The nurse:

- keeps a bowel record each shift, with the Bristol type, and acts on the unit's plan when no stool has been passed;
- considers impaction before giving an antidiarrheal to an older adult with new loose stool and a history of constipation;
- reviews the medication list with the prescriber and pharmacist (section 8.5);
- checks kidney function before magnesium- or phosphate-containing products;
- offers the toilet after meals, with privacy, support for the feet and time.

Pregnancy: iron supplements and hormonal changes often cause constipation; the person checks with their prescriber or pharmacist before using any laxative.

Younger adults with constipation and warning signs, such as rectal bleeding or weight loss, still need assessment; age alone does not rule out serious disease.

25.2 Inflammatory Bowel Disease

Crohn Disease and Ulcerative Colitis

Inflammatory bowel disease (IBD) is a group of chronic conditions in which the immune system keeps the lining of the gut inflamed. The two main forms are Crohn disease and ulcerative colitis. Both are believed to arise when an inherited tendency meets environmental triggers and the immune response to the normal gut bacteria becomes excessive. Both follow a pattern of flares and remission, and both differ from irritable bowel syndrome, which does not inflame or damage the bowel.

Crohn disease can affect any part of the gut from the mouth to the anus, most often the end of the small intestine (the ileum) and the colon. Diseased segments are separated by normal "skip" areas, and inflammation runs through the full thickness of the bowel wall. Deep inflammation can scar the bowel into a narrowed **stricture** or create a **fistula**, an abnormal tunnel to the skin, bladder, vagina or another loop of bowel. Disease around the anus, with abscesses and fistulas, is common.

Ulcerative colitis (UC) affects only the colon. It begins in the rectum and spreads upward without gaps, and it inflames the inner lining rather than the whole wall. Its extent is described as **proctitis** (rectum only), left-sided colitis, or extensive colitis (Bressler et al., 2015). Table 25.2 compares the two diseases.

Canada has some of the highest rates of IBD in the world, and most people are diagnosed before age 30 (Crohn's and Colitis Canada, 2023). The Canadian Context box gives the numbers.

Manifestations depend on the form and location. UC typically causes bloody diarrhea, urgency, cramping and **tenesmus**, a painful feeling of needing to pass stool even when the rectum is empty. Crohn disease often causes abdominal pain, frequently in the right lower quadrant, with diarrhea, weight loss, fatigue and perianal pain or drainage. During a flare, either form may cause fever, a fast heart rate, anemia and dehydration.

Extraintestinal manifestations are features of IBD outside the gut. They include joint pain and swelling, eye inflammation (uveitis or episcleritis), mouth ulcers, and skin conditions such as erythema nodosum and pyoderma gangrenosum (Moran et al., 2025). **Erythema nodosum** appears as tender, warm, raised lumps, usually on the shins. On lighter skin they look pink to red. Inflammation often does not look red on medium and darker skin, where the lumps may look violet, brown or darker than the surrounding skin, or be hard to see at all, so the nurse also feels for warm, tender lumps and compares both legs (Wounds International, 2023). **Pyoderma gangrenosum** starts as a painful pustule or nodule that breaks down into a painful ulcer. A painful red eye, blurred vision or new sensitivity to light needs same-day assessment.

Diagnostics confirm the diagnosis, measure severity and rule out infection:

- **Stool tests** for bacteria and *C. difficile* (section 4.4), because infection can mimic or trigger a flare.
- **Fecal calprotectin**, a protein released by white blood cells into the stool. It is very sensitive for bowel inflammation but not specific, since infection and some drugs also raise it. In UC, a value under 100 mcg/g makes healing of the lining likely, while a value over 200 mcg/g should prompt discussion of endoscopy (Moran et al., 2025).
- **Endoscopy with biopsies:** colonoscopy confirms the diagnosis; in a severe flare, a limited flexible sigmoidoscopy is used instead.
- **Imaging**, such as computed tomography, magnetic resonance imaging or bowel ultrasound, to assess the small bowel and look for strictures, fistulas and abscesses.
- **Blood tests:** complete blood count for anemia, C-reactive protein (CRP, in mg/L) for inflammation, albumin, potassium and kidney function. Reference ranges vary by laboratory.

Treatment and Nursing Care

Treatment aims to bring a flare under control (**induction**), keep the disease quiet (**maintenance**) and heal the bowel lining. In UC, complete remission means normal stool frequency, no blood, and a healed lining on endoscopy (Bressler et al., 2015). Corticosteroids calm a flare but are not used for maintenance. A person who cannot stop them within three months, relapses within three months of stopping, or needs two or more courses in a year is **corticosteroid-dependent** and needs a steroid-sparing plan (Bressler et al., 2015).

Canadian guidelines match the drug to the disease. For mild to moderate UC, an aminosalicylate is first-line, given rectally for proctitis (Bressler et al., 2015). Rectal forms work best when the patient lies on the left side and holds the dose as long as possible. Each drug needs time to work, and the Toronto consensus sets check points: response to an aminosalicylate is judged at 4 to 8 weeks, to oral corticosteroids within 2 weeks, and to anti-TNF induction at 8 to 12 weeks (Bressler et al., 2015). The nurse explains these time frames so that patients do not stop a drug too soon. Patients often ask about probiotics and fecal microbiota transplant; the consensus does not recommend either for UC outside clinical trials (Bressler et al., 2015). For Crohn disease, the Canadian Association of Gastroenterology (CAG) suggests against using aminosalicylates or antibiotics for induction or maintenance (Panaccione et al., 2019). In both diseases, **biologic therapy**, made from living cells and given by infusion or injection, is recommended when conventional treatment fails. Newer biologics and oral small-molecule drugs have been approved since these guidelines, and the specialist team chooses among them. The Medications box summarizes the classes. Before a biologic or other immunosuppressant starts, the nurse confirms that screening for tuberculosis and hepatitis B and a vaccine review are done (section 21.3).

Nursing care during and between flares includes:

- **nutrition and anemia:** weighing the patient, recording intake and referring to a dietitian (Chapter 24); iron deficiency is common (section 20.2);
- **pain:** the nurse checks with the prescriber or IBD team before a patient with IBD is given a nonsteroidal anti-inflammatory drug (NSAID);
- **fatigue and mental health:** people with IBD are 1.5 to 2 times as likely as other people to have a psychiatric disorder (Crohn's and Colitis Canada, 2023), so the nurse asks about mood, sleep, anxiety and coping;
- **a flare action plan:** knowing the early signs (more stools, blood, pain, waking at night), whom to call, and continuing maintenance drugs when well.

Surgery is needed when drugs fail or complications develop. In UC, removing the colon and rectum cures the bowel disease and creates an ileostomy or an internal pouch (section 25.6). In Crohn disease, surgery removes or widens diseased segments, but the disease can return.

Across the lifespan, IBD looks different at each stage. Seniors are now the fastest-growing group living with IBD in Canada (Crohn's and Colitis Canada, 2023). Older adults often take other drugs and have other illnesses, so the nurse reviews interactions and infection risk with the pharmacist and watches closely for the effects of corticosteroids on glucose, mood, bone and sleep. Young adults are the group most often newly diagnosed. Their care includes school and work plans, relationships and sexuality, body image (Chapter 2), and planning for pregnancy, since some drugs, such as methotrexate, must be stopped well before conception. Young people moving from pediatric to adult care need a planned handover so that follow-up is not lost.

Recognizing a Severe Flare

Acute severe ulcerative colitis is a medical emergency that needs hospital admission and intravenous (IV) corticosteroids (Moran et al., 2025). Its most feared complication is **toxic megacolon**, in which the inflamed colon widens markedly on an abdominal X-ray and the patient becomes systemically ill. The thinned colon can perforate, and toxic megacolon is an indication for colectomy (Moran et al., 2025).

The nurse watches for:

- rising stool frequency with more blood;
- fever and a rising heart rate;
- new or increasing abdominal distension and tenderness;
- a fall in stool frequency in a patient who looks sicker, which should not be taken as a sign that the flare is settling, because it may come with colonic dilation.

The nurse keeps a stool chart (number of stools, consistency and blood), checks vital signs often, follows daily blood results, including CRP, and reports a rising pulse or temperature or worsening pain or tenderness at once (Chapter 6). The nurse keeps the patient NPO if surgery is possible, and gives VTE prophylaxis as ordered, because every patient admitted to hospital with IBD should receive it unless contraindicated (Moran et al., 2025). Antidiarrheals are not given: the Canadian loperamide monograph contraindicates loperamide in acute ulcerative colitis and says to stop it at once if the abdomen becomes distended (Kenvue Canada, 2026). Any drug that slows the bowel, including an opioid, is given only as the prescriber directs, with close reassessment. Replacing fluid and potassium matters, because diarrhea causes large losses (section 3.5). Some patients do not respond to IV steroids and need rescue drugs or surgery (Bitton et al., 2012), so the nurse prepares the patient early for the possibility of surgery and an ileostomy.

Table 25.2 Crohn disease and ulcerative colitis compared (Bressler et al., 2015; Panaccione et al., 2019; Moran et al., 2025)

Feature	Crohn disease	Ulcerative colitis
Location	Any part from mouth to anus; most often the ileum and colon	Colon only; always involves the rectum
Pattern	Patchy, with normal skip areas between diseased segments	Continuous, spreading upward from the rectum
Depth	Full thickness of the bowel wall	Inner lining of the colon

Feature	Crohn disease	Ulcerative colitis
Typical symptoms	Abdominal pain, diarrhea, weight loss, perianal pain or drainage	Bloody diarrhea, urgency, tenesmus, cramping
Complications	Strictures, fistulas, abscesses, perianal disease	Severe bleeding, toxic megacolon
Aminosalicylates	The CAG suggests against them for induction or maintenance	First-line for mild to moderate disease
Effect of surgery	Removes diseased bowel, but disease can recur	Removing the colon and rectum cures the bowel disease

CANADIAN CONTEXT

Inflammatory Bowel Disease in Canada

Crohn's and Colitis Canada's *2023 Impact of Inflammatory Bowel Disease in Canada* report, released on June 1, 2023, gives these estimates (Crohn's and Colitis Canada, 2023):

- About 322,600 people in Canada were living with IBD in 2023, or 0.8% of the population, up from about 270,000 (0.7%) in 2018.
- By 2035, about 470,000 people (1.1% of the population) are expected to be living with IBD.
- About 11,000 new diagnoses were expected in 2023, roughly one every 48 minutes, rising to about 14,000 a year by 2035.
- New diagnoses are rising fastest in children under 6, and seniors are the fastest-growing group living with IBD, because of better treatment and an aging population.

The report notes added barriers to IBD care for people with low incomes, for Indigenous peoples, and for people living in rural, remote and northern communities. It also notes that IBD is now appearing in newcomer families with no earlier history of it. For people far from larger centres, endoscopy, infusions and surgery can mean long travel.

The nurse asks about travel, costs, work and school, and access to drug coverage, and helps connect patients with virtual follow-up, IBD nurses and patient organizations. For cultural safety and structural barriers, see Chapter 2.

MEDICATIONS

Drugs for Inflammatory Bowel Disease

No doses are given. The specialist team selects drugs by disease, severity and response (Bressler et al., 2015; Panaccione et al., 2019).

- **Aminosalicylates (5-ASA):** mesalamine (also called mesalazine), sulfasalazine. Mainly for UC, orally or rectally. The nurse stresses taking them every day, even when well.
- **Corticosteroids:** prednisone, budesonide; IV methylprednisolone or hydrocortisone in hospital. For flares only, never maintenance. The nurse monitors glucose, mood, sleep and infection, and warns against stopping suddenly (Chapter 23).
- **Thiopurines:** azathioprine. For maintenance. The nurse reinforces regular blood tests and reporting of fever or sore throat.
- **Methotrexate:** mainly for Crohn disease, by injection. Given once weekly; the nurse confirms the weekly schedule to prevent fatal daily dosing errors and teaches pregnancy prevention.
- **Anti-tumour necrosis factor (anti-TNF) biologics:** infliximab, adalimumab, golimumab. The nurse confirms screening (section 21.3), watches for infusion reactions and teaches infection signs.
- **Anti-integrin:** vedolizumab, which acts selectively on the gut.
- **Interleukin (IL)-12/23 and IL-23 blockers:** ustekinumab, mirikizumab. The nurse teaches self-injection and storage.
- **Janus kinase (JAK) inhibitors:** tofacitinib, upadacitinib. Oral; the nurse reviews the monograph's serious warnings, which for tofacitinib include serious infections, blood clots, major heart events and cancer (Health Canada, 2022).
- **Sphingosine 1-phosphate (S1P) receptor modulators:** ozanimod. Oral; starting treatment causes a temporary fall in heart rate, so the dose is increased in steps (Bristol-Myers Squibb Canada, 2024).

GOING DEEPER

Acute Severe Ulcerative Colitis

Required for RN students; optional for PN students.

Acute severe UC is still defined by criteria first published by Truelove and Witts (1955), which current guidelines use (Moran et al., 2025). The patient has six or more bloody stools in 24 hours plus at least one sign of systemic illness: a heart rate over 90 beats per minute, fever, anemia, or a raised erythrocyte sedimentation rate (ESR). Guidelines and hospitals differ slightly in the exact cut-offs they use for temperature, hemoglobin and ESR, so the nurse follows the local protocol.

On admission, stool is tested for infection, including *C. difficile*, blood tests and abdominal imaging are done, and a flexible sigmoidoscopy is arranged. IV corticosteroids start, with fluid and electrolyte replacement as needed and VTE prophylaxis (Moran et al., 2025).

The CAG's Toronto consensus advises that patients who have not responded to IV steroids by 72 hours move early to rescue therapy with infliximab or cyclosporine at an experienced centre; giving one rescue drug after the other is not recommended (Bitton et al., 2012). Response is judged on day 3. More than 8 stools in 24 hours, or 3 to 8 stools with a CRP over 45 mg/L, predicted colectomy in about 85% of patients in the study that set these thresholds (Travis et al., 1996).

Colectomy with an ileostomy is needed when rescue therapy fails, or for toxic megacolon, perforation or severe bleeding. Early referral to the colorectal surgeon and stoma team matters, because delay increases surgical complications (Moran et al., 2025).

25.3 Diverticular Disease and Appendicitis

Diverticular Disease

Diverticulosis is the presence of **diverticula**, small pouches that bulge outward through weak points in the colon wall, often in the sigmoid colon. It becomes more common with age, and most people never have symptoms. **Diverticular disease** covers the problems these pouches can cause: inflammation and bleeding.

Diverticulitis is inflammation of one or more diverticula. It typically causes steady pain in the left lower quadrant, tenderness, fever, nausea and a change in bowel habit, with a raised white blood cell count and CRP. It is **uncomplicated** when inflammation stays local. It is **complicated** when an abscess, perforation, fistula, narrowing or obstruction develops. A fistula to the bladder can cause air or stool in the urine and repeated urinary infections. Bleeding from diverticula is a separate problem: sudden, usually painless passage of red or maroon blood from the rectum, which needs prompt assessment (Chapter 6).

Lifestyle factors linked to diverticulitis include a poor-quality diet, obesity, physical inactivity, smoking and NSAID use (Peery et al., 2021).

Computed tomography (CT) is often needed to confirm the diagnosis and look for complications (Peery et al., 2021). Colon cancer is rarely mistaken for diverticulitis, but it can be. A colonoscopy after recovery is therefore planned based on the person's history and previous colonoscopy results (Peery et al., 2021), and is advised after complicated diverticulitis (American Society of Colon and Rectal Surgeons [ASCRS], n.d.).

Treatment matches severity. The American Gastroenterological Association (AGA) advises that antibiotics can be used selectively in mild, uncomplicated diverticulitis in a patient whose immune system works normally, and are strongly advised for immunocompromised patients (Peery et al., 2021). Many patients with mild disease recover at home with rest, fluids and acetaminophen, advancing their diet as they feel able. Complicated diverticulitis needs hospital care, with IV fluids and antibiotics, and drainage of an abscess where needed. Urgent removal of the sigmoid colon is advised for diffuse peritonitis (ASCRS, n.d.), sometimes with a temporary colostomy (section 25.6). The decision on planned surgery after recovery is individualized, not based on the number of episodes alone (Peery et al., 2021).

In hospital, the nurse tracks the trend in pain, temperature, heart rate and white blood cell count. Worsening despite treatment suggests an abscess or perforation and is reported at once. Patients taking corticosteroids or other immunosuppressants may show few abdominal signs even when seriously ill, so subtle changes matter. The nurse also assesses hydration and intake and output, and teaches patients at home to return for worsening or spreading pain, fever, vomiting or inability to drink, rectal bleeding, or air or stool in the urine. After recovery, the nurse supports a high-quality diet with fibre, a healthy weight, regular activity and not smoking. Patients should avoid NSAIDs, except aspirin taken to prevent heart attack or stroke (Peery et al., 2021).

Appendicitis

Appendicitis is inflammation of the appendix, usually after its opening is blocked. Pressure builds, bacteria multiply and blood supply falls, and the wall can die and perforate. An **appendicolith**, a hard stone of stool, raises the risk of perforation (Di Saverio et al., 2020).

In the classic pattern, pain begins as a vague ache around the umbilicus that moves over hours to the right lower quadrant and becomes sharp and constant, worse with movement or coughing, with loss of appetite, nausea and a low-grade fever. Many patients do not follow this pattern. **Older adults** often report milder pain and seek care later. Perforation rates in patients over 50 have been reported at 55% to 70%, and the Alvarado score is unreliable for judging severity in older patients (Di Saverio et al., 2020). Pregnant people also present atypically and need early surgical review.

The World Society of Emergency Surgery (WSES) recommends clinical scores, such as the Appendicitis Inflammatory Response score and the Adult Appendicitis Score, with ultrasound, to reduce the use of CT. When CT is needed, low-dose CT with contrast is preferred. In pregnancy, magnetic resonance imaging (MRI) follows an inconclusive ultrasound (Di Saverio et al., 2020).

Laparoscopic appendectomy is the preferred treatment, and uncomplicated appendicitis in adults should be operated on within 24 hours of admission (Di Saverio et al., 2020). WSES also advises discussing an antibiotics-first approach with selected adults who have uncomplicated appendicitis and no appendicolith. Patients need to know the trade-offs: about 8% fail treatment during the first admission, about 20% are readmitted within a year, and one trial found recurrence of 39.1% at five years (Di Saverio et al., 2020). The nurse supports this informed choice (section 1.5). Antibiotics-first treatment is advised against in pregnancy (Di Saverio et al., 2020). A patient treated without surgery is taught to return at once if pain, fever or vomiting comes back or worsens.

WSES prefers the laparoscopic approach over open surgery where it is available (Di Saverio et al., 2020). After laparoscopic appendectomy for uncomplicated appendicitis, the hospital stay is often short, and some centres use an enhanced recovery pathway (Chapter 7). Discharge teaching is then a main safety measure: the nurse confirms that the patient can drink, pass urine, walk and manage pain, and knows to return for fever, increasing abdominal pain, vomiting or redness and drainage at a port site.

Before surgery, the nurse keeps the patient NPO, starts IV fluids and gives antibiotics and analgesia as ordered. Laxatives and enemas are not given. Analgesia should not be withheld: a Cochrane review found that opioid analgesia did not increase errors in diagnosis or treatment decisions (Manterola et al., 2011). After surgery, care follows Chapter 7. After perforated appendicitis, the nurse watches for fever, increasing pain or slow return of bowel function, which can signal an abscess. Mortality is about 5% after perforation compared with under 0.1% when the appendix is not gangrenous (Di Saverio et al., 2020), which is why early recognition matters.

CLINICAL SAFETY

A Rigid, Silent Abdomen

Peritonitis is inflammation of the lining of the abdominal cavity, most often from a perforated appendix, diverticulum or other part of the bowel. It can lead quickly to sepsis and shock (section 4.6; Chapter 6).

Warning signs:

- sudden, severe pain that becomes constant and spreads across the abdomen, sometimes after a short-lived easing of pain when the organ bursts;
- a hard, board-like abdomen with guarding and tenderness;
- the patient lying very still, because movement and coughing hurt;
- fever, a rising heart rate, fast breathing and falling blood pressure.

The nurse:

- calls the prescriber at once, or the rapid response team if vital signs are abnormal (Chapter 6);
- keeps the patient NPO and prepares for IV access, blood work and imaging;
- reports using SBAR (situation, background, assessment, recommendation).

Quiet or absent bowel sounds may accompany peritonitis, but present bowel sounds do not rule it out (Breum et al., 2015). Pain relief is not withheld while waiting for the surgeon: opioid analgesia does not increase diagnostic errors (Manterola et al., 2011).

25.4 Bowel Obstruction and Ileus

Mechanical Obstruction and Paralytic Ileus

A **bowel obstruction** is any problem that stops intestinal contents from moving forward. In a **mechanical obstruction**, something blocks the inside of the bowel, presses on it from outside or twists it. In **paralytic ileus**, nothing blocks the bowel: the muscle of the bowel wall stops moving contents along, so gas and fluid build up as if a blockage were present (Vogel et al., 2016).

Most obstructions involve the small bowel. **Adhesions**, bands of scar tissue that form inside the abdomen after surgery or inflammation, cause about 60% to 70% of small bowel obstructions (Di Saverio et al., 2013; ten Broek et al., 2018). Other causes include internal and groin hernias, tumours, Crohn disease (section 25.2), intussusception (one segment of bowel telescoping into the next) and, rarely, a gallstone (Di Saverio et al., 2013). In adults, the most common causes of large bowel obstruction are colorectal cancer, diverticular disease (section 25.3) and **volvulus**, a twist of a loop of colon on its own mesentery. In Western countries, sigmoid volvulus mostly affects people in their 60s to 80s who live with chronic illness, cognitive or neurologic impairment or long-standing constipation (Vogel et al., 2016). Table 25.3 compares the two levels.

Above a blockage, swallowed air, gas and digestive juices collect and stretch the bowel. Fluid trapped in the bowel and lost through vomiting leads to dehydration, and vomiting can cause electrolyte losses and metabolic alkalosis (Pisano et al., 2018; Chapter 3).

Manifestations of small bowel obstruction are crampy (colicky) pain that comes in waves, abdominal distension, and nausea with or without vomiting. As it progresses, the patient stops passing stool and gas. A partial obstruction can still let watery stool through, which can look like gastroenteritis. Older adults often report less pain, so a mild complaint does not rule out obstruction (ten Broek et al., 2018). In large bowel obstruction, the patient usually stops passing gas and stool and feels bloated; vomiting is less common than with small bowel obstruction (Pisano et al., 2018).

The most dangerous complication is **strangulation**: the blood supply to a trapped segment is cut off, so the bowel becomes ischemic, then dies and can perforate. A **closed-loop obstruction**, in which a segment is blocked at both ends, as in volvulus, calls for surgery without delay (ten Broek et al., 2018). Signs that suggest strangulation are pain that becomes constant, fever, tachycardia, signs of peritonitis (section 25.3), a rising white blood cell count and metabolic acidosis. A raised serum lactate can point to ischemia, but it is not specific (Di Saverio et al., 2013). Physical examination detects strangulation only about half the time (ten Broek et al., 2018), so the nurse treats these cues as an emergency, reports them at once and calls for rapid help when vital signs worsen (Chapter 6).

Postoperative ileus is the expected pause in bowel movement after surgery, measured from the operation until the patient passes gas or stool and tolerates an oral diet. When distension, vomiting and intolerance of food persist, it is called prolonged ileus. Reported rates of postoperative ileus range from 10% to 30% (Shereef et al., 2023). Prevention through enhanced recovery (fewer opioids, minimally invasive surgery, no routine nasogastric tubes, early eating and walking) is covered in Chapter 7 (Gustafsson et al., 2019). Ileus also accompanies peritonitis and serious infection, electrolyte disturbances such as low potassium (Chapter 3), and drugs that slow the bowel, especially opioids (Chapter 5) and anticholinergic drugs (Vogel et al., 2016).

Acute colonic pseudo-obstruction is marked swelling of the colon without any blockage. It mostly affects older, seriously ill hospital patients and people recovering from surgery or trauma. The risk of ischemia or perforation rises as the cecum widens beyond about 12 cm and when swelling lasts more than 6 days (Vogel et al., 2016).

Diagnosis and Nursing Care

CT is the preferred test. It confirms the obstruction, shows its level and often its cause, and detects a closed loop, ischemia or free fluid (ten Broek et al., 2018; Pisano et al., 2018). Plain X-rays add little (ten Broek et al., 2018; Figure 25.1). In adhesive small bowel obstruction, a water-soluble contrast drink also guides care: contrast that reaches the colon on an X-ray within 24 hours suggests the obstruction is resolving, and contrast that does not suggests nonoperative care is failing (ten Broek et al., 2018). Initial bloodwork includes a complete blood count, electrolytes, urea, creatinine and lactate, along with a nutrition assessment (ten Broek et al., 2018).

Nonoperative care resolves about 70% to 90% of adhesive obstructions (ten Broek et al., 2018). The nurse:

- keeps the patient NPO and supports **nasogastric (NG) decompression**: an NG tube drains swallowed air and fluid to relieve distension and vomiting (Di Saverio et al., 2013). Placement and verification are taught in Chapter 24. The nurse keeps the tube draining or on suction as ordered and records the amount and appearance of drainage.
- gives IV fluids and electrolyte replacement as ordered and follows potassium and creatinine results (Di Saverio et al., 2013; Chapter 3).
- keeps strict intake and output, counting NG drainage, vomitus and urine.
- reassesses vital signs, pain, distension and the passage of gas or stool at regular intervals, and escalates any sign of strangulation.
- takes steps to prevent aspiration (ten Broek et al., 2018), such as raising the head of the bed, and gives frequent mouth and nostril care.
- gives analgesia as ordered and reassesses; in ileus and pseudo-obstruction, opioids and anticholinergic drugs are kept to a minimum (Vogel et al., 2016).
- helps the patient walk as tolerated; walking is part of supportive care for pseudo-obstruction (Vogel et al., 2016).
- watches older adults for delirium and functional decline; frailty predicts a slower recovery (ten Broek et al., 2018; Chapter 8).

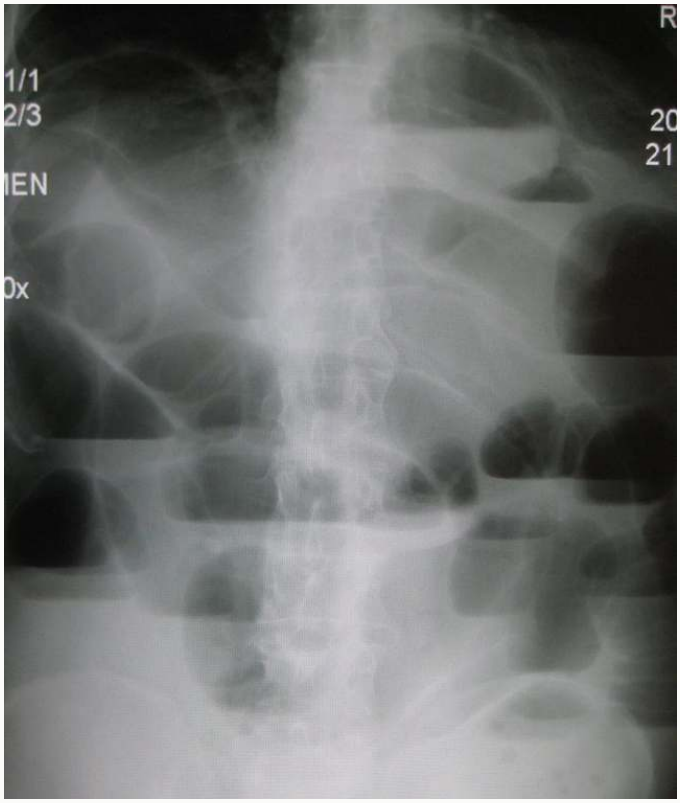

Figure 25.1 An upright abdominal X-ray in small bowel obstruction: dilated loops with many air-fluid levels. X-rays like this may be taken, but CT is the preferred test because it shows the level and cause and signs of ischemia. (credit: "Upright X-ray demonstrating small bowel obstruction" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

A trial of nonoperative care for adhesive obstruction can safely continue for up to 72 hours. Peritonitis, strangulation or ischemia calls for surgery without delay (ten Broek et al., 2018). Surgery may divide adhesions or remove dead bowel. In large bowel obstruction caused by cancer, options include resection, sometimes with an end colostomy, or a colonic stent (Pisano et al., 2018). Sigmoid volvulus without signs of ischemia is first untwisted through an endoscope, and colectomy is then often advised to prevent recurrence (Alavi et al., 2021). Pseudo-obstruction is first treated with supportive care; medication or endoscopic decompression follows if it does not resolve (Alavi et al., 2021).

Returning bowel function shows as passing gas or stool, less distension, falling NG drainage and returning appetite. The NG tube is then removed and the diet advanced on the prescriber's order.

Table 25.3 Small and large bowel obstruction compared (Di Saverio et al., 2013; ten Broek et al., 2018; Pisano et al., 2018; Vogel et al., 2016; Alavi et al., 2021)

Feature	Small bowel	Large bowel
Common causes	Adhesions (about 60% to 70%), hernias, tumours, Crohn disease	Colorectal cancer, diverticular disease, volvulus
Pain	Crampy pain in waves; older adults may report little pain	Crampy pain with bloating
Vomiting	Nausea, with or without vomiting	Less common than in small bowel obstruction
Stool and gas	Stop as it progresses; watery stool can pass a partial blockage	Usually no gas or stool
Main danger	Strangulation and ischemia	Perforation; ischemia in volvulus

Feature	Small bowel	Large bowel
Preferred imaging	CT; water-soluble contrast study in adhesive obstruction	CT
Usual first treatment	NPO, NG decompression, IV fluids; surgery for strangulation or no resolution	Depends on cause: surgery, stent or endoscopic untwisting of sigmoid volvulus

CLINICAL JUDGMENT

Vomiting and a Swollen Abdomen

Names and details are fictional; this is a composite story.

Grace Ningiuk, 79, is on day 3 after surgical repair of a hip fracture. She takes an oral opioid for pain and has been mostly in bed. She has not passed stool since admission.

- **Recognize cues:** Grace has vomited twice since breakfast. Her abdomen is round, tense and tender all over, and she says she has not passed gas today. Temperature 37.3 °C, heart rate 96, blood pressure 124/70 mm Hg. Potassium is 3.1 mmol/L. She has no hernia and no previous abdominal surgery.
- **Analyze cues:** Opioids, immobility, low potassium and recent surgery all slow the bowel. Paralytic ileus or colonic pseudo-obstruction fits, but a mechanical obstruction must be ruled out.
- **Prioritize hypotheses:** The main risks are aspiration from vomiting, worsening dehydration and low potassium, and, if the colon keeps widening, ischemia or perforation.
- **Generate solutions:** Stop oral intake, report to the prescriber using SBAR, anticipate imaging, an NG tube, IV fluids with potassium replacement and a review of her opioid, and help her move.
- **Take action:** The nurse sits Grace upright, stops oral intake until she has spoken with the prescriber, and reports. Abdominal imaging shows a widened colon without blockage. An NG tube is placed, IV fluids with potassium are started, and the prescriber switches her pain plan to an opioid-sparing regimen.
- **Evaluate outcomes:** By the next morning, Grace passes gas, her abdomen is softer and her potassium is 3.8 mmol/L. The nurse keeps checking her abdomen, intake and output, and watches for new pain, fever or tachycardia.

25.5 Colorectal Cancer Care

Risk and Screening

Colorectal cancer is cancer of the colon or rectum. It can develop from **adenomas**, a type of polyp (Figure 25.2); the risk depends on the polyp's type, size and number (Canadian Cancer Society [CCS], n.d.-a). In Canada, an estimated 25,300 people will be diagnosed with colorectal cancer in 2026 (14,100 men and 11,200 women), about 10% of all new cancers. Excluding non-melanoma skin cancers, it is the fourth most commonly diagnosed cancer and the third leading cause of cancer death in both men and women, with about 9,200 deaths expected in 2026. About 1 in 17 men and 1 in 19 women will develop it in their lifetime. New-case rates are falling, partly because screening finds and removes polyps before they become cancer (Brenner et al., 2026; CCS, 2026). About 67% of people diagnosed survive at least 5 years. Stage matters: Canadian estimates of 5-year net survival for colon cancer are about 92% at stage 1 and 11% at stage 4 (CCS, 2023).

Risk factors include (CCS, n.d.-a):

- **Factors a person cannot change:** older age; a parent, sibling or child with colorectal cancer; a personal history of polyps or colorectal cancer; inflammatory bowel disease, especially long-standing, extensive ulcerative colitis (section 25.2); and inherited syndromes such as familial adenomatous polyposis and Lynch syndrome.
- **Factors linked to how people live:** physical inactivity and long periods of sitting, overweight and obesity, alcohol, smoking, diets high in red and processed meat and low in fibre. Type 2 diabetes is also linked to higher risk.

Screening looks for cancer or polyps in people who have no symptoms. The **fecal immunochemical test (FIT)** is an at-home test that checks one stool sample for tiny amounts of blood. It needs no change in diet or medications (Ontario Health, 2026). **Colonoscopy** examines the whole colon with a flexible scope and lets the endoscopist remove polyps.

The Canadian Task Force on Preventive Health Care (CTFPHC, 2016) recommends screening adults aged 60 to 74 (strong recommendation) and 50 to 59 (weak recommendation) with FIT or a guaiac fecal test every 2 years, or flexible sigmoidoscopy every 10 years. It recommends against screening adults aged 75 and older and against colonoscopy as a screening test for people at average risk. These recommendations do not apply to people with symptoms, a personal history of colorectal cancer or polyps, inflammatory bowel disease, a parent, sibling or child with colorectal cancer, or an inherited syndrome.

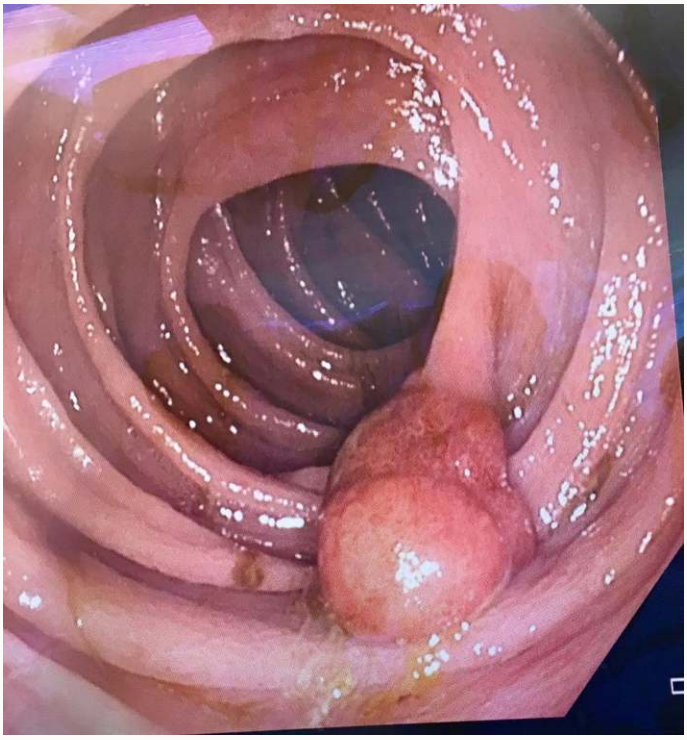

Figure 25.2 A colon polyp seen during colonoscopy. Removing adenomatous polyps during colonoscopy can prevent them from becoming cancer.

Provinces and territories run their own programs. Ontario's ColonCancerCheck changed on July 1, 2026 (Government of Ontario, 2026a):

- **Average risk:** FIT every 2 years from age 45 to 74 (previously from age 50). Average risk means no parent, sibling or child with colon cancer, or only one diagnosed at age 60 or older (Ontario Health, 2026).
- **Abnormal FIT:** more testing is needed, which does not mean cancer. The program recommends colonoscopy within 8 weeks.
- **Increased risk:** one parent, sibling or child diagnosed before age 60, or two or more diagnosed at any age. These people have colonoscopy every 5 years, starting at age 40 or 10 years before the youngest relative's diagnosis, whichever comes first.

Screening is not for people with symptoms. Blood in the stool (bright red or very dark), new and lasting diarrhea or constipation, a feeling that the bowel does not empty, new and lasting abdominal discomfort, unexplained weight loss, iron-deficiency anemia or narrower stools call for assessment by a physician or nurse practitioner (NP) instead (Government of Ontario, 2026a).

Screening is not shared equally. In 2017 Canadian survey data, people with lower incomes, some immigrant groups and people who speak an Indigenous language were less likely to have been screened, and many recent immigrants had not been tested because they did not know the test existed (Canadian Partnership Against Cancer, 2025). Structural barriers, such as having no primary care provider, language, the cost of travel and past experiences of racism in health care, can also limit access (Chapter 2). In Ontario, people without a family physician or NP can order a FIT kit through Health811 (call 8-1-1), some regions run mobile screening coaches, and people in First Nations communities can ask their health centre or nursing station (Government of Ontario, 2026a). The nurse asks every eligible adult about screening, explains the test in plain language or through an interpreter, and helps the person get a kit.

Surgery and Recovery

Surgery is the main treatment for most colorectal cancers that have not spread. The surgeon removes the affected segment and joins the healthy ends in an **anastomosis**. A **colectomy** removes part of the colon, for example a right or left hemicolectomy or a sigmoid colectomy. A **low anterior resection** removes a tumour in the middle or upper rectum. An **abdominoperineal resection** removes a tumour close to the anus; because the lower rectum and anal sphincter are removed, the colostomy is permanent (CCS, n.d.-b). In an emergency, such as obstruction or perforation, the surgeon may remove the tumour and bring the colon out as an end colostomy instead of joining it (Hartmann procedure) (Pisano et al., 2018). A temporary colostomy or ileostomy, meant to be closed later, may be made to let the bowel rest and heal (CCS, n.d.-b). Protecting a new join from leaking is one of its main purposes (Parini et al., 2023). Stomas are covered in section 25.6.

Enhanced recovery recommendations for elective colorectal surgery include eating within hours of surgery, early walking, opioid-sparing pain control and early removal of the urinary catheter (Gustafsson et al., 2019; Chapter 7). Chemotherapy and radiation are covered in Chapter 9.

Complications include bleeding, infection, venous thromboembolism, ileus (section 25.4), and sexual and bladder problems after rectal surgery (CCS, n.d.-b). The most feared is an **anastomotic leak**, leakage of bowel contents from the join into the abdomen. It usually appears within the first week and can lead to peritonitis, abscess, sepsis and death (Vun et al., 2025). The nurse watches for:

- new or worsening abdominal pain, fever, tachycardia or low blood pressure;
- peritoneal signs such as guarding and rebound tenderness;
- ileus that does not resolve, or a patient who stops progressing;
- drain fluid that becomes cloudy, purulent or smells of stool, or increases in volume (Vun et al., 2025).

These findings are reported at once using SBAR (Chapter 6). The surgeon usually orders bloodwork and a contrast CT scan (Vun et al., 2025). In older adults, new confusion may be the first sign of any serious complication (Chapter 8).

Patients often fear cancer, the operation and a possible stoma all at once. The nurse invites questions, involves the people the patient chooses, and arranges a NSWOC visit before surgery when a stoma is possible (section 25.6). Before discharge, the nurse reviews wound care, activity, diet, signs to report and follow-up.

PATIENT EDUCATION

Bowel Preparation Before Colonoscopy

A clean colon lets the endoscopist see small polyps. The nurse teaches the person to:

- follow the written instructions for their own product exactly, including timing; products and schedules differ (Government of Alberta, 2022).
- eat low-fibre foods for the days the instructions state, then take only clear fluids, meaning liquids a person can see through, such as water, clear broth, clear juice and sports drinks, but nothing red, purple or blue and no milk (Government of Alberta, 2022).
- drink a variety of clear fluids, not water alone, which can lower sodium (Ferring Inc., 2024).
- change medications only as the prescriber or endoscopy team directs. Iron and fibre supplements are often stopped several days before; other medications, such as blood thinners and diabetes medications, may need to be adjusted or stopped, so the person asks for a specific plan (Government of Alberta, 2022; Chapters 19 and 22). People with diabetes check their blood glucose more often while on clear fluids.
- know that other pills taken close to the preparation may not be fully absorbed (Ferring Inc., 2024).
- report vomiting, dizziness on standing, confusion or very little urine (Ferring Inc., 2024).

Older adults, frail people and those with kidney disease or who take diuretics need extra attention to fluids and electrolytes, and some preparations are not used in severe kidney disease (Ferring Inc., 2024).

25.6 Ostomy Care and Teaching

Types of Ostomies

An **ostomy** is a surgically created opening into the bowel or urinary tract that lets stool or urine leave the body. The **stoma** is the end of bowel brought through the abdominal wall and folded back on itself at the skin (Ostomy Canada Society, 2025). More than 165,000 people in Canada are estimated to live with an ostomy (Ostomy Canada Society, 2025).

- A **colostomy** brings part of the colon to the skin (Figure 25.3). Output depends on location: a stoma in the ascending colon produces mushy stool, while a sigmoid colostomy produces more formed stool (Ostomy Canada Society, 2025).
- An **ileostomy** brings the end of the small bowel (ileum) to the skin. Output is liquid to paste-like and contains digestive enzymes that irritate skin (Ostomy Canada Society, 2025).

- An **end stoma** has one opening. In a **loop ostomy**, a loop of bowel is brought up and opened, and a plastic rod may support it for the first 1 to 2 weeks (Ostomy Canada Society, 2025).
- An ostomy is **temporary** when it protects healing bowel and will be closed later, and **permanent** when the rectum and anal sphincter have been removed (CCS, n.d.-b).

Urostomy and other urinary diversions are covered in Chapter 28. Table 25.4 compares colostomy and ileostomy.

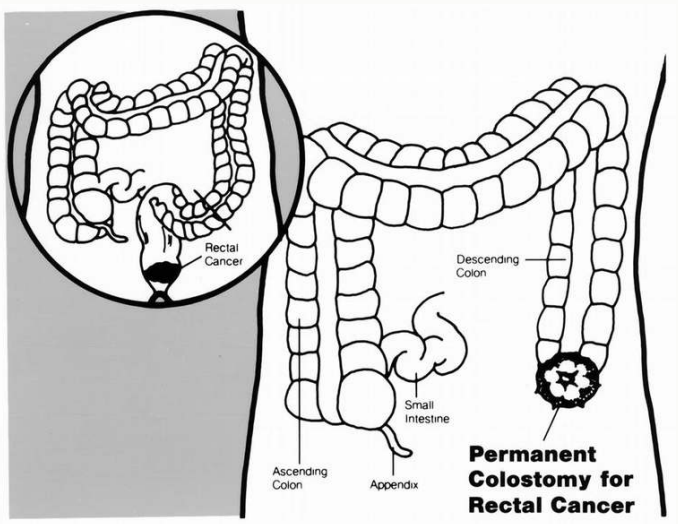

Figure 25.3 A permanent colostomy after surgery for rectal cancer (inset). The end of the descending colon is brought out through the left lower abdomen, where stool is collected in a pouch. (credit: National Cancer Institute, public domain)

Stoma and Peristomal Skin Assessment

A healthy stoma (Figure 25.4) is moist, smooth and pink to red on every skin tone, because the nurse is looking at bowel lining, not skin. It may bleed slightly when cleaned. A stoma has no nerve endings, so it does not hurt to touch; pain usually comes from the skin around it (Ostomy Canada Society, 2025). A new stoma is often swollen at first and shrinks over the following weeks (Parini et al., 2023). The nurse assesses the stoma regularly after surgery and reports at once a stoma that loses its pink-to-red colour and looks dusky or black, because a change in stoma colour can mean the blood supply is failing (Nurses Specialized in Wound, Ostomy and Continence Canada [NSWOCC], 2023) and the tissue may die (stoma necrosis) (Parini et al., 2023). Other stomal complications are separation of the stoma from the skin, retraction below skin level, prolapse (the bowel pushing out farther than usual), narrowing and bleeding (Parini et al., 2023). Stoma complications are reported in 20% to 70% of patients, and most are managed without surgery (Parini et al., 2023).

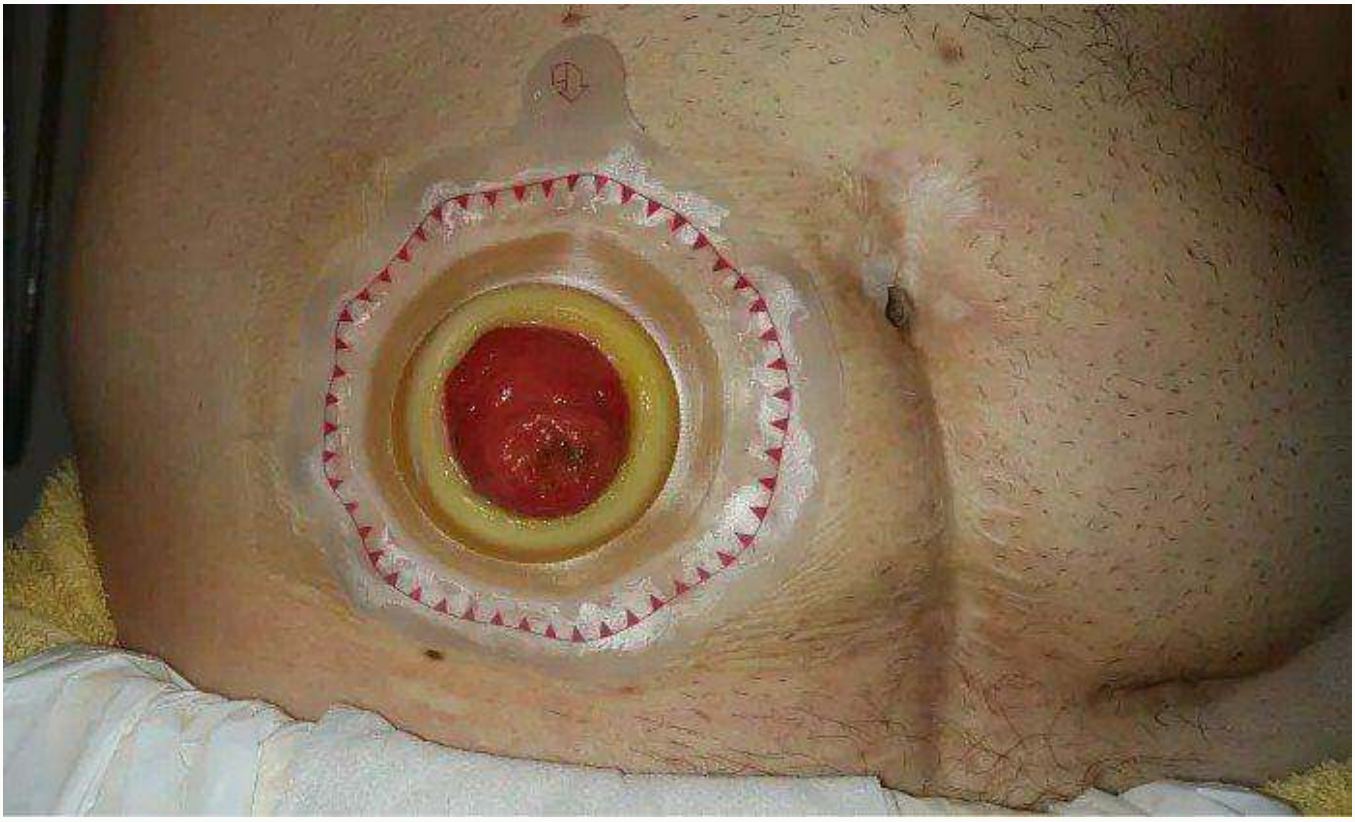

Figure 25.4 A healthy ileostomy stoma: moist and red, with the skin barrier cut to fit closely around it. (credit: “Ostomy wafer being worn by an ileostomy patient” by Eric Polsinelli (VeganOstomy)/Wikimedia Commons, CC BY 4.0)

Figure 25.5 A large parastomal hernia around a colostomy in an older man: the abdominal wall bulges around the stoma, under the pouch. A flexible pouching system is preferred over a firm, convex one.

A **parastomal hernia** is a bulge of abdominal contents through the opening in the abdominal wall around the stoma (Figure 25.5). It is common and becomes easier to see when the person stands, coughs or strains. A hernia with increasing pain, nausea and vomiting, falling output or a change in stoma colour may be trapped or strangulated and is an emergency (NSWOCC, 2023).

Peristomal skin, the skin around the stoma, should look like the person's skin elsewhere on the abdomen. Peristomal skin problems are the most common complications after ostomy surgery (Chabal et al., 2021). They include (Zane Cohen Centre, n.d.):

- **Irritant dermatitis** from stool leaking under the barrier, often because the opening is too large or the skin is creased. The skin is sore, weepy or broken in the shape of the leak.
- **Mechanical injury** from pulling the barrier off too quickly, especially in older adults or people on long-term corticosteroids.
- **Allergic dermatitis**, an itchy rash or blisters matching the shape of a product.
- **Fungal (Candida) infection**: a solid patch with an irregular edge and small separate spots around it ("satellite lesions").
- **Folliculitis**: small pustules at hair follicles, often from removing a barrier too fast or shaving.

Inflammation does not always look red. On darker skin it may appear purple, brown or darker than the surrounding skin, and it can be easy to miss (Wounds International, 2023). The nurse compares the peristomal skin with the person's skin away from the stoma in

good natural or ambient light, feels for warmth, swelling and induration, and asks about burning, itching and stinging (Pusey-Reid et al., 2023; Wounds International, 2023). A history of repeated leaks is itself a finding to report.

Pouching and Daily Care

A **pouching system** has a skin barrier (wafer or flange) that sticks to the skin and a pouch that collects output. In a one-piece system the two are joined (Figure 25.6); in a two-piece system the pouch attaches to a separate barrier. Barriers can be flat or convex, and the NSWOC helps choose one that fits the person's abdomen; with a parastomal hernia, a flexible system is preferred over firm convexity (NSWOCC, 2023).

Good care prevents most leaks. The nurse teaches the person to:

- measure the stoma and cut the barrier opening no more than about 3 to 4 mm larger than the stoma base, then check the fit in a mirror (Zane Cohen Centre, n.d.). Stoma size changes, especially in the first weeks, so the opening is rechecked (Chabal et al., 2021).
- empty a drainable pouch when it is about one-third full (Ostomy Canada Society, 2023).
- change the system on a regular schedule, often every 3 to 7 days, and right away if it leaks (Ostomy Canada Society, 2023).
- remove the barrier gently, pushing the skin away from the adhesive (Zane Cohen Centre, n.d.).
- clean the skin gently with warm water, avoid oily products that stop the barrier sticking, dry it well and check it at each change (Ostomy Canada Society, 2023).

The nurse starts teaching early, has the person practise with each change, and includes a family member or friend if the person wishes.

Figure 25.6 A one-piece, drainable pouch over an ileostomy. The pouch is emptied when it is about one-third full. (credit: “Ileostomy with bag” by Remedios44/Wikimedia Commons, CC BY-SA 4.0)

Stoma site marking is done before planned surgery. An NSWOC or surgeon chooses a flat site within the rectus abdominis muscle, away from folds, scars and the navel, and checks it with the person sitting, standing and bending (NSWOCC, 2023). Canadian guidance recommends that everyone who expects or lives with an ostomy have access to an NSWOC, a registered nurse with advanced education in wound, ostomy and continence care, for marking, education and follow-up (Registered Nurses' Association of Ontario [RNAO], 2019). The nurse refers early when leaks continue, skin breaks down or the person struggles to cope.

High-Output Ileostomy and Dehydration

A **high-output ileostomy** produces enough output to cause water and sodium depletion, generally more than about 1.5 to 2 L in 24 hours (Nightingale, 2022). One Canadian patient resource defines it for adults as more than 1.5 L a day or emptying the pouch every 2 hours (Alberta Health Services [AHS], 2025). It can begin in the first weeks after surgery. Early causes include sepsis, ileus and sudden withdrawal of opioids (Nightingale, 2022).

Signs of dehydration include thirst, dry mouth, dizziness, low blood pressure, muscle cramps, less urine and dark urine (AHS, 2025). Untreated dehydration can damage the kidneys (Nightingale, 2022; Chapter 27). The nurse:

- measures and records output from the pouch and urine output;
- weighs the patient daily and checks blood pressure lying and standing;

- follows sodium, potassium, magnesium and creatinine results as ordered (Nightingale, 2022; Chapter 3);
- gives oral rehydration solution, IV fluids and antidiarrheal medication such as loperamide as ordered (Nightingale, 2022); and
- reports rising output, falling urine output, dizziness or abnormal results to the RN or prescriber.

Living With an Ostomy

- **Diet:** at first, the person eats soft, lower-fibre foods, chews well and eats small amounts often. Corn, nuts and seeds, dried fruit, stringy fruit, tough greens and sausage casings can block an ileostomy; cramps with little or no output, nausea or vomiting are signs of a blockage that need urgent care. Banana, applesauce, oatmeal, white bread or pasta and smooth peanut butter thicken output (AHS, 2025).
- **Fluids and salt:** people with an ileostomy are taught not to restrict salt and to drink regularly (AHS, 2025).
- **Medications:** when a large part of the bowel has been removed, medicines may not be fully absorbed, and extended-release and enteric-coated tablets must not be crushed. The nurse reports whole tablets seen in the pouch and asks the pharmacist about other forms (Ostomy Canada Society, 2024a).
- **Odour and gas:** these are normal. Eggs, fish, garlic, onions and some vegetables add odour; carbonated drinks, beer, straws and chewing gum add gas (AHS, 2025).
- **Travel:** pack supplies in carry-on luggage, take twice the usual amount and tell airport screeners about the pouch before screening (Ostomy Canada Society, 2024c).
- **Body image, sexuality and intimacy:** many people worry about their partner's reaction and about leaks. Guidance recommends assessing body image, sexuality, anxiety and depression (RNAO, 2019). The nurse raises the topic, suggests emptying the pouch beforehand and using a pouch cover or small pouch, and refers for sexual problems after rectal surgery, such as erectile changes or pain with intercourse (Ostomy Canada Society, 2024b). Cultural and religious practices around cleanliness and prayer, and the needs of 2SLGBTQI+ people, are discussed with the person (Chapter 2).
- **Peer support:** Ostomy Canada Society offers local chapters, peer support groups and a trained visitor program.
- **Supply costs:** coverage varies by province and territory. Ontario's Assistive Devices Program covers up to $975 a year for each ostomy for a permanent ostomy, or a temporary one needed for 6 months or longer, with a higher limit for people in long-term care or receiving social assistance (Government of Ontario, 2026b).

Table 25.4 Colostomy and ileostomy compared (Ostomy Canada Society, 2025; AHS, 2025; Nightingale, 2022; NSWOCC, 2023)

Feature	Colostomy	Ileostomy
Usual location	Colon; sigmoid colostomy on the left lower abdomen is common	End of the ileum; usually the right lower abdomen
Output consistency	Mushy (ascending colon) to formed (sigmoid colon)	Liquid at first, then paste-like
Output volume	Lower	Higher; more than about 1.5 L a day is high output
Skin risk	Lower; stool contains few digestive enzymes	Higher; enzymes in output irritate skin quickly
Dehydration risk	Low	High, especially in the first weeks after surgery
Pouch emptying	Less often	Often; many people empty 6 to 8 times a day
Diet notes	Usual diet; adjust for gas and odour	Low fibre at first; chew well; foods that can block; do not limit salt

GOING DEEPER

Fluid and Electrolyte Losses With a High-Output Ileostomy

Required for RN students; optional for PN students.

Ileostomy output is rich in sodium, and the small bowel lining near a stoma lets sodium move freely between blood and bowel. When a person drinks water, tea, coffee, juice or other fluids with less than about 90 mmol/L of sodium, sodium moves from the

blood into the bowel and is lost in the output. The person feels thirstier, drinks more of the same fluids and loses even more. Telling such a patient to "drink as much as possible" can make output and dehydration worse (Nightingale, 2022).

Management, as ordered, often includes:

- limiting hypotonic drinks and replacing them with an oral rehydration solution containing at least 90 mmol/L of sodium, sipped through the day; standard sports drinks contain too little sodium for this purpose;
- drugs that slow transit, such as loperamide, and sometimes acid suppression;
- IV fluids when the patient is dehydrated or has acute kidney injury.

Sodium depletion raises renin and aldosterone, which also increases potassium loss. Low magnesium is common and can cause fatigue, cramps, tetany and, if severe, seizures (Nightingale, 2022; Chapter 3). The RN tracks daily weight, intake and output, lying and standing blood pressure, and sodium, potassium, magnesium and creatinine, aiming with the team for a urine output of at least 800 mL a day (Nightingale, 2022).

SCOPE IN PRACTICE

Ostomy Care, Bowel Care and Who Does What

CNO's Scope of Practice standard explains nursing roles through **authority, competence and context** (College of Nurses of Ontario [CNO], 2025; Chapter 1, section 1.3).

- **Authority:** emptying and changing a pouch and teaching ostomy care do not involve putting anything into the body, and both RNs and RPNs do them routinely. Putting an instrument, hand or finger beyond the anal verge, as in a digital rectal examination or removal of impacted stool, or into an artificial opening such as a stoma, is a controlled act authorized to RNs and RPNs. It requires an order or medical directive unless the regulation lets the nurse initiate it in that setting. Nurses cannot initiate controlled acts in public hospitals (CNO, 2025).
- **Competence:** the nurse needs the knowledge, skill and judgment to perform the procedure safely and manage the outcomes, including knowing when to stop and report, such as when a stoma has changed colour.
- **Context:** an RPN may be the main nurse for a stable patient learning ostomy care. When output climbs, skin breaks down or a stoma changes colour, the patient's needs are changing: the RPN consults the RN and the NSWOC and keeps acting on what they see. Assigning patients by stability is an employer practice, not a CNO rule.

Employer policy and province or territory shape these roles. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (CNO, 2026).

PRACTICE STORY

The Pouch That Kept Leaking

Names and details are fictional; this is a composite story.

Nurse: Farah Barakat, RPN. Years in practice: 6. Setting: surgical unit, Ontario.

Desmond Clarke, 34, was on day 4 after a total colectomy and end ileostomy for ulcerative colitis. When I started my evening shift, he showed me his third pouch of the day. "It just won't stay on," he said. "Maybe I'm doing it wrong."

I emptied the pouch and measured 650 mL of watery output. The flowsheet showed 2,300 mL from the stoma in the past 24 hours. He had been drinking water and ginger ale all day because the surgeon told him to "keep drinking." His urine was dark, and when he stood up he gripped the rail and said the room was moving.

When I removed the barrier, the stoma was moist and red, which was reassuring. The skin around it was another story. Desmond's skin is deep brown. Beside the stoma, a crescent of skin was darker than the rest of his abdomen, with a purplish sheen, shiny and weeping. It was not red at all. It matched exactly where the output had been tracking. He said it burned "like a sunburn." I measured the stoma: the opening in his barrier was almost a centimetre too big, likely cut when the stoma was still swollen.

I resized the barrier, protected the skin as our NSWOC had taught me, and fitted a new pouch. Then I reported to Joanne, the RN, using SBAR: high output, orthostatic dizziness, dark urine and broken peristomal skin. She assessed him, called the surgical resident, and orders followed for bloodwork, IV fluids, an oral rehydration solution and loperamide. I put in an NSWOC referral for the morning.

The next day the NSWOC changed his system and spent an hour teaching him. Desmond told me, "I thought the leaks were my fault." I learned that a leaking pouch is often a cue, not a nuisance. Sometimes it is telling you about the stoma, the skin and the whole patient.

> Reflect: Which parts of Desmond's care were within my authority and competence as an RPN, and at what point did his changing needs mean I had to consult the RN? What might have been missed if I had looked only for redness?

Chapter 25 Summary

Introduction

- Changes in bowel function are common and private; the nurse asks plainly, recognizes what is serious and acts early.
- This chapter covers bowel assessment, constipation and diarrhea, IBD, diverticular disease, appendicitis, obstruction, colorectal cancer and ostomy care.

25.1 Bowel Function, Constipation and Diarrhea

- The nurse compares bowel findings with the person's usual pattern, examines the abdomen in the order inspect, auscultate, percuss, palpate, and records stool with the Bristol Stool Form Scale.
- Bowel sounds are inaccurate and poorly agreed between listeners; the nurse weighs flatus, stool, distension, nausea, vomiting and pain more heavily.
- Constipation is prevented with fluids, fibre, activity, privacy and a regular toileting routine, and treated with laxatives chosen by class.
- Liquid stool after days without formed stool may be overflow around an impaction; an antidiarrheal makes it worse.
- Loperamide is not used in bloody diarrhea with fever, acute ulcerative colitis or antibiotic-associated colitis, and never replaces fluid and electrolyte replacement.
- Fecal incontinence is treated at its cause, with prompt toileting, skin protection and dignity.

25.2 Inflammatory Bowel Disease

- Crohn disease is patchy and full-thickness, anywhere from mouth to anus; ulcerative colitis is continuous from the rectum and limited to the colon lining.
- About 322,600 people in Canada were living with IBD in 2023, with about 470,000 expected by 2035.
- Extraintestinal manifestations include joint, eye, mouth and skin involvement; erythema nodosum may look violet, brown or darker on darker skin, so the nurse palpates and compares.
- Fecal calprotectin tracks inflammation; endoscopy with biopsy confirms the diagnosis; stool tests rule out infection.
- Corticosteroids treat flares but not maintenance; biologics and other advanced drugs follow screening for tuberculosis and hepatitis B (section 21.3).
- In a severe flare, fever, a rising heart rate, distension and tenderness, or fewer stools in a sicker patient, may mean toxic megacolon: the nurse escalates at once, and antidiarrheals are not given.

25.3 Diverticular Disease and Appendicitis

- Diverticulosis is common and usually silent; diverticulitis causes left lower quadrant pain and fever and may be complicated by abscess, perforation, fistula or obstruction.
- Antibiotics are used selectively in mild, uncomplicated diverticulitis and are strongly advised in immunocompromised patients.
- Appendicitis classically moves from periumbilical to right lower quadrant pain; older adults often present late and mildly, with high perforation rates.
- Laparoscopic appendectomy is preferred; antibiotics-first is an option for selected adults without an appendicolith.
- A rigid abdomen with fever and tachycardia suggests peritonitis: the nurse keeps the patient NPO and escalates at once; analgesia is not withheld.

25.4 Bowel Obstruction and Ileus

- Adhesions cause about 60% to 70% of small bowel obstructions; colorectal cancer, diverticular disease and volvulus are the main causes of large bowel obstruction.
- Crampy pain, distension, vomiting and no gas or stool are typical; older adults may report little pain.
- Constant pain, fever, tachycardia, peritoneal signs and a rising lactate suggest strangulation, which needs surgery without delay.
- Paralytic ileus and colonic pseudo-obstruction occur without a blockage, often with surgery, opioids, low potassium or serious illness.
- Nursing care includes NPO, NG decompression, IV fluids and electrolytes, strict intake and output, frequent reassessment and early escalation.

25.5 Colorectal Cancer Care

- About 25,300 people in Canada are expected to be diagnosed with colorectal cancer in 2026; screening helps explain falling rates.
- The CTFPHC (2016) recommends fecal testing every 2 years (or sigmoidoscopy every 10 years) from 50 to 74 (strong for 60 to 74, weak for 50 to 59); Ontario offers FIT every 2 years from 45 to 74 since July 1, 2026.
- People at increased risk need colonoscopy; people with symptoms need diagnostic assessment, not screening.
- Lower-income, some immigrant and Indigenous-language-speaking groups are screened less often; nurses help remove barriers.
- After colorectal surgery, the nurse watches for anastomotic leak: new pain, fever, tachycardia and changed drain fluid in the first week.

25.6 Ostomy Care and Teaching

- Colostomy output ranges from mushy to formed; ileostomy output is liquid to paste-like, irritates skin and raises dehydration risk.
- A healthy stoma is moist and pink to red on all skin tones; a dusky, purple or black stoma is reported at once.
- On darker skin, peristomal inflammation may look purple, brown or darker; the nurse compares skin, feels for warmth and asks about burning.
- A barrier opening only slightly larger than the stoma prevents most leaks; persistent leaks call for NSWOC referral.
- High-output ileostomy causes sodium, water and magnesium loss; hypotonic drinks make it worse.
- Teaching covers diet, fluids, medications, travel, intimacy, peer support and supply funding.

Key Terms (52)

abdominoperineal resection: surgery that removes the lower rectum and anal sphincter for a tumour near the anus, leaving a permanent colostomy.

acute colonic pseudo-obstruction: marked widening of the colon without a mechanical blockage, usually in older, seriously ill or postoperative patients.

acute severe ulcerative colitis: A flare of UC with frequent bloody stools and signs of systemic illness that needs hospital admission and IV corticosteroids.

adenoma: a type of polyp in the colon or rectum that can become cancer over time.

adhesions: bands of scar tissue inside the abdomen, usually after surgery or inflammation; the most common cause of small bowel obstruction.

anastomosis: a surgical join between two ends of bowel after a segment is removed.

anastomotic leak: leakage of bowel contents from a surgical join into the abdomen; it usually appears within the first week after surgery.

appendicitis: Inflammation of the appendix, usually after its opening is blocked.

appendicolith: A hard stone of stool in the appendix that raises the risk of perforation and of failure of antibiotic treatment.

biologic therapy: A drug made from living cells, such as an anti-TNF agent, given by infusion or injection to block a specific part of the immune response.

bowel obstruction: any problem that stops intestinal contents from moving forward, either a mechanical blockage or a loss of bowel movement (ileus).

Bristol Stool Form Scale: A seven-type picture chart that describes stool form, from separate hard lumps (type 1) to entirely liquid stool (type 7), and gives a rough guide to transit time.

closed-loop obstruction: an obstruction in which a segment of bowel is blocked at both ends, as in volvulus; it carries a high risk of strangulation.

colonoscopy: examination of the whole colon with a flexible scope, which allows polyps to be removed and tissue samples taken.

colorectal cancer: cancer of the colon or rectum, which can develop from an adenomatous polyp.

colostomy: an ostomy that brings part of the colon to the abdominal surface.

constipation: Stools that are infrequent, hard or difficult to pass, often with straining or a sense of incomplete emptying.

corticosteroid-dependent: Unable to stop corticosteroids within three months, relapsing within three months of stopping, or needing two or more courses in a year.

Crohn disease: A form of IBD that can affect any part of the gut from mouth to anus, in patchy segments, with inflammation through the full thickness of the bowel wall.

diarrhea: An increase in loose or watery stools above the person's usual pattern.

diverticulitis: Inflammation of one or more diverticula, usually causing left lower quadrant pain and fever.

diverticulosis: The presence of diverticula, small pouches that bulge outward through weak points in the colon wall.

erythema nodosum: Tender, warm, raised lumps, usually on the shins, that look pink to red on lighter skin and violet, brown or darker than surrounding skin on darker skin.

extraintestinal manifestations: Features of IBD outside the gut, such as joint pain, eye inflammation, mouth ulcers and erythema nodosum.

fecal calprotectin: A protein released by white blood cells into the stool; a sensitive but non-specific marker of bowel inflammation.

fecal immunochemical test (FIT): an at-home screening test that detects tiny amounts of human blood in a stool sample.

fecal impaction: A mass of hard stool in the rectum or colon that the person cannot pass.

fecal incontinence: The involuntary loss of liquid or solid stool.

fistula: An abnormal tunnel between the bowel and the skin, bladder, vagina or another loop of bowel.

high-output ileostomy: ileostomy output large enough to cause water and sodium depletion, generally more than about 1.5 to 2 L in 24 hours.

ileostomy: an ostomy that brings the end of the ileum to the abdominal surface; its output is liquid to paste-like.

inflammatory bowel disease (IBD): A group of chronic, relapsing conditions in which the immune system keeps the lining of the gut inflamed; the main forms are Crohn disease and ulcerative colitis.

loop ostomy: an ostomy made by bringing a loop of bowel to the surface and opening it, often as a temporary diversion.

low anterior resection: surgery that removes a tumour in the middle or upper rectum, usually joining the colon to the remaining rectum.

mechanical obstruction: a bowel obstruction caused by something that blocks, compresses or twists the bowel, such as adhesions, a hernia, a tumour or volvulus.

nasogastric decompression: drainage of swallowed air and gastrointestinal fluid through a nasogastric tube to relieve distension and vomiting.

Nurse Specialized in Wound, Ostomy and Continence (NSWOC): a registered nurse with advanced education and clinical skills in wound, ostomy and continence care.

ostomy: a surgically created opening into the bowel or urinary tract through which stool or urine leaves the body.

overflow diarrhea: Liquid stool that leaks around a fecal impaction and can be mistaken for ordinary diarrhea.

paralytic ileus: a loss of the bowel's propulsive movement without any physical blockage, causing gas and fluid to build up.

parastomal hernia: a bulge of abdominal contents through the abdominal wall opening around a stoma.

peristomal skin: the skin around a stoma, which should look like the person's skin elsewhere on the abdomen.

peritonitis: Inflammation of the lining of the abdominal cavity, often from a perforated organ, causing a rigid abdomen and risk of sepsis.

postoperative ileus: the expected pause in bowel movement after surgery, lasting until the patient passes gas or stool and tolerates oral intake.

pouching system: the skin barrier and pouch that protect the skin and collect stoma output; one-piece or two-piece.

stoma: the end of bowel brought through the abdominal wall and folded back at the skin; healthy stomas are moist and pink to red.

stoma site marking: choosing and marking the best location for a planned stoma before surgery, with the person sitting, standing and bending.

strangulation: loss of blood supply to a trapped segment of bowel, leading to ischemia, necrosis and perforation; a surgical emergency.

tenesmus: A painful feeling of needing to pass stool even when the rectum is empty.

toxic megacolon: Marked widening of an inflamed colon, seen on X-ray, with systemic illness and a risk of perforation.

ulcerative colitis (UC): A form of IBD limited to the colon, starting in the rectum and spreading upward without gaps, that inflames the inner lining.

volvulus: a twist of a loop of bowel, most often the sigmoid colon or cecum, on its own mesentery.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Ms. Leah Tremblay (Questions 1–4): Ms. Leah Tremblay, 24, a university student with ulcerative colitis diagnosed two years ago, is admitted to a medical unit in Ontario with a flare. She reports nine bloody stools in the past 24 hours, cramping and urgency. Vital signs: heart rate 104 beats per minute, temperature 37.9 °C, blood pressure 112/70 mm Hg. Hemoglobin is 112 g/L. IV methylprednisolone has been started. A registered practical nurse (RPN) is caring for her with a registered nurse (RN) on the team.

1. [CORE] Which set of data will best show the RPN whether Ms. Tremblay's flare is responding to treatment?

a. Bowel sounds in all four quadrants each shift, with a note of whether they are hypoactive or hyperactive

b. Her rating of cramping before and after each dose of analgesic, recorded on the pain flow sheet

c. The number of stools and amount of blood in each 24 hours, with her heart rate and temperature

d. Her daily meal intake and her fluid preferences, recorded by the dietary aide on the tray card

Answer: c — Recognize cues (section 25.2). Stool frequency, blood, heart rate and temperature are the markers used to track a UC flare and to judge response to IV steroids (c). Bowel sounds (a) are unreliable and do not measure flare activity. Pain ratings (b) matter for comfort but do not track inflammation. Meal intake and preferences (d) support nutrition but do not show response to treatment.

2. [CORE] On day 2, Ms. Tremblay's abdomen is more distended and tender. Her heart rate is 122 beats per minute and her temperature 38.6 °C. She says, "At least I've only had two bowel movements today." How should the RPN interpret these findings?

a. The fall in stool frequency shows the corticosteroid is working, and the fever is an expected drug effect

b. The findings may signal toxic megacolon, and the drop in stools is a warning sign rather than a sign of improvement

c. The distension most likely reflects gas from the cramping, and the fast heart rate reflects her anxiety

d. The findings suggest dehydration from the earlier diarrhea, which should settle once she drinks more fluid by mouth over the next few hours

Answer: b — Analyze cues (section 25.2, Recognizing a Severe Flare). Distension, tenderness, fever and tachycardia with fewer stools in a patient who looks sicker may mean the colon has dilated and stopped moving (b). Corticosteroids do not cause fever (a), and fewer stools are not reassuring with these signs. Gas and anxiety (c) do not explain fever with a rising heart rate. Dehydration (d) does not explain new distension and tenderness, and oral fluids would delay escalation.

3. [CORE] Before she became unwell, Ms. Tremblay asks whether she can take the loperamide she keeps at home when her bowel movements are frequent. Which response by the RPN is most accurate?

a. "Yes. It is safe to take whenever stools are frequent, as long as you drink plenty of extra fluid."

b. "Yes, but only at night, so your sleep is not interrupted by urgency during a flare."

c. "Only if your stools are also watery; it is not a problem when there is only a small amount of blood in them."

d. "Not during a flare. It can contribute to dangerous swelling of the colon, so call your team instead."

Answer: d — Take action, teaching (sections 25.1 and 25.2). The Canadian loperamide monograph contraindicates it in acute ulcerative colitis and in dysentery with blood and fever, and says to stop it at once if the abdomen becomes distended; slowing the bowel during a flare can contribute to colonic dilation (d). Extra fluid (a) does not make it safe. Timing (b) does not change the risk. Blood in the stool (c) is a reason not to use it.

4. [CORE] Later, Ms. Tremblay is tearful. She says she is afraid she will "end up with a bag," has missed her exams, and "doesn't see the point anymore." What should the RPN do first?

a. Acknowledge her fears, ask directly whether she is thinking of harming herself, and report her answers to the RN

b. Reassure her that most people with ulcerative colitis never need surgery, then suggest that she rest quietly and try to sleep until she feels more like herself

c. Give her a pamphlet about ostomies so she can learn more about the surgery and feel less worried

d. Tell her that feeling low is an expected side effect of corticosteroids and will pass once the dose is reduced

Answer: a — Take action (section 25.2; Chapter 1, section 1.3). "Doesn't see the point anymore" is a cue that needs a direct question about self-harm, and the RPN consults the RN and team as her needs change (a). False reassurance (b) dismisses her fear and misses the risk. A pamphlet (c) does not address her distress. Steroids can affect mood, but labelling her feelings as a side effect (d) leaves the safety risk unassessed. Psychiatric disorders are more common in people with IBD.

5. [CORE] A patient's stool is documented as Bristol type 1. What does this finding suggest?

a. Rapid transit through the bowel, with too little time for water to be absorbed

b. Slow transit through the bowel, with constipation and hard stool

c. Normal transit, with stool that is soft, smooth and easy to pass

d. Bleeding high in the gastrointestinal tract, with black, sticky stool

Answer: b — Section 25.1. Types 1 and 2 are hard lumps and suggest slow transit and constipation (b). Rapid transit (a) produces types 5 to 7. Smooth, soft, formed stool (c) is type 3 or 4. The scale describes form, not colour; black, tarry stool (d) suggests upper GI bleeding (section 24.5).

6. [CORE] On the second day after surgery, a nurse hears bowel sounds in all four quadrants. The patient has passed no gas, feels nauseated and has a firm, distended abdomen. Which conclusion is best supported?

a. The bowel is working normally because bowel sounds are present in all quadrants

b. The nausea is most likely caused by anxiety, because the bowel sounds are normal

c. Bowel sounds alone cannot confirm bowel function, and the other findings need to be reported

d. The patient should be given a stimulant laxative so that gas and stool can be passed

Answer: c — Section 25.1. Bowel sounds are inaccurate and poorly agreed between listeners, so they should not drive decisions (c); no flatus, nausea and distension need reporting. Present bowel sounds (a) do not prove normal function. Attributing nausea to anxiety (b) ignores the other cues. A laxative (d) could harm a patient with possible obstruction and is not given without assessment and an order.

7. [CORE] A patient is starting psyllium for constipation. Which instruction should the nurse include?

a. Take each dose with a full glass of water or other fluid, and keep drinking fluids through the day

b. Take each dose with only a small sip of water, so the powder stays thick and works faster

c. Take it only when you have not had a bowel movement for at least five days in a row

d. Stop drinking fluids for one hour after each dose so the fibre can absorb water from the bowel

Answer: a — Section 25.1, Table 25.1. Bulk-forming laxatives absorb water and need enough fluid to soften stool safely (a). Too little fluid (b, d) can make stool harder and risks blockage. Psyllium is a regular measure, not a rescue taken after days without stool (c).

8. [CORE] A patient on IV antibiotics for pneumonia develops five watery stools in 12 hours. The patient asks for "something to stop the diarrhea." What is the nurse's best action?

a. Give loperamide from the unit stock, then reassess the patient's stool pattern in 48 hours

b. Encourage the patient to eat more fibre and drink more fluids to firm the stool, and reassess the stool at the next shift

c. Hold the antibiotic until the diarrhea stops, then inform the prescriber at the next rounds

d. Start contact precautions as policy directs, notify the prescriber, and send a stool sample if ordered

Answer: d — Section 25.1; section 4.4. New diarrhea after antibiotics may be *C. difficile* infection, so precautions, testing and notification come first (d). Loperamide (a) must not be used until infection is considered; the monograph contraindicates it in pseudomembranous colitis after broad-spectrum antibiotics. Fibre (b) delays assessment. The nurse does not hold an ordered antibiotic (c) without speaking to the prescriber.

9. [CORE] An older adult with fecal incontinence is embarrassed and has started refusing fluids "to avoid accidents." Which nursing action best protects her dignity and health?

a. Place an absorbent pad under her and check it at the end of the shift, so that her sleep and rest are not interrupted

b. Set a regular toileting schedule, answer her call bell promptly, and explain why fluids still matter

c. Agree to limit her fluids to small sips, since this is her choice and will reduce leakage

d. Ask a family member to stay with her overnight so she can be helped to the toilet

Answer: b — Section 25.1, Fecal Incontinence in Brief. Regular toileting, prompt help and teaching address the cause and her fears while preventing dehydration (b). Leaving a pad until the end of the shift (a) harms skin and dignity. Restricting fluids (c) risks dehydration and constipation, and the nurse explores her choice rather than simply agreeing. Family presence (d) shifts nursing responsibility and does not address the problem.

10. [CORE] Which finding is more typical of Crohn disease than of ulcerative colitis?

a. Continuous inflammation starting in the rectum and spreading upward through the colon

b. Inflammation limited to the inner lining of the colon, with bloody diarrhea

c. Patchy disease with normal areas between, and inflammation through the full bowel wall

d. Tenesmus with urgency, from inflammation that always includes the rectum

Answer: c — Section 25.2, Table 25.2. Skip lesions and full-thickness inflammation are features of Crohn disease (c). Continuous disease from the rectum (a), inflammation of the inner lining with bloody diarrhea (b), and tenesmus from rectal involvement (d) are typical of ulcerative colitis.

11. [CORE] A patient with known ulcerative colitis has a fecal calprotectin of 450 mcg/g. Stool tests for infection are negative. How should the nurse understand this result?

a. It suggests active bowel inflammation and supports discussion of endoscopy with the specialist

b. It confirms a new diagnosis of colorectal cancer and will need surgery

c. It is within the range expected for a person whose ulcerative colitis is in remission and needs no change in treatment

d. It shows that the patient is dehydrated and needs IV fluids at once

Answer: a — Section 25.2. In UC, a calprotectin over 200 mcg/g suggests the lining is not healed and should prompt discussion of endoscopy (a). Calprotectin reflects inflammation; it does not diagnose cancer (b). Values under 100 mcg/g make healing likely, so 450 mcg/g is not consistent with remission (c). It does not measure hydration (d).

12. [CORE] Which findings in a patient with inflammatory bowel disease are extraintestinal manifestations? Select all that apply.

a. Tender, raised lumps on both shins that look dark brown on the patient's deep brown skin

b. A painful red eye with blurred vision and new sensitivity to light

c. Painful swelling of the knees and ankles during a flare

d. A fistula draining from the skin near the anus

e. Painful ulcers on the inside of the mouth

f. Cramping lower abdominal pain before each bowel movement

Answer: a, b, c, e — Section 25.2. Erythema nodosum (a), which may look violet, brown or darker than surrounding skin on darker skin tones; eye inflammation (b); joint involvement (c); and mouth ulcers (e) are extraintestinal manifestations. A perianal fistula (d) and cramping before bowel movements (f) are features of the bowel disease itself.

13. [CORE] A patient with Crohn disease is to start infliximab. What should the nurse confirm before the first infusion?

a. That the patient has stopped all other IBD medications for at least one week

b. That the patient has eaten a high-fibre meal beforehand to protect the bowel lining during the infusion

c. That a colonoscopy has been completed within the past 24 hours

d. That screening for tuberculosis and hepatitis B, and a vaccine review, have been completed

Answer: d — Section 25.2; section 21.3. Before a biologic starts, screening for tuberculosis and hepatitis B and a vaccine review are needed (d). Other IBD drugs (a) are adjusted only by the specialist, and some are given with anti-TNF therapy. Diet (b) and a recent colonoscopy (c) are not requirements for an infusion.

14. [CORE] A patient recovering from uncomplicated diverticulitis asks how to lower the risk of another episode. Which advice is consistent with current guidance?

a. Eat a low-fibre diet for life, so stool passes through the colon more slowly

b. Eat a high-quality diet with fibre, stay active, and avoid NSAIDs unless aspirin is prescribed for the heart

c. Take a course of antibiotics each month, even when well, to prevent the pouches in the colon from becoming infected again

d. Plan surgery to remove the sigmoid colon after a second episode, to prevent a third

Answer: b — Section 25.3. The AGA links diverticulitis to diet quality, inactivity, obesity, smoking and NSAIDs, with aspirin for cardiovascular prevention the exception (b). A lifelong low-fibre diet (a) is not advised. Routine antibiotics (c) are not recommended; antibiotics are used selectively for acute episodes. Surgery is individualized and not based on the number of episodes alone (d).

15. [CORE] An RPN is caring for a patient admitted with diverticulitis. The patient's pain is suddenly much worse and spreading, the abdomen is hard, and the heart rate has risen from 92 to 118 beats per minute. What should the RPN do first?

a. Call the RN and the prescriber at once, or a rapid response if criteria are met, and keep the patient NPO

b. Give the next scheduled dose of oral antibiotic early, then reassess the abdomen and vital signs in one hour

c. Apply a warm pack to the abdomen and help the patient into a comfortable position to rest

d. Document the findings and report them to the RN at the end-of-shift handover

Answer: a — Section 25.3, Clinical Safety box; Chapter 6. Sudden spreading pain, a rigid abdomen and tachycardia suggest perforation and peritonitis. Every nurse who notices deterioration acts at once and escalates, and the RPN consults the RN as the patient's needs change (a). Oral antibiotics (b) and a warm pack (c) delay urgent care. Waiting until handover (d) is unsafe.

16. [CORE] An RPN in an Ontario long-term care home suspects fecal impaction in a resident. The resident has no order or medical directive for a digital rectal examination or disimpaction. What should the RPN do?

a. Perform a digital rectal examination, because confirming the impaction is in the resident's best interest

b. Give a sodium phosphate enema from stock, then report the result to the prescriber the next day

c. Assess the abdomen and bowel record, then contact the prescriber for direction and an order

d. Ask an unregulated care provider to perform the examination, then document the findings

Answer: c — Section 25.1; Scope in Practice box in section 25.6; Chapter 1, section 1.3. Putting a finger beyond the anal verge is a controlled act; the RPN needs authority (an order or directive), competence and a supportive context (c). Acting without an order (a) or giving an unordered enema (b) is outside authority. Delegating to an unregulated care provider (d) is not appropriate without the required authority and employer policy.

17. [CORE] A patient in the emergency department has suspected appendicitis and rates her pain 8 out of 10. A colleague says analgesia should wait until the surgeon has examined her, "so we don't mask the signs." What is the nurse's best response?

a. Agree, because pain medicine given before the surgical examination is likely to hide a perforation

b. Offer a warm pack and repositioning instead, since these do not affect the diagnosis

c. Give only half of the ordered dose, so that some of the pain remains for the examination

d. Give the ordered analgesic, because evidence shows opioids do not increase diagnostic errors

Answer: d — Section 25.3, Clinical Safety box. A Cochrane review found opioid analgesia in acute abdominal pain does not increase errors in diagnosis or treatment decisions, so pain should be treated (d). Withholding (a) or underdosing (c) analgesia causes needless suffering. Comfort measures (b) are helpful additions but do not replace ordered analgesia.

18. [RN] **Ms. Okoro, 38, is on day 3 of IV methylprednisolone for acute severe ulcerative colitis. In the past 24 hours she has had 6 bloody stools, and her CRP is 62 mg/L. What is the RN's best interpretation?**

a. She meets day-3 criteria that predict colectomy, so rescue therapy or surgery should be discussed now

b. She is responding well to IV steroids, because her stool count is below the threshold of 8 a day

c. She should continue IV steroids for at least another 7 days before her response to treatment can be fairly judged

d. Her CRP is expected to rise with corticosteroids, so only her stool frequency should be followed

Answer: a — Section 25.2, Going Deeper box. On day 3, 3 to 8 stools a day with a CRP over 45 mg/L, or more than 8 stools, predicted colectomy in about 85% of patients; Canadian consensus advises moving early to rescue therapy when there is no response to IV steroids by 72 hours (a). Fewer than 8 stools (b) is not reassuring when CRP is high. Waiting 7 more days (c) delays rescue and raises surgical risk. Corticosteroids do not raise CRP (d), and CRP is part of the assessment.

19. [RN] **Mr. Hughes, 84, has had no formed stool for 6 days and has had small amounts of liquid stool leaking through the day. He is newly confused and has a firm abdomen. The prescriber is about to order loperamide. What is the RN's best action?**

a. Give the loperamide as ordered, since frequent liquid stool risks dehydration in older adults

b. Question the order, explain that overflow around an impaction is likely, and request assessment and a bowel plan

c. Restrict his fluids until the leakage stops, to reduce the volume of liquid stool

d. Start contact precautions and wait for the stool test results before taking any further action on his bowel symptoms

Answer: b — Section 25.1 and Lifespan box. Liquid leakage after days without formed stool, with confusion and a firm abdomen, suggests impaction with overflow; an antidiarrheal would worsen it, so the RN advocates for assessment and a bowel plan (b). Loperamide (a) is the wrong treatment. Fluid restriction (c) worsens constipation and dehydration. Infection is worth considering, but waiting for results (d) delays treating the likely cause.

20. [RN] **Mrs. Lavoie, 79, has had 2 days of mild lower abdominal discomfort and loss of appetite. Her temperature is 37.6 °C, and she says, "It's not that bad." Her white blood cell count is mildly raised. Which statement about appendicitis in older adults best guides the RN's actions?**

a. Older adults usually have more severe pain than younger adults, so mild pain makes appendicitis unlikely

b. Clinical scores such as the Alvarado score reliably rule out complicated appendicitis in older adults

c. Older adults often present late with milder symptoms and have high perforation rates, so prompt surgical assessment is needed

d. Appendicitis is rare after age 60, so the RN should first look for another cause such as constipation

Answer: c — Section 25.3. Older adults often present atypically and late, and perforation rates over age 50 have been reported at 55% to 70%, so mild symptoms need prompt surgical assessment (c). Pain is often milder, not more severe (a). The Alvarado score is unreliable for judging severity in older adults (b). Appendicitis occurs at any age, and assuming another cause (d) risks delay.

Case: Ernesto Salgado (Questions 21–26): Ernesto Salgado, 78, comes to the emergency department with 18 hours of crampy abdominal pain that comes in waves. He has vomited green fluid four times and has not passed gas since last evening. He had a sigmoid colectomy 6 years ago and an open appendectomy as a young man. His abdomen is distended, and he says the pain is "not too bad between the waves." Vital signs: temperature 37.2 °C, heart rate 98, blood pressure 128/76 mm Hg, respiratory rate 18, oxygen saturation 96% on room air. Laboratory results: potassium 3.2 mmol/L, creatinine 128 µmol/L (85 µmol/L three months ago), lactate 1.6 mmol/L. CT shows an adhesive small bowel obstruction without signs of ischemia. He is admitted to the surgical unit for nonoperative care.

21. [CORE] Which findings in Mr. Salgado's assessment are consistent with a small bowel obstruction? Select all that apply.

a. Crampy pain that comes in waves
b. Oxygen saturation of 96% on room air
c. Repeated vomiting of green fluid
d. No gas passed since last evening
e. Temperature of 37.2 °C
f. Previous abdominal surgery

Answer: a, c, d, f — Colicky pain in waves, vomiting and no passage of gas are typical of small bowel obstruction, and previous abdominal surgery points to adhesions, the most common cause (section 25.4). His oxygen saturation (b) is normal and unrelated. A temperature of 37.2 °C (e) is normal; fever would instead raise concern for strangulation.

22. [CORE] Which explanation best accounts for Mr. Salgado's potassium and creatinine results?

a. Muscle breakdown from lying on the floor for a long period before he came to hospital
b. Fluid and potassium lost through vomiting and fluid trapped in the swollen bowel
c. Chronic kidney disease that has slowly progressed over the past three months
d. A laboratory error, since an obstruction does not change potassium or creatinine

Answer: b — Vomiting and fluid held in the obstructed bowel cause dehydration and potassium loss; the creatinine rise from his recent baseline fits reduced kidney blood flow (section 25.4; Chapter 3). Nothing suggests a long lie (a). A rise over three months with this acute illness points to an acute cause, not slowly progressing kidney disease (c). Obstruction commonly causes fluid and electrolyte changes, so dismissing the results (d) is unsafe.

23. [CORE] Which problem should the nurse address first in Mr. Salgado's plan of care?

a. Constipation caused by low fibre intake before admission
b. Anxiety about a possible operation and a long hospital stay
c. Risk for falls related to his age and the unfamiliar hospital setting
d. Fluid volume deficit and low potassium from vomiting and bowel losses

Answer: d — Dehydration and hypokalemia are present now and can affect kidney function and heart rhythm, so they come first (section 25.4). His lack of stool is caused by the obstruction, not by low fibre (a). Anxiety (b) and fall risk (c) are real and are addressed, but they are less urgent than his physiologic losses.

24. [CORE] An NG tube has been inserted and placed on suction as ordered. Two hours later, it has drained nothing, Mr. Salgado feels more nauseated and his abdomen is more distended. What should the nurse do first?

a. Check that the tube is patent and working as policy directs, then report if drainage does not resume
b. Give him small sips of water to rinse his mouth and help loosen any thick secretions in the tube
c. Remove the NG tube, because the lack of drainage shows that it is no longer needed
d. Record the finding and reassess at the next scheduled check in four hours

Answer: a — No drainage with rising nausea and distension suggests a blocked or displaced tube, so the nurse checks it as policy directs and reports if drainage does not return (section 25.4; Chapter 24). Sips of water (b) break NPO. A silent tube with worsening symptoms does not mean decompression is no longer needed (c). Waiting four hours (d) risks vomiting and aspiration.

25. [RN] On day 2, Mr. Salgado says his pain is "constant now, not coming and going." Temperature 38.4 °C, heart rate 124, blood pressure 104/62 mm Hg. His abdomen is tender with guarding. Lactate is 4.1 mmol/L. Which action should the RN take first?

a. Give the ordered as-needed opioid and reassess the pain in one hour before calling anyone
b. Increase the NG suction to a higher setting to relieve the distension more quickly
c. Report to the surgeon at once using SBAR, because these cues suggest strangulation
d. Encourage him to walk in the hallway to stimulate the return of bowel movement

Answer: c — Constant pain, fever, tachycardia, guarding and a rising lactate suggest strangulation and ischemia, which need surgery without delay (section 25.4; Chapter 6). Analgesia (a) is given as ordered, but waiting an hour to report delays surgery. Changing suction settings without an order (b) does not treat ischemia. Walking (d) is part of care for an uncomplicated course, not for a deteriorating patient.

26. [CORE] Mr. Salgado has surgery to divide the adhesions and remove a short segment of dead bowel. Which finding 3 days later best shows that his bowel function is returning?

a. His NG drainage has increased from 200 mL to 700 mL over the past shift
b. He is passing gas, his abdomen is softer and he says he feels hungry
c. His pain score is 2 out of 10 after a dose of oral acetaminophen
d. His incision is clean and dry, with edges that are well approximated

Answer: b — Passing gas, less distension and a returning appetite are signs that bowel function is returning (section 25.4). Rising NG drainage (a) suggests ileus is continuing. Good pain control (c) and a healing incision (d) are positive, but neither shows bowel function.

27. [CORE] A patient had a bowel resection 4 days ago and has had postoperative ileus. Which finding best shows that the ileus is resolving?

a. Bowel sounds were heard once during a 1-minute check this morning

b. The abdomen is more rounded than yesterday but not tender to touch

c. The patient is passing gas and has kept down clear fluids for 12 hours

d. The patient has had no nausea since the antiemetic dose given an hour ago

Answer: c — Postoperative ileus ends when the patient passes gas or stool and tolerates oral intake (section 25.4). Bowel sounds (a) are unreliable on their own (section 25.1). Increasing roundness (b) suggests ongoing distension. Relief from an antiemetic (d) does not show that the bowel is moving.

28. [CORE] A 47-year-old in Ontario with no symptoms asks about colon cancer screening. No one in their family has had colon cancer. What should the nurse tell them?

a. "You are eligible for an at-home stool test, called FIT, every 2 years."

b. "Screening starts at age 50, so you can wait until then to think about it."

c. "You should book a colonoscopy every 5 years, starting as soon as possible."

d. "Screening is only needed if you notice blood in your stool or other symptoms."

Answer: a — Since July 1, 2026, Ontario's program offers FIT every 2 years to people at average risk from age 45 to 74 (section 25.5). Age 50 (b) was the previous starting age. Colonoscopy every 5 years (c) is for people at increased risk. Screening is for people without symptoms; symptoms need diagnostic assessment (d).

29. [CORE] A patient's FIT result is abnormal. They say, "So I have cancer." Which response by the nurse is most accurate?

a. "Not necessarily. Repeat the stool test in 2 years, and we will compare the two results."

b. "Yes, but colon cancer found through screening is almost always curable with surgery."

c. "Probably not. An abnormal result is usually caused by something you ate the day before."

d. "Not necessarily. It means you need a colonoscopy, ideally within the next 8 weeks."

Answer: d — An abnormal FIT means more testing is needed, not that cancer is present, and the program recommends colonoscopy within 8 weeks (section 25.5). Repeating FIT in 2 years (a) is for normal results. Option b states cancer as fact. FIT does not require diet changes, and blaming food (c) is false reassurance that may delay follow-up.

30. [CORE] A 58-year-old asks the nurse for a FIT kit. They mention 2 months of narrower stools, occasional dark red blood and fatigue. What is the best response?

a. "A FIT kit is a good idea; you can order one through Health811 and send it in."

b. "These symptoms need assessment by your physician or NP now, rather than a screening test."

c. "Narrow stools are common with age; screening every 2 years will catch any problem."

d. "Wait to see if the symptoms continue for another month before doing anything."

Answer: b — Screening is for people without symptoms. Rectal bleeding, narrower stools and possible anemia need prompt diagnostic assessment (section 25.5). A FIT kit (a) could delay diagnosis. Option c dismisses warning signs. Waiting (d) delays care.

31. [CORE] An 81-year-old with chronic kidney disease who takes a diuretic is preparing for colonoscopy. Which teaching point is most important for this patient?

a. "Stop all of your usual medications the day before, including the diuretic and heart pills."

b. "Drink only plain water during the preparation so that your bowel is as clear as possible."

c. "Drink a variety of clear fluids, and call if you vomit, feel dizzy or pass very little urine."

d. "Have a full meal the evening before so that you have the energy for the preparation."

Answer: c — Older adults and people with kidney disease or on diuretics are at higher risk of fluid and electrolyte problems during bowel preparation; drinking varied clear fluids and reporting vomiting, dizziness or low urine output are key (section 25.5, Patient Education box). Medications are changed only as the prescriber directs (a). Water alone (b) can lower sodium. A full meal (d) breaks the low-fibre and clear-fluid instructions.

32. [CORE] On the first day after surgery, the nurse finds that a patient's new colostomy is dark purple, almost black, and dry. What should the nurse do?

a. Report the finding to the surgeon at once, because the stoma's blood supply may be failing

b. Document the colour as expected swelling and reassess the stoma at the next pouch change

c. Apply a barrier ring and a convex pouch to support the stoma and protect the skin around it

d. Ask the patient to lie flat for an hour to improve blood flow to the stoma, then reassess

Answer: a — A healthy stoma is moist and pink to red on every skin tone; a dusky, dark or black stoma may be losing its blood supply and needs immediate surgical review (section 25.6). It is not expected (b). Changing pouching products (c) does not address ischemia, and convexity adds pressure. Repositioning (d) delays reporting.

33. [CORE] The nurse is assessing the peristomal skin of a patient with deep brown skin who has had several pouch leaks. Which findings suggest irritant dermatitis? Select all that apply.

a. The stoma is moist and red, and bleeds slightly when cleaned

b. The skin beside the stoma is darker and purplish compared with the rest of the abdomen

c. The patient describes burning and stinging under the barrier

d. The skin around the stoma looks the same as the skin on the opposite side

e. A shiny, weepy area matches the path where output has leaked

f. The affected area feels warmer than the surrounding skin

Answer: b, c, e, f — On darker skin, inflammation may look darker, purple or brown rather than red; burning, a weepy area that follows the leak and warmth all point to irritant dermatitis (section 25.6). A moist red stoma that bleeds slightly when cleaned (a) is normal. Skin that matches the rest of the abdomen (d) is healthy.

34. [CORE] A patient's ileostomy pouch has leaked twice today. The barrier opening is about 1 cm wider than the stoma all around. Which action should the nurse take?

a. Add tape around the edges of the barrier to hold it more firmly in place

b. Change the pouch less often, so the skin has time to rest between changes

c. Cut the next opening smaller than the stoma, so the barrier presses snugly against it

d. Re-measure the stoma and cut the opening no more than about 3 to 4 mm larger

Answer: d — An opening only slightly larger than the stoma base protects the skin and reduces leaks (section 25.6). Tape (a) does not stop output reaching exposed skin. Leaving a leaking pouch in place (b) worsens skin damage. An opening smaller than the stoma (c) can injure the stoma.

35. [CORE] Which statement by a patient with a new ileostomy shows understanding of diet teaching?

a. "I should eat lots of raw vegetables and nuts now to keep my output regular."

b. "I'll chew my food well and add foods like corn and nuts back slowly, in small amounts."

c. "I should cut back on salt, because the ileostomy will make me hold extra fluid."

d. "If I have cramps and no output for several hours, I'll eat more fibre to push it through."

Answer: b — Chewing well and reintroducing foods that can cause a blockage slowly and in small amounts lowers the risk of a food blockage (section 25.6). Raw vegetables and nuts early on (a) can cause blockage. People with an ileostomy lose sodium and should not limit salt (c). Cramps with no output may signal a blockage, which needs urgent care, not more fibre (d).

36. [CORE] An RPN in a long-term care home in Ontario suspects that a resident has a fecal impaction. Which statement about the RPN's authority to remove the impaction digitally is accurate?

a. The RPN cannot remove an impaction in any setting, because only RNs and physicians are authorized for this act.

b. The RPN may remove it whenever the resident seems uncomfortable, because no order or directive is ever needed.

c. It is a controlled act; the RPN needs an order or directive, or a setting where initiation is permitted.

d. A personal support worker should remove it, because helping with bowel care is a routine daily living activity.

Answer: c — Putting an instrument, hand or finger beyond the anal verge is a controlled act authorized to RNs and RPNs; it needs an order or directive unless initiation is permitted in that setting, and employer policy applies (section 25.6, Scope in Practice box). RPNs are authorized for this controlled act (a). Authority still requires the right mechanism, competence and a supportive setting (b). Disimpaction is not a routine activity of daily living (d).

37. [CORE] A patient with an ileostomy tells the nurse they have seen whole tablets of their extended-release heart medication in the pouch. What should the nurse do?

a. Report it to the prescriber and ask the pharmacist about another form of the medication

b. Crush the extended-release tablets from now on so that they dissolve before they reach the stoma

c. Reassure the patient that the medication was absorbed before the tablet shell passed through

d. Tell the patient to take a second tablet whenever a whole one is seen in the pouch

Answer: a — Medicines may not be fully absorbed after bowel surgery, and a whole tablet in the pouch suggests the dose was not absorbed, so the nurse reports it and asks for another form (section 25.6). Crushing extended-release tablets (b) can release a full day's dose at once. The nurse cannot assume the drug was absorbed (c). Extra doses without an order (d) are unsafe.

38. [RN] A patient with a new ileostomy has had 2,600 mL of output in 24 hours. He has been drinking about 3 L of water and tea a day "to keep up." Results: sodium 131 mmol/L, magnesium 0.58 mmol/L, creatinine 142 µmol/L (90 µmol/L at admission). Which plan should the RN expect the team to order?

a. Encourage him to drink even more water and tea, aiming for at least 4 L each day

b. Stop all oral fluids and food until the ileostomy output falls below 1 L each day

c. Give a diuretic to protect the kidneys and lower the extra fluid he is drinking

d. Limit hypotonic drinks, use a high-sodium oral rehydration solution and replace magnesium

Answer: d — Hypotonic fluids draw sodium into the bowel and increase output, so they are limited and replaced with an oral rehydration solution of at least 90 mmol/L sodium; low magnesium is replaced (section 25.6, Going Deeper box). More water (a) worsens losses. Stopping all intake (b) is not the standard first step. A diuretic (c) would worsen dehydration and kidney injury.

39. [RN] Five days after a low anterior resection, a patient reports new abdominal pain. Temperature 38.3 °C, heart rate 118, blood pressure 108/64 mm Hg. Drain fluid, clear yesterday, is now cloudy and smells foul. What should the RN suspect and do?

a. Postoperative ileus; keep the patient NPO and reassess tomorrow morning

b. Anastomotic leak; report to the surgeon at once and anticipate a CT scan

c. Surgical site infection; take a swab of the incision and continue to monitor

d. Expected inflammation after surgery; give acetaminophen and recheck in four hours

Answer: b — New pain, fever, tachycardia and cloudy, foul drain fluid within the first week suggest an anastomotic leak, which needs urgent surgical review and usually a contrast CT (section 25.5). Ileus (a) does not explain fever and changed drain fluid. A wound infection (c) does not explain the drain changes, and only monitoring delays treatment. These signs are not expected (d).

40. [CORE] A 39-year-old in Ontario has no symptoms. Their father was diagnosed with colon cancer at age 52. When should screening begin, and with which test?

a. Colonoscopy at age 40, repeated every 5 years if normal

b. Colonoscopy at age 42, which is 10 years before the father's diagnosis

c. FIT every 2 years starting at age 45, the same as people at average risk

d. FIT every 2 years starting now, because the father was diagnosed before 60

Answer: a — One parent diagnosed before age 60 means increased risk. Colonoscopy starts at age 40 or 10 years before the relative's diagnosis (42), whichever comes first, and is repeated every 5 years (section 25.5). Age 42 (b) is later than 40. FIT (c, d) is the test for people at average risk.

26 Liver, Biliary and Pancreatic Disorders

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain liver, biliary and pancreatic function, and interpret liver tests and jaundice on a range of skin tones.
2. Describe viral hepatitis A, B and C and steatotic liver disease, and support testing, treatment, vaccination and Canada's elimination goals without stigma.
3. Recognize and manage the complications of cirrhosis, including ascites, spontaneous bacterial peritonitis, variceal bleeding and hepatic encephalopathy.
4. Provide non-judgmental care for people with alcohol-related liver disease, recognize acute liver failure, and support patients through liver transplant.
5. Care for adults with gallstones, cholecystitis and cholangitis, and after ERCP and cholecystectomy.
6. Recognize and manage acute and chronic pancreatitis, including early recognition of organ failure, using the CJMM.
7. Distinguish RN and RPN roles in liver and pancreatic care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 3, 5, 6	Clinician; Scholar	Foundations of Practice
2, 4	Advocate; Educator	Foundations of Practice; Ethical Practice
7	Professional; Collaborator	Legal Practice; Collaborative Practice

Introduction

The liver works quietly. It can lose much of its function before a person feels unwell, and many adults learn they have liver disease only when a blood test comes back abnormal or a complication brings them to hospital. By then, the nurse may be caring for someone with a swollen abdomen, yellow eyes, sudden confusion or vomited blood. Each of these findings has a cause that can be found and treated, and the nurse is often the first to notice it.

Liver disease is common in Canada. In 2021, an estimated 262,000 people were living with chronic hepatitis B and 214,000 with chronic hepatitis C, and about four in ten of them did not know it (Périnet et al., 2025). Steatotic liver disease linked to metabolic risk factors is even more common. These conditions fall hardest on groups that already face barriers to care, so stigma-free nursing is part of treatment.

This chapter is the book's home for the liver, the biliary tree and the pancreas. Section 26.1 reviews what these organs do, the liver tests nurses see and how to assess jaundice on a range of skin tones. Section 26.2 covers viral hepatitis and steatotic liver disease, and section 26.3 covers cirrhosis and its complications. The second half of the chapter turns to alcohol-related liver disease, acute liver failure and transplant (26.4), gallbladder and biliary disease (26.5), and acute and chronic pancreatitis (26.6).

The chapter builds on earlier ones. Scope of practice, the Clinical Judgment Measurement Model (CJMM) and consent are taught in Chapter 1 (sections 1.3 to 1.5), and stigma and cultural safety in Chapter 2. Fluids, sodium and potassium are in Chapter 3, sepsis in Chapter 4, acetaminophen and opioid safety in Chapter 5, and rapid response in Chapter 6. Delirium is in Chapter 8, alcohol use disorder and harm reduction in Chapter 11, transfusion in section 20.6, and hepatitis vaccines in section 21.6.

26.1 The Liver, Biliary Tree and Pancreas

What These Organs Do

The liver sits in the right upper abdomen, under the ribs (Figure 26.1). It receives blood from two sources: the hepatic artery brings oxygen, and the **portal vein** brings blood from the stomach, intestines, pancreas and spleen. Everything absorbed from the gut therefore passes through the liver before it reaches the rest of the body. This layout explains why scarring of the liver raises pressure in the portal vein, the problem behind many complications of cirrhosis (section 26.3).

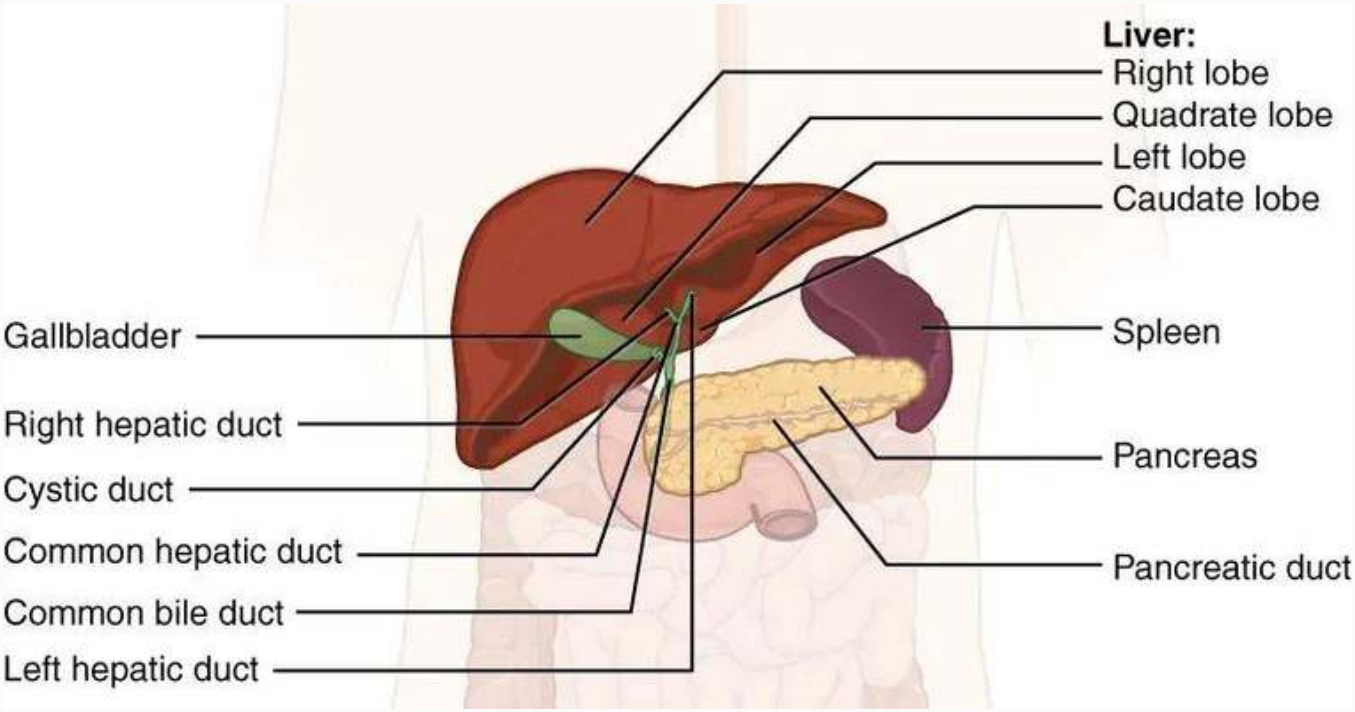

Figure 26.1 The liver, gallbladder and pancreas, with the ducts that carry bile and pancreatic juice to the duodenum. The image is cropped to the upper abdomen. (credit: modification of Figure 23.24, "Accessory Organs," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The liver does several jobs that nurses see at the bedside:

- **Metabolism:** it stores glucose as glycogen and releases it between meals, makes glucose when stores run low, and processes fats and proteins. It turns ammonia, a toxic product of protein breakdown, into urea, which the kidneys excrete.
- **Proteins:** it makes albumin, the main protein that holds fluid in the blood vessels, and most clotting factors.
- **Bilirubin and bile:** it takes up bilirubin, a yellow pigment from the breakdown of old red blood cells, joins it to another molecule (conjugation) and secretes it into bile. Bile also contains bile salts, which help the gut absorb fats and fat-soluble vitamins, including vitamin K.
- **Drug and toxin clearance:** it breaks down many drugs, hormones and alcohol, so liver disease can make usual drug doses act longer or more strongly.

Bile flows from the liver through small ducts into the hepatic ducts and then the common bile duct, which empties into the duodenum. The gallbladder stores and concentrates bile between meals and contracts after a fatty meal. The pancreatic duct usually joins the common bile duct near the duodenum, which is why a gallstone stuck at that point can cause both jaundice and pancreatitis (sections 26.5 and 26.6).

The pancreas has two roles. Its exocrine part makes digestive enzymes (lipase, amylase and proteases) and bicarbonate, which flow into the duodenum. Its endocrine part, the islets, makes insulin and glucagon; diabetes is covered in Chapter 22.

Liver Tests the Nurse Sees

The blood tests often called "liver function tests" are better called liver tests, because most of them show injury rather than function (Kwo et al., 2017). Results are reported in SI units, and reference ranges vary by laboratory, so the nurse always compares a result with the range on the report.

- **Alanine aminotransferase (ALT) and aspartate aminotransferase (AST), in U/L:** enzymes released when liver cells are injured. ALT is found mainly in the liver; AST also comes from heart and muscle (Kwo et al., 2017). As an example of a Canadian range, Alberta's provincial laboratory lists adult ALT as below 40 U/L for females and below 60 U/L for males (Alberta Precision Laboratories, 2020).
- **Alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT), in U/L:** rise when bile flow is blocked (cholestasis). A raised GGT suggests that a raised ALP comes from the liver rather than bone (Kwo et al., 2017).
- **Total and conjugated bilirubin, in µmol/L:** a raised conjugated bilirubin usually points to liver cell disease or blocked bile ducts (Kwo et al., 2017).
- **Albumin (g/L) and the international normalized ratio (INR):** reflect the liver's ability to make proteins. The INR changes faster than albumin, which has a half-life of about three weeks. Both can also change for reasons outside the liver, such as poor nutrition, vitamin K deficiency or warfarin (Kwo et al., 2017).
- **Platelets (× 10^9/L):** an adult range in one Canadian laboratory is 140 to 400 × 10^9/L (Alberta Health Services, 2023). In chronic liver disease, a low count can be a clue to portal hypertension, because an enlarged spleen holds back platelets.
- **Lipase (U/L):** a pancreatic enzyme used to diagnose acute pancreatitis (section 26.6).

Patterns help more than single values. Injury to liver cells (hepatocellular injury) raises ALT and AST more than ALP, while blocked bile flow (cholestatic injury) raises ALP more than ALT and AST. In alcohol-related liver injury, AST is often at least twice ALT. An ALT above 1,000 U/L calls for a careful history of acetaminophen use and points toward drug or toxin injury, very low blood flow to the liver or acute viral hepatitis (Kwo et al., 2017).

Figure 26.2 Yellow sclerae in jaundice. The sclerae are a reliable place to look for jaundice on every skin tone. The image is cropped to the eye. (credit: modification of “Jaundice” by OpenRN/Nursing Skills, 2e, CC BY 4.0)

Jaundice

Jaundice is a yellow colour of the skin, sclerae and mucous membranes caused by a high level of bilirubin in the blood. Its causes fall into three groups:

- **Prehepatic:** too much bilirubin is produced, as when red blood cells break down quickly in hemolytic anemia (Chapter 20). The excess is mostly unconjugated. The most common cause of a mildly raised unconjugated bilirubin is Gilbert syndrome, a harmless inherited difference in conjugation (Kwo et al., 2017).
- **Hepatic:** sick liver cells cannot take up, conjugate or secrete bilirubin, as in hepatitis or cirrhosis.
- **Posthepatic:** bile cannot drain because a stone, stricture or tumour blocks the ducts. Conjugated bilirubin backs up into the blood and spills into the urine, which turns dark, while stools turn pale because little bilirubin reaches the gut.

Jaundice is easy to miss on darker skin, where changes in skin colour are harder to see (Pusey-Reid et al., 2023). The nurse looks at the sclerae (Figure 26.2), especially the part nearest the cornea, and inside the mouth, especially the hard palate. Calluses can make the palms and soles look yellow when no jaundice is present, so these sites can mislead (Pusey-Reid et al., 2023). The light matters: natural or indirect light is best, and fluorescent light, which casts a bluish tint, can hide true colour (Pusey-Reid et al., 2023). The

nurse compares findings with the patient's usual appearance and asks the patient or family whether the eyes or skin look different. Dark urine and pale stools are useful clues on any skin tone.

Cholestasis can cause **pruritus** (itching), which can be intense and disrupt sleep. Simple comfort measures, such as keeping the skin moisturized and the nails short, may ease discomfort and limit skin damage from scratching. The nurse checks for scratch injuries and reports itching that disturbs sleep, because drug treatment may help.

26.2 Viral Hepatitis and Steatotic Liver Disease

Hepatitis A, B and C

Hepatitis means inflammation of the liver. Viruses are a leading cause, and the three seen most in Canada differ in how they spread, whether they last and how they are prevented and treated (Table 26.1).

Hepatitis A is caused by the hepatitis A virus, which spreads by the fecal-oral route: from person to person, on contaminated objects, or in contaminated food or water. Symptoms appear 15 to 50 days after exposure. Young children often have no symptoms, while adults usually have poor appetite, nausea, fatigue, fever and jaundice for less than two months. Hepatitis A does not become chronic, but older adults and people with chronic liver disease have a higher risk of acute liver failure (Public Health Agency of Canada [PHAC], 2023). Hand hygiene and the hepatitis A vaccine, recommended for adults with chronic liver disease and other groups at risk, prevent it (PHAC, 2023; section 21.6).

Hepatitis B is caused by the hepatitis B virus, which spreads through infected blood and body fluids, mainly by sharing drug-use equipment, through sex and from a birthing parent to the newborn (PHAC, 2026). Up to half of adults have no symptoms. The age at infection decides the course: 90% to 95% of infected infants develop chronic infection, compared with 3% to 10% of adolescents and adults. Chronic hepatitis B can lead to cirrhosis and **hepatocellular carcinoma** (liver cancer) (PHAC, 2026). In 2021, an estimated 0.68% of people in Canada were living with chronic hepatitis B; the estimate was 4.2% among immigrants from countries where hepatitis B is common (Périnet et al., 2025). The 2025 guideline from the Canadian Association for the Study of the Liver (CASL) and the Association of Medical Microbiology and Infectious Disease (AMMI) Canada recommends one-time screening for all adults with a three-test panel: hepatitis B surface antigen (HBsAg), antibody to the surface antigen (anti-HBs) and antibody to the core antigen (anti-HBc) (Osiowy et al., 2025). The antivirals entecavir, tenofovir disoproxil fumarate and tenofovir alafenamide control the virus (Osiowy et al., 2025) and help prevent cirrhosis and liver cancer (PHAC, 2024). The hepatitis B vaccine is covered in section 21.6.

Hepatitis C is caused by the hepatitis C virus (HCV), which spreads mainly through blood. PHAC (2021) advises offering a test to anyone with a risk factor, such as ever sharing drug-use equipment, tattooing or piercing with unsterile equipment, blood products or transplant before 1992, or birth in a region where hepatitis C is common. Hepatitis C is often silent (PHAC, 2021). Testing takes two steps. A positive antibody (anti-HCV) test shows current or past infection, and a test for HCV ribonucleic acid (RNA), the virus's genetic material, then shows whether the virus is still present (PHAC, 2021; Shah et al., 2018). In 2021, an estimated 36.9% of people who had injected drugs in the past 12 months were living with chronic hepatitis C, and half of them did not know it (Périnet et al., 2025). Many people have never been offered a test: PHAC (2021) reports that 67% of Canadians say they have never been tested for hepatitis C.

Hepatitis C is curable. Tablets called **direct-acting antivirals**, taken for 8 to 24 weeks, cure more than 90% of people, measured as a **sustained virologic response**: no virus found 12 weeks after treatment ends (PHAC, 2021; Shah et al., 2018). Pan-genotypic regimens, which work against all genotypes, include sofosbuvir–velpatasvir and glecaprevir–pibrentasvir (Shah et al., 2018). Side effects are few, and anyone with a positive HCV RNA test is referred to a provider experienced in hepatitis care (PHAC, 2021). There is no vaccine.

In hospital, routine practices protect staff and other patients from hepatitis B and C (Chapter 4). The nurse helps a patient on antiviral treatment take every dose, asks the pharmacist to check new drugs for interactions, and makes sure follow-up testing is booked. A nurse exposed to blood through a needlestick follows the employer's exposure protocol at once.

Canadian screening advice differs. The Canadian Task Force on Preventive Health Care (2017) recommends against screening adults who are not at elevated risk. CASL recommends risk-based testing plus one-time screening of everyone born from 1945 to 1975, and disagrees with the Task Force (Shah et al., 2018). PHAC (2021) advises testing anyone with a risk factor or clinical sign of liver disease.

Stigma keeps people from testing and treatment. People in key populations report discrimination in health care, and PHAC (2024) names structural causes: anti-Indigenous racism rooted in colonial policies, anti-Black racism, and unequal income, housing and food security. In 2021, an estimated 3.3% of First Nations people were living with chronic hepatitis C; estimates for Inuit and Métis were not available (Périnet et al., 2025). The nurse uses person-first language ("a person who injects drugs"), offers testing without judgment, links people to treatment, supports Indigenous-led and peer-based services (PHAC, 2024), and offers harm reduction supplies (Chapter 11).

Table 26.1 Hepatitis A, B and C compared (PHAC, 2021, 2023, 2026; Osiowy et al., 2025; Shah et al., 2018)

Feature	Hepatitis A	Hepatitis B	Hepatitis C
How it spreads	Fecal-oral: contaminated hands, objects, food or water	Blood and body fluids: shared drug-use equipment, sex, birthing parent to newborn	Mainly blood: shared drug-use equipment, unsterile tattooing or medical equipment, blood products before 1992
Becomes chronic?	Never	3% to 10% of infected adults; 90% to 95% of infected infants	Often; some people clear the virus on their own
Vaccine?	Yes	Yes	No
Key tests	Hepatitis A antibody tests	HBsAg, anti-HBs and anti-HBc; one-time screening for all adults	Anti-HCV antibody, then HCV RNA to confirm current infection
Treatment	Supportive care	Long-term antivirals for those who meet criteria	Direct-acting antivirals for 8 to 24 weeks; cure in more than 90%
Nursing focus	Hand hygiene; vaccinate people with chronic liver disease; watch older adults for liver failure	Screening, vaccination of contacts, adherence and cancer surveillance	Offer testing without stigma, link to cure, harm reduction

CANADIAN CONTEXT

Toward Eliminating Viral Hepatitis in Canada

Canada's sexually transmitted and blood-borne infections (STBBI) action plan for 2024 to 2030 commits Canada to the World Health Organization's 2030 targets for hepatitis B and C (PHAC, 2024):

- a 90% reduction in new chronic infections;
- a 65% reduction in deaths;
- 90% of infections diagnosed;
- 80% of eligible people treated.

How close is Canada? A national modelling study estimated that, in 2021, 57.5% of people with chronic hepatitis B and 58.5% with chronic hepatitis C had been diagnosed. Both figures were close to the 2025 interim target of 60%. Deaths from hepatitis C had fallen below the 2025 target, and more people were treated for hepatitis C than were newly infected each year from 2015 to 2021. New hepatitis C infections, estimated at 8,212 in 2021 (21.47 per 100,000 people), remained well above target (Périnet et al., 2025).

The plan notes that hepatitis B and C rates have not fallen in line with global targets, even though a vaccine prevents hepatitis B and treatment cures hepatitis C (PHAC, 2024). Nurses help close the gap each time they offer a test, explain a result without blame, help a patient start and finish treatment, give a hepatitis B vaccine or connect someone with harm reduction.

Metabolic Dysfunction-Associated Steatotic Liver Disease

Steatotic liver disease is the umbrella term for fat build-up in the liver (steatosis) from any cause. In 2023, an international Delphi process with 236 experts from 56 countries replaced the older names, partly because many panel members found "fatty" and "nonalcoholic" stigmatizing or inaccurate (Rinella et al., 2023). The new terms are:

- **Metabolic dysfunction-associated steatotic liver disease (MASLD)** (formerly nonalcoholic fatty liver disease, NAFLD): steatosis plus at least one cardiometabolic risk factor, such as overweight or a large waist, raised blood glucose or type 2 diabetes, high blood pressure, high triglycerides or low high-density lipoprotein (HDL) cholesterol, with no other cause found.
- **Metabolic dysfunction-associated steatohepatitis (MASH)** (formerly nonalcoholic steatohepatitis, NASH): MASLD with inflammation and liver cell injury.
- **MetALD:** MASLD in a person who also drinks more alcohol, about 20 to 50 g a day for women and 30 to 60 g a day for men (Rinella et al., 2023).

MASLD is common. Diabetes Canada's 2025 chapter reports that it affects about 20.8% of Canadians and MASH about 5.2%, and that worldwide, about 69% of people with type 2 diabetes have MASLD (Kim et al., 2025). The amount of scarring (fibrosis) decides the outlook. Only about 20% of people with MASH develop severe liver complications, and cardiovascular disease is still the most common cause of death in this group. MASLD is on track to become the main reason for liver transplant in Canada (Kim et al., 2025).

Most people have no symptoms. Diabetes Canada recommends screening everyone with prediabetes or type 2 diabetes with the FIB-4 index, a score calculated from age, AST, ALT and platelets. A low score can be managed in primary care, an intermediate score needs further testing, such as transient elastography (a scan that measures liver stiffness), and a high score calls for referral to a liver specialist. Screening is repeated every 1 to 2 years, and statins are continued unless cirrhosis becomes decompensated (Kim et al., 2025). MASLD is not limited to type 2 diabetes; the chapter reports that about 22% of adults with type 1 diabetes also have it (Kim et al., 2025).

Care centres on lifestyle and on the conditions that drive the disease. Sustained weight loss of at least 5% to 10% of body weight is recommended, and more than 10% is preferred to reverse fibrosis; people without overweight are encouraged to lose 3% to 5%. Regular aerobic and resistance exercise lowers liver fat, and alcohol should be limited because it speeds progression (Kim et al., 2025). Diabetes, blood pressure and lipids are managed as usual (Chapter 22). The nurse avoids blaming language about weight (Chapter 2), sets small goals with the patient and links them to a dietitian.

26.3 Cirrhosis and Its Complications

How Cirrhosis Develops

Cirrhosis is advanced scarring of the liver. Long-term injury from hepatitis B or C, alcohol or MASLD inflames liver cells. As cells die and are replaced, bands of scar tissue form and the remaining cells grow into nodules. The scarred liver resists blood flow, and the number of working cells falls.

Two problems follow. First, blood backs up in the portal vein, causing **portal hypertension**. Pressure builds in the veins that drain the gut and spleen, the spleen enlarges and new veins form to bypass the liver. Second, liver function fails, so albumin and clotting factors fall, bilirubin and ammonia rise, and drugs clear more slowly.

Cirrhosis is **compensated** when the person has no major complications. It becomes **decompensated** when overt ascites, variceal bleeding or overt hepatic encephalopathy develops (de Franchis et al., 2022). Decompensation marks a turning point in survival, and AASLD guidance advises that clinically significant ascites should prompt consideration of referral for transplant assessment (Biggins et al., 2021).

Manifestations include fatigue, weight and muscle loss, jaundice, easy bruising, a swollen abdomen and leg edema. Breast enlargement in men and swollen veins on the abdominal wall can also appear (Kwo et al., 2017). Two skin signs suggest advanced disease with portal hypertension (Kwo et al., 2017):

- **Spider angioma:** a small, red central spot with fine vessels radiating outward, usually on the face, neck, upper chest or arms. Pressing the centre makes it fade. Redness is harder to see on darker skin and may show as an area darker than the surrounding skin (Pusey-Reid et al., 2023), so the nurse looks closely and checks blanching under good light (Figure 26.3).
- **Palmar erythema:** redness of the palms, mostly at the base of the thumb and little finger (Figure 26.4). On darker skin the change may be subtle (Pusey-Reid et al., 2023); the nurse compares the palms with the backs of the hands and asks whether the

colour is new.

Clinicians grade severity with the Child-Pugh class and the Model for End-Stage Liver Disease (MELD) score (de Franchis et al., 2022; Kamath et al., 2001), described in the Going Deeper box.

Ascites and Spontaneous Bacterial Peritonitis

Ascites (Figure 26.5) is fluid in the peritoneal cavity and is often the first sign of decompensation (Biggins et al., 2021). Portal hypertension pushes fluid out of the vessels, and the body responds to the shift by holding on to sodium and water. The nurse sees a swollen abdomen, bulging flanks, weight gain, shortness of breath when the abdomen is tense, and leg edema.

Treatment starts with diet and diuretics. AASLD guidance calls for dietary sodium of about 2 g (about 90 mmol) a day; fluid is restricted only when serum sodium becomes very low, at about 125 mmol/L or below (Biggins et al., 2021). The usual diuretics are spironolactone with furosemide. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen are avoided because they can cause low sodium, diuretic resistance and kidney injury (Biggins et al., 2021). The nurse weighs the patient daily on the same scale, measures abdominal girth at the marked site, tracks intake and output, and watches sodium, potassium and creatinine (Chapter 3).

Figure 26.4 Palmar erythema in a 79-year-old woman: redness of the palms, most marked at the base of the thumb and little finger. (credit: "Palmar erythema" by Jmarchn/Wikimedia Commons, CC BY-SA 3.0)

When ascites is large or tense, a **paracentesis** drains fluid through a needle or catheter in the abdominal wall (Figure 26.6). When more than 5 L is removed, albumin is given to prevent a drop in circulating volume (Biggins et al., 2021). Safety points are in the Clinical Safety box, and role details in section 26.4. When ascites keeps returning despite treatment, a transjugular intrahepatic portosystemic shunt (TIPS), a stent placed through the liver to connect the portal and hepatic veins, may be considered to lower portal pressure; it can make hepatic encephalopathy worse (Biggins et al., 2021).

Spontaneous bacterial peritonitis (SBP) is infection of ascitic fluid without an obvious source. Signs can be fever, abdominal pain or tenderness, new confusion, worsening kidney function, or nothing at all: up to a third of patients have no symptoms (Biggins et al., 2021). For this reason, a diagnostic paracentesis is done for every patient with ascites admitted to hospital. SBP is diagnosed when the fluid holds more than 250 neutrophils/mm³ (0.25×10^9/L), and intravenous (IV) antibiotics start at once (Biggins et al., 2021). The nurse reports fever, new pain or confusion promptly and watches for sepsis (Chapter 4). Preventive antibiotics are given to patients who have had SBP before and to patients with cirrhosis who have upper gastrointestinal (GI) bleeding (Biggins et al., 2021).

Varices and Variceal Bleeding

Portal hypertension enlarges the veins at the lower esophagus and upper stomach. These thin-walled **esophageal varices** can rupture and bleed heavily. For people with clinically significant portal hypertension, a nonselective beta-blocker, such as propranolol or carvedilol, should be considered to prevent decompensation (de Franchis et al., 2022). The nurse checks heart rate and blood pressure before each dose and teaches the patient not to stop it suddenly.

A variceal bleed is an emergency. The patient may vomit bright red blood or coffee-ground material, pass black stools, or show only rising heart rate, falling blood pressure and confusion. The nurse stays with the patient, turns them to the side if vomiting, calls for help through the rapid response process (Chapter 6), and starts care while the team gathers. Baveno VII sets the priorities (de Franchis et al., 2022):

- **Airway:** intubation before endoscopy for patients with altered consciousness or active vomiting of blood.
- **Volume and blood:** large-bore IV access, cautious fluid and a restrictive transfusion strategy, targeting hemoglobin of 70 to 80 g/L (section 20.6). Fresh frozen plasma is not recommended, because it does not correct the clotting problem.
- **Vasoactive drug:** a drug such as octreotide, started as soon as possible and continued for 2 to 5 days.
- **Antibiotics:** antibiotic prophylaxis is part of treatment; ceftriaxone is considered in advanced cirrhosis.
- **Endoscopy:** within 12 hours of arrival, to band the varices (Figure 26.7).
- **Bridge:** if bleeding cannot be controlled, balloon tamponade or an esophageal stent holds pressure until definitive treatment.

Figure 26.5 Massive ascites from portal hypertension in cirrhosis: a tense, rounded abdomen with prominent surface veins. (credit: "Hepaticfailure" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

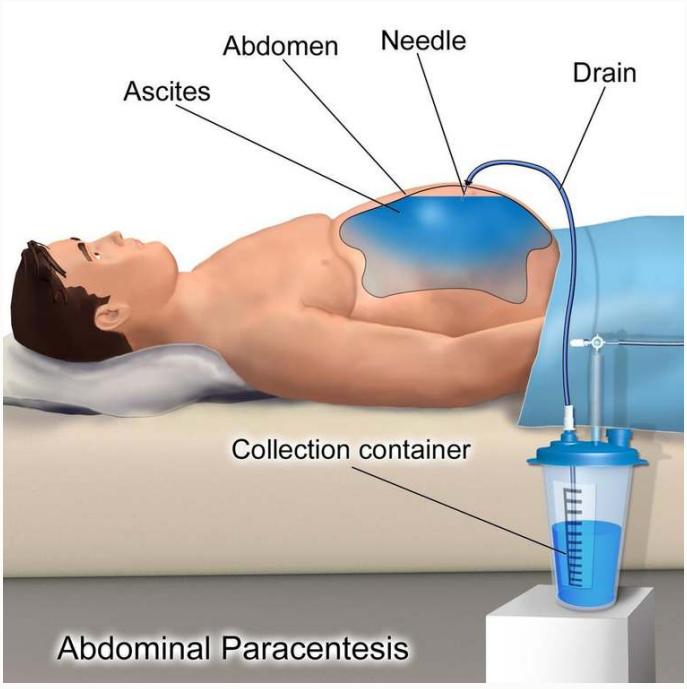

Figure 26.6 Abdominal paracentesis: a needle or catheter in the abdominal wall drains ascitic fluid into a collection container. (credit: "Blausen 0004 AbdominalParacentesis" by BruceBlaus/Wikimedia Commons, CC BY 3.0)

Because blood in the gut can trigger encephalopathy, lactulose by mouth or enema is used to remove it (de Franchis et al., 2022). For selected patients with advanced cirrhosis who are at high risk of treatment failure, a TIPS within 72 hours, ideally within 24 hours, is indicated (de Franchis et al., 2022). After the bleed, the nurse watches for fresh bleeding, infection and confusion. Non-variceal bleeding is covered in Chapter 24.

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a disturbance of brain function that results from liver failure, from blood

bypassing the liver, or from both (Vilstrup et al., 2014). Ammonia and other toxins from the gut reach the brain. HE ranges from subtle changes found only by testing to coma. The West Haven grades describe it in plain terms (Vilstrup et al., 2014):

- **Grade I:** mild loss of awareness, anxiety or euphoria, short attention span, trouble with simple arithmetic, and a changed sleep pattern.
- **Grade II:** lethargy, disorientation to time, obvious personality change, inappropriate behaviour and asterixis.
- **Grade III:** very drowsy but rousable, confused and grossly disoriented.
- **Grade IV:** coma.

Asterixis is a flapping of the hands when the patient holds the arms out with wrists bent back and fingers spread. It is a brief loss of muscle tone, not a tremor, and kidney failure can also cause it (Vilstrup et al., 2014).

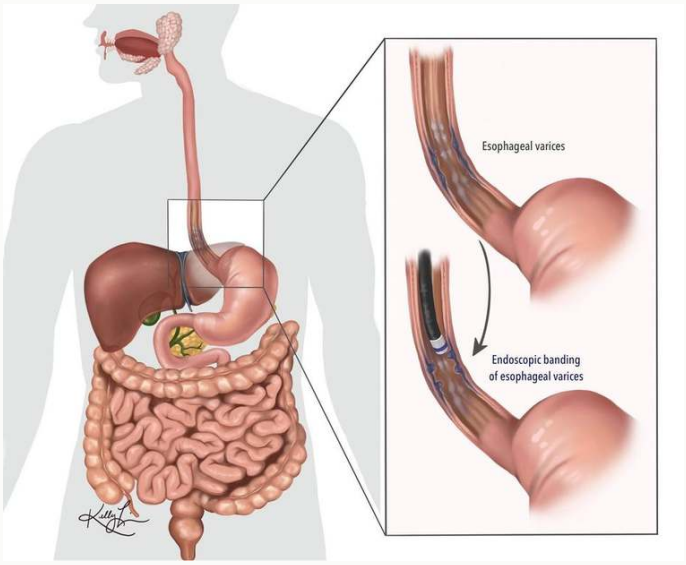

Figure 26.7 Esophageal varices and endoscopic band ligation: elastic bands are placed around the enlarged veins to stop or prevent bleeding. (credit: "Endoscopic Banding for Esophageal Varices" by Kel898/Wikimedia Commons, CC BY-SA 4.0)

Most episodes have a trigger, and finding and treating it is the first step; nearly 90% of patients can be treated by correcting the trigger (Vilstrup et al., 2014). Common triggers are infection, GI bleeding, too much diuretic or dehydration, electrolyte problems such as low sodium, and constipation. Sedating drugs such as benzodiazepines and opioids, and alcohol, can cause confusion that looks like HE or adds to it (Vilstrup et al., 2014). The nurse checks vital signs, blood glucose and the bowel record, looks for melena (black, tarry stool) and signs of infection, and reviews recent drugs.

Lactulose is the first-choice treatment. It is titrated to two to three soft bowel movements a day (Vilstrup et al., 2014). Gut bacteria break it down into acids, which trap ammonia in the colon so that it leaves in the stool (Sanis Health, 2015). Too much lactulose can cause dehydration, high sodium, perianal skin breakdown and aspiration, and can even worsen HE (Vilstrup et al., 2014), so the nurse counts and describes every stool. When a patient cannot swallow safely, lactulose can be given by nasogastric tube or as an enema (Vilstrup et al., 2014). Rifaximin, an antibiotic that stays mostly in the gut, is added to lactulose to prevent overt HE from coming back (Lupin Pharma Canada, 2025; Vilstrup et al., 2014).

Safety comes first. Patients with HE fall, wander, pull out lines and cannot always swallow safely. The nurse uses fall precautions, checks swallowing before oral drugs, and reassesses orientation every shift. Patients at grade III or IV who cannot protect their airway need intensive monitoring, ideally in critical care (Vilstrup et al., 2014). Delirium from other causes can look the same (Chapter 8).

Living With Cirrhosis

People with cirrhosis do best with steady, practical support:

- **Alcohol:** stopping completely protects the liver; the nurse offers support without judgment (Chapter 11).
- **Medications:** NSAIDs are avoided (Biggins et al., 2021). People with liver disease may need a lower acetaminophen limit than the label states and should ask their prescriber or pharmacist (Health Canada, 2016; Chapter 5). The nurse teaches patients to check every product for hidden acetaminophen and to avoid sleeping pills unless prescribed.
- **Nutrition:** protein is not restricted; guidance is 1.2 to 1.5 g/kg a day, with small meals spread through the day and a late-evening snack, because fasting speeds muscle loss (Vilstrup et al., 2014). Sodium stays at about 2 g a day if ascites is present.
- **Vaccines:** hepatitis A and B vaccines for people who are not immune (PHAC, 2023, 2026; section 21.6).

- **Liver cancer surveillance:** ultrasound, often with a blood test for alpha-fetoprotein, every 6 months for people with cirrhosis (Kim et al., 2025; Osiowy et al., 2025).
- **Driving:** people who have had HE should stop driving until the licensing authority clears them (Vilstrup et al., 2014).
- **Planning ahead:** palliative care can run alongside treatment and transplant assessment (Biggins et al., 2021; Chapter 10).

Access shapes all of this. A person in a rural, remote or northern community may need to travel far for endoscopy, ultrasound or transplant assessment. The nurse plans visits ahead, explains travel support, and makes sure the patient knows which warning signs need 9-1-1 rather than waiting for the next appointment.

Table 26.2 brings together the main complications of cirrhosis and the nurse's first actions.

Table 26.2 Complications of cirrhosis and the nurse's first actions (Biggins et al., 2021; de Franchis et al., 2022; Vilstrup et al., 2014)

Complication	What the nurse sees	First nursing actions	Treatment principles
Ascites	Swollen abdomen, bulging flanks, weight gain, breathlessness when tense	Daily weight, abdominal girth, intake and output; check sodium, potassium and creatinine	Sodium about 2 g a day; spironolactone and furosemide; paracentesis with albumin when more than 5 L is drained
Spontaneous bacterial peritonitis	Fever, abdominal pain, new confusion, rising creatinine, or no symptoms	Report promptly; prepare for diagnostic paracentesis; screen for sepsis	IV antibiotics when the fluid neutrophil count exceeds 250/mm³; prevention in high-risk patients
Variceal bleeding	Vomited blood, black stools, rising heart rate, falling blood pressure, confusion	Turn to side, call rapid response, large-bore IV access, prepare blood and drugs	Vasoactive drug, antibiotics, restrictive transfusion, endoscopy within 12 hours
Hepatic encephalopathy	Day-night reversal, confusion, asterixis, drowsiness	Look for triggers, check glucose, count stools, fall and aspiration precautions	Treat the trigger; lactulose to 2 to 3 soft stools a day; rifaximin to prevent recurrence
Hepatorenal syndrome	Falling urine output and rising creatinine	Report; strict intake and output; ask the prescriber about holding diuretics and nephrotoxic drugs	Stop diuretics; albumin with a vasoconstrictor; urgent transplant assessment

GOING DEEPER

Portal Hypertension, the Hepatorenal Syndrome and the MELD Score

Required for RN students; optional for PN students.

Portal pressure is measured as the hepatic venous pressure gradient, the difference between pressure in a wedged hepatic vein catheter and the free hepatic vein. A gradient of 10 mm Hg or higher defines clinically significant portal hypertension, the point at which varices and ascites become likely and beta-blockers are considered (de Franchis et al., 2022).

Portal hypertension also widens blood vessels in the gut and around the body. Effective blood volume falls, so the kidneys sense poor perfusion and constrict their own arteries. When this goes far enough, the **hepatorenal syndrome** develops: acute kidney injury (AKI) in cirrhosis without shock, kidney damage or nephrotoxic drugs to explain it. AASLD defines AKI as a rise in creatinine of at least 26.5 µmol/L within 48 hours or of 50% within 7 days. Treatment stops diuretics, gives albumin with a vasoconstrictor drug, and prompts urgent transplant referral (Biggins et al., 2021). AKI is covered in Chapter 27.

The MELD score combines bilirubin, creatinine and INR to predict the risk of death within 3 months, and transplant programs use it to rank patients on the waiting list (Kamath et al., 2001). Updated versions add other values. Because creatinine is part of the score, hepatorenal syndrome raises MELD and the urgency of transplant.

CLINICAL SAFETY

Paracentesis and Sedatives in Liver Disease

Before paracentesis, the nurse confirms consent (section 1.5), records baseline vital signs, weight and girth, asks the patient to empty the bladder and checks whether blood tests were ordered. In cirrhosis, the INR does not accurately reflect how well the blood clots (de Franchis et al., 2022), so the nurse follows the team's orders on any blood products rather than expecting a raised INR to be corrected first.

During and after, the nurse watches for hypotension, dizziness, bleeding or leakage at the site, new abdominal pain and fever. When a large volume is drained, albumin is given as ordered (Biggins et al., 2021). The nurse records the volume and colour of the fluid and labels samples promptly.

Sedatives: benzodiazepines, opioids and other sedating drugs can cause or deepen confusion in people with cirrhosis and hide the signs of HE (Vilstrup et al., 2014). The liver clears many of these drugs slowly. The nurse:

- assesses orientation and asterixis before giving any sedating drug;
- questions a new sedative order for a patient with cirrhosis who is agitated, and looks first for a trigger such as bleeding, infection or constipation;
- uses non-drug measures for sleep and agitation;
- reports any drop in level of consciousness at once.

PATIENT EDUCATION

Taking Lactulose at Home

Lactulose keeps ammonia from building up and protects thinking. Teach the patient and family to:

- take it every day as prescribed, even when feeling well;
- aim for two to three soft bowel movements a day and adjust the dose as the prescriber has shown (Sanis Health, 2015; Vilstrup et al., 2014);
- mix it with water, juice or milk if the sweet taste is a problem (Sanis Health, 2015);
- expect gas, bloating or cramps at first; these usually settle (Sanis Health, 2015);
- avoid other laxatives unless the prescriber advises them (Sanis Health, 2015);
- call the prescriber for frequent watery stools, dizziness or very little urine, which may mean dehydration;
- call the prescriber for fewer than two stools a day, or for confusion, sleepiness by day or flapping hands;
- call 9-1-1 for black or bloody stools, vomited blood or a person who is hard to wake;
- protect the skin around the anus with gentle cleaning and a barrier cream.

Lactulose contains some sugars, so people with diabetes should check blood glucose as advised (Sanis Health, 2015).

SCOPE IN PRACTICE

Paracentesis, Large-Volume Fluids and Who Does What

Paracentesis is performed by a physician, or by a nurse practitioner (NP) who has the competence and employer authorization to do it. Before the procedure, the nurse confirms that the person doing it has obtained consent (section 1.5), and records baseline vital signs, weight and abdominal girth. During and after it, the nurse monitors blood pressure, heart rate, mental status and the puncture site.

CNO's Scope of Practice standard frames who does what through authority, competence and context (College of Nurses of Ontario [CNO], 2025; section 1.3):

- **Authority:** Giving albumin or other IV solutions is the controlled act of administering a substance by injection, which RNs and RPNs are authorized to perform with an order. Albumin is a blood product, so the employer's blood product policy also applies (section 20.6). Draining an existing peritoneal catheter requires an order and follows employer policy.
- **Competence:** The nurse needs the knowledge, skill and judgment to manage a drain, recognize a drop in blood pressure or new confusion after fluid removal, and act.
- **Context:** In many settings, RNs and RPNs both care for a patient whose ascites is drained routinely and whose condition is stable; this is a common employer practice, not a CNO rule. When blood pressure falls, urine output drops or confusion appears, the patient's needs have changed. The RPN consults the RN, and any nurse who sees deterioration acts at once and escalates (Chapter 6).

Employers can limit but not expand a nurse's scope; employer policy and province or territory matter. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (CNO, 2026).

PRACTICE STORY

Drowsy After Dinner

Names and details are fictional; this is a composite story.

Nurse: Kavita Pillai, RN. Years in practice: 7. Setting: medical unit, Ontario.

At 1900, my RPN colleague, Dale, told me that Mr. Antoine Lefebvre, 64, "just seems tired tonight." Mr. Lefebvre has cirrhosis and was admitted 3 days ago with ascites. At lunch, he had joked with me about the hospital food. At 1900, he was asleep with his dinner tray untouched, and he took a long time to answer my questions. He thought it was morning. When he held his arms out, his hands flapped. That was asterixis, and it told me that hepatic encephalopathy had worsened.

Lactulose was ordered, but I didn't want to stop there. I asked myself what had set this off. I thought of infection, constipation, sedatives, dehydration and electrolytes. Then I thought of bleeding. His chart showed two soft stools today, and Dale said the second one had been very dark. When I checked his brief, the stool was black, tarry and foul-smelling. His heart rate was 108, up from 84 at noon, and his blood pressure was 102/60, down from 128/74. He takes a beta-blocker, which can blunt a rising heart rate (Chapter 24).

I called the hospitalist and gave an SBAR report: worsening encephalopathy and melena with a falling blood pressure in a patient with cirrhosis and known varices. She came within minutes. We placed a second large-bore IV, sent blood work, including a group and screen, and kept him NPO. I raised the head of the bed and turned him on his side to protect his airway. The hospitalist ordered IV octreotide and ceftriaxone and arranged endoscopy. She called the ICU because his airway might need protection.

Later, endoscopy showed a bleeding varix. Over the next 2 days, as the bleed stopped and the lactulose worked, his confusion cleared. Dale's "just seems tired" was the first cue, and it was right.

Reflect: Which cues told the nurses that this was more than tiredness? When Dale noticed the change, what should an RPN do next, and why does the change in the patient's condition matter for who provides his care?

26.4 Alcohol-Related Liver Disease, Acute Liver Failure and Transplant

This section covers liver injury from alcohol, sudden failure of a previously healthy liver, and liver transplant. Cirrhosis and its complications are covered in section 26.3.

Alcohol-Related Liver Disease

Alcohol-related liver disease (ALD) is liver injury caused by drinking alcohol over time. Fat builds up in liver cells first (steatosis). Some people go on to an acute inflammatory illness, then to fibrosis and cirrhosis, and some develop liver cancer (Jophlin et al., 2024). This book uses "alcohol-related liver disease"; American guidelines use "alcohol-associated liver disease," which means the same thing.

ALD is one of the main reasons people develop advanced liver disease or die of liver disease, and it is often diagnosed late (Jophlin et al., 2024). In Canada, deaths and hospitalizations wholly caused by alcohol rose during the COVID-19 pandemic. A study of people aged 15 and older estimated that, from April 2020 to December 2022, deaths fully attributable to alcohol were 17.6% higher, and hospitalizations 8.1% higher, than expected. Alcoholic liver disease contributed more to this excess than any other condition, with deaths up 22% and hospitalizations up 23% (Shi et al., 2025). Excess hospitalizations rose more among females (15.6%) than among males (5.7%) (Shi et al., 2025).

Risk rises with the amount of alcohol and the years of drinking, with daily or binge drinking and with drinking outside meals. Sex, inherited gene variants, obesity, metabolic syndrome and chronic viral hepatitis also add risk (Jophlin et al., 2024). Canada's Guidance on Alcohol and Health describes risk as a continuum: 2 standard drinks a week or fewer is low risk, and each added drink raises the risk of several conditions, liver disease among them (Canadian Centre on Substance Use and Addiction [CCSA], 2023; Chapter 11).

Alcohol-associated hepatitis is the acute inflammatory stage. The typical picture is jaundice that begins within about 2 months of heavy drinking in a person who has drunk heavily for at least 6 months, with a raised bilirubin and an AST that is higher than the ALT (Jophlin et al., 2024). The nurse checks for jaundice in the sclerae, palms and oral mucosa, which works on every skin tone (section 26.1). A MELD score above 20 marks severe disease with a high risk of death in the short term (Jophlin et al., 2024; see the Going Deeper box in section 26.3).

Stopping alcohol is the most important treatment at every stage. Care for severe alcohol-associated hepatitis includes:

- **Corticosteroids,** which the guideline suggests for severe disease unless there is an untreated infection, GI bleeding, uncontrolled diabetes or severe kidney failure. The response is checked after 4 to 7 days, and the drug is stopped if the patient is not responding (Jophlin et al., 2024).
- **N-acetylcysteine,** which may be added to the corticosteroid for a short course (Jophlin et al., 2024).
- **Nutrition support,** including thiamine and other vitamins (Jophlin et al., 2024; Chapter 11; Chapter 24).
- **Early liver transplant** for a few carefully selected people who do not respond, and palliative care for those who are not candidates (Jophlin et al., 2024; Chapter 10).

Nursing care starts with the CJMM (section 1.4). The nurse watches for withdrawal, infection, bleeding and hepatic encephalopathy. Benzodiazepines for withdrawal can bring on hepatic encephalopathy in a person with poor liver function, so they are used with care and close monitoring (Jophlin et al., 2024; Chapter 11). The guideline recommends screening for alcohol use at every visit with a short tool such as the Alcohol Use Disorders Identification Test–Consumption (AUDIT-C), a brief intervention, and treatment of alcohol use disorder by a team that includes addiction specialists (Jophlin et al., 2024). The nurse uses person-first, non-judgmental language ("a person who drinks alcohol," not "an alcoholic") (Chapter 2; Chapter 11).

Acute Liver Failure

Acute liver failure (ALF) is a sudden, severe loss of liver function in a person without cirrhosis. It is defined by an INR of 1.5 or higher and any degree of encephalopathy, arising within 26 weeks of the start of the illness (Lee et al., 2011).

Causes. Acetaminophen overdose is the leading cause in the United States and Europe (Lee et al., 2011), and ISMP Canada (2017) reports that acetaminophen is the most common cause of liver failure in Canada. Other causes include hepatitis A, B and E, other drugs, a sudden drop in blood flow to the liver ("shock liver"), autoimmune hepatitis, Wilson disease and some pregnancy-related conditions. About 15% of cases have no cause found (Lee et al., 2011).

About 4,500 Canadians are hospitalized each year for acetaminophen overdose, and about 6% of them have liver injury (ISMP Canada, 2017). Most overdoses are intentional, but nearly 20% are not. Between 2006 and 2011, the proportion of acetaminophen-related injuries that followed an unintentional overdose climbed from 27% to 45% (ISMP Canada, 2017). Unintentional overdose often comes from taking two products that both contain acetaminophen, from prescription products that combine acetaminophen with an opioid, and from one brand name covering products with different ingredients. Most injuries occur above the maximum daily dose (Chapter 5), but injury at lower doses has been reported in people with liver disease, heavy alcohol use or malnutrition, or with long-term use (ISMP Canada, 2017). A person who took an intentional overdose also needs a suicide risk assessment and mental health follow-up.

Treatment of acetaminophen overdose. N-acetylcysteine (NAC), marketed in Canada as acetylcysteine, is the antidote. Clinicians give it to anyone who may have taken an acetaminophen overdose, even when the time of ingestion is unknown or the blood level is low, and it can still be of value 2 days or more after ingestion. Activated charcoal may help when the overdose was taken within about 3 to 4 hours (Lee et al., 2011). The nurse or prescriber can call the Ontario Poison Centre (1-800-268-9017) at any hour for expert advice; it serves both the public and health professionals (Ontario Poison Centre, n.d.). Other provinces and territories have their own poison centres.

Nursing priorities in ALF (Lee et al., 2011):

- **Brain:** frequent neurological checks, a quiet room and no sedatives unless ordered. Worsening encephalopathy can signal brain swelling.
- **Glucose:** frequent checks, because confusion can hide hypoglycemia. A continuous glucose infusion is often needed.
- **Bleeding:** watching for bleeding. Plasma and platelets are kept for active bleeding or invasive procedures, because routine plasma hides the INR trend.
- **Infection:** cultures and prompt reporting of fever, new confusion or falling blood pressure (Chapter 4).
- **Kidneys and electrolytes:** urine output, kidney function, avoiding nephrotoxic drugs, and phosphate, magnesium and potassium (Chapter 3).
- **Nutrition:** early enteral feeding (Chapter 24).

A patient with any encephalopathy belongs in an intensive care unit (ICU), and the transplant centre is called early. Transfer is advised even for mild encephalopathy, because moving the patient later may become unsafe (Lee et al., 2011).

Liver Transplant in Brief

A **liver transplant** replaces a failing liver with a whole liver from a deceased donor or part of a liver from a living donor. In 2025, Canada performed 3,174 organ transplants, and 19% were liver transplants. At the end of 2025, 4,344 people were waiting for an organ. Of the 678 people removed from wait-lists in 2025, 31% had died while waiting (Canadian Institute for Health Information [CIHI], 2026).

Ontario has two adult liver transplant programs, in Toronto and London. Provincial criteria call for referral of people with decompensated cirrhosis, typically at a MELD 3.0 score of 11 or more, and of people with acute liver failure; listing typically requires a score of 15 or more (Ontario Health [Trillium Gift of Life Network], 2025). Complications such as ascites, encephalopathy, bleeding from portal hypertension (including varices) and liver cancer prompt referral (section 26.3). People with ALD must be prepared to commit to not drinking alcohol at all (Ontario Health [Trillium Gift of Life Network], 2025), and a psychosocial assessment, rather than a fixed period without alcohol alone, guides the decision (Jophlin et al., 2024). The University Health Network program in Toronto reports more than 800 living donor liver transplants; donors are assessed carefully, and their recovery takes at least 6 weeks (University Health Network, n.d.).

After transplant, the person takes immunosuppressants for life (section 21.3). Teaching covers (Johns Hopkins Medicine, 2017):

- Never stop or skip anti-rejection drugs, and check with the transplant team before starting any new prescription, over-the-counter or herbal product.
- Have drug-level blood tests at the scheduled times; rejection may cause no symptoms and show only in blood work.
- Report fever, jaundice, dark urine, generalized itching, pain over the new liver, swelling or unusual tiredness.
- Report early signs of infection, a common cause of readmission.
- Avoid live vaccines, protect the skin from the sun, avoid alcohol and keep lifelong follow-up.

26.5 Gallbladder and Biliary Disease

The gallbladder stores bile and squeezes it into the duodenum after meals (section 26.1). Stones that form in it cause pain when they block the outflow, and the most serious problems arise when a stone moves into the common bile duct.

Gallstones and Cholecystitis

Cholelithiasis means stones in the biliary tract, most often in the gallbladder (Figure 26.8). A Canadian surgical guideline estimates that about 10% of the general population have gallstones. Most never have symptoms, and about 1% to 3% a year develop significant symptoms (Aubin & Ball, 2018). Risk factors include (Aubin & Ball, 2018):

- older age, female sex and a family history;
- obesity, rapid weight loss and pregnancy;
- parenteral nutrition and some drugs, such as ceftriaxone;
- conditions that slow bile flow or change bile, such as spinal cord injury, cirrhosis, Crohn disease and removal of the last part of the small intestine.

Biliary colic is pain caused when a stone briefly blocks the cystic duct. The pain is in the right upper quadrant (RUQ) or epigastrium, often after a meal, and may spread to the back with nausea and vomiting. It usually lasts from about 30 minutes to 4 hours. Pain that lasts longer suggests cholecystitis (Aubin & Ball, 2018).

Acute cholecystitis is inflammation of the gallbladder, usually because a stone stays stuck in its neck. The wall can become ischemic and gangrenous, and it can perforate (Aubin & Ball, 2018). The pain persists, and fever and RUQ tenderness are common. A **Murphy sign** is present when the patient suddenly stops breathing in because of pain as the examiner presses under the right rib margin (Aubin & Ball, 2018). No single finding confirms or rules out cholecystitis (Pisano et al., 2020). A suspected diagnosis rests

on a local sign (Murphy sign or RUQ pain, tenderness or mass) plus a sign of inflammation (fever, a high white cell count or a raised C-reactive protein), and imaging confirms it (Aubin & Ball, 2018). Abdominal ultrasound is the first test (Pisano et al., 2020). Older adults, men, people with diabetes and people who are immunosuppressed are at higher risk of complicated disease, so clinicians keep a low threshold for suspecting it (Aubin & Ball, 2018).

Early treatment is nothing by mouth (NPO), IV fluids, pain relief (Chapter 5) and antibiotics (Aubin & Ball, 2018). Where a surgeon is available, laparoscopic cholecystectomy is done early: ideally within 7 days of admission and within 10 days of the start of symptoms. Patients too unwell for surgery have the gallbladder drained instead (Pisano et al., 2020). The nurse reassesses pain, watches for sepsis (Chapter 4) and escalates a rising heart rate, falling blood pressure or new confusion (Chapter 6). Preoperative care is in Chapter 7.

Figure 26.8 Gallstones removed from one patient, on a 1 mm grid. (credit: "Human gallstones 2015 G1" by George Chernilevsky/Wikimedia Commons, CC BY-SA 4.0)

Laparoscopic cholecystectomy removes the gallbladder through small incisions. Patients often go home soon after, so teaching starts early (Interior Health, 2015; Quinte Health, 2022):

- **Shoulder or neck pain:** common in the first 48 hours. It comes from the carbon dioxide gas used to inflate the abdomen and fades as the gas is absorbed. Lying flat and warmth to the shoulders, not the abdomen, may help.
- **Breathing and walking:** deep breathing and coughing every hour while awake, with a pillow pressed against the abdomen, and regular walks.
- **Eating:** fluids first, then foods as tolerated. Loose stools from bile trickling into the bowel usually settle; persistent diarrhea is reported.
- **Bowels:** opioids can cause constipation, so the patient avoids straining and may need a mild laxative.
- **Return to work:** often within about 7 to 10 days; heavy work and sports are cleared with the surgeon.

The patient calls the surgeon or goes to an emergency department for:

- fever (Interior Health uses above 38.3 °C) or chills;
- abdominal pain that grows worse or is not controlled;
- nausea or vomiting lasting more than 24 hours;
- yellow eyes or skin, or dark urine;
- redness, pus or bleeding at an incision;
- trouble breathing, chest pain or being unable to pass urine (Interior Health, 2015; Quinte Health, 2022).

These signs can point to a complication, such as bleeding or infection, that needs prompt review.

Choledocholithiasis and Cholangitis

Choledocholithiasis is a stone in the common bile duct. It blocks bile flow and can cause jaundice, acute pancreatitis (section 26.6) or cholangitis. Raised liver tests or bilirubin alone do not prove a duct stone. A second imaging test, such as magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound, is used when the risk is moderate (Pisano et al., 2020). A confirmed duct stone is removed before cholecystectomy (Aubin & Ball, 2018).

Acute cholangitis is infection of the bile ducts behind a blockage. The **Charcot triad** of fever, jaundice and abdominal pain points strongly to cholangitis, but it appeared in only about 1 in 4 patients (26.4%) in the study behind the Tokyo criteria (Kiriyama et al., 2012). The nurse therefore does not wait for all three. The Tokyo Guidelines diagnose cholangitis from signs of inflammation, signs

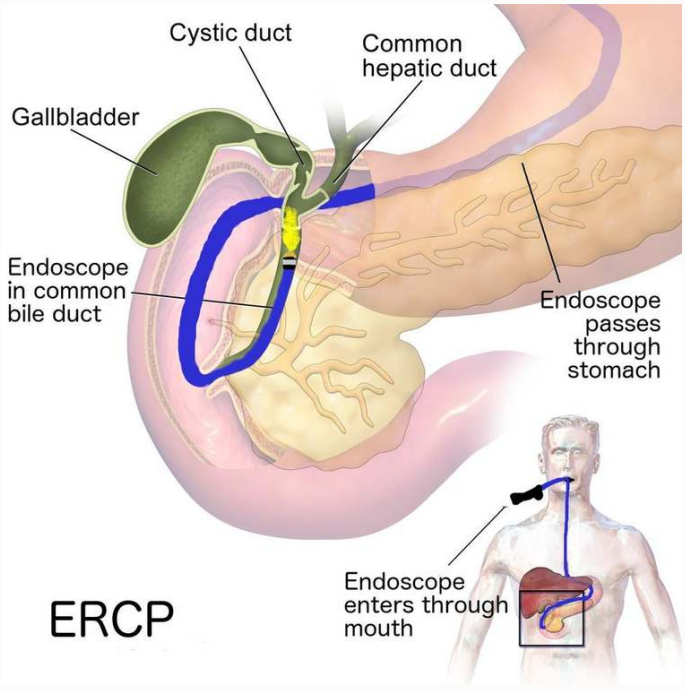

Figure 26.9 Endoscopic retrograde cholangiopancreatography (ERCP): the endoscope enters through the mouth and passes through the stomach to the duodenum, where instruments reach the common bile duct. (credit: "ERCP" by Drus1a/Wikimedia Commons, CC BY-SA 4.0)

of blocked bile flow and imaging (Kiriyama et al., 2012). They grade severity: age 75 or older is one of five factors, and any two of them make the disease moderate (Kiriyama et al., 2012). Severe cholangitis means organ dysfunction, such as low blood pressure or confusion (Chandrasekhara et al., 2017; Kiriyama et al., 2018).

Treatment is antibiotics, fluids and drainage of the blocked duct. Drainage is urgent in severe cholangitis and early in moderate cholangitis (Kiriyama et al., 2012, 2018). When cholangitis accompanies acute pancreatitis, the American College of Gastroenterology (ACG) guideline supports **endoscopic retrograde cholangiopancreatography (ERCP)** within 24 hours (Tenner et al., 2024). Sepsis care is in Chapter 4.

ERCP passes an endoscope through the mouth into the duodenum to reach the bile and pancreatic ducts (Figure 26.9). Through it, the endoscopist can cut the duct opening (sphincterotomy), remove stones and place stents. After ERCP, the nurse monitors for (Chandrasekhara et al., 2017):

- **Post-ERCP pancreatitis:** the most common serious complication, seen in about 3% to 10% of patients. New or worse abdominal pain is the key cue. A raised enzyme level alone does not make the diagnosis, because levels rise briefly in many patients.
- **Bleeding:** right away or delayed by hours to weeks.
- **Perforation:** severe epigastric or back pain, a rigid abdomen, fever and a fast heart rate. Signs may take hours to appear.
- **Cholangitis:** fever, jaundice and pain.
- **Sedation problems:** low oxygen levels, low blood pressure and aspiration.

To prevent post-ERCP pancreatitis, the ACG guideline supports a rectal nonsteroidal anti-inflammatory drug (NSAID) for patients having ERCP unless it is contraindicated, and a temporary pancreatic duct stent for those at high risk (Tenner et al., 2024).

CLINICAL JUDGMENT

Fever, Jaundice and Pain After a Gallstone Attack

Names and details are fictional; this is a composite story.

Kwame Mensah, 71, was seen in the emergency department 2 days ago for biliary colic and sent home with a surgical referral. He returns with RUQ pain, chills and less to eat or drink. His daughter says he is "not himself." He has dark brown skin.

- **Recognize cues:** Temperature 38.9 °C, heart rate 114, blood pressure 98/58 mm Hg, respiratory rate 24. His sclerae and the mucosa under his tongue look yellow; his skin colour is unchanged. His urine is dark. He is slow to answer and unsure of the date.
- **Analyze cues:** Fever with jaundice and pain after a known gallstone attack suggests a stone in the common bile duct with infection behind it. New confusion and low blood pressure suggest organ dysfunction.
- **Prioritize hypotheses:** Severe acute cholangitis with sepsis comes first. Acute cholecystitis and delirium from another cause are possible, but neither changes the urgent plan.
- **Generate solutions:** Early recognition and escalation, IV access, blood work and cultures, IV fluids and antibiotics as ordered, NPO, and urgent biliary drainage, usually by ERCP.
- **Take action:** The nurse calls the rapid response team using SBAR (Chapter 6), draws blood cultures before the first antibiotic dose as ordered (Chapter 4), starts IV fluids as ordered and keeps him NPO. The nurse turns on the bed alarm and stays with him.

- **Evaluate outcomes:** After ERCP removes the stone, his blood pressure and alertness improve over 24 hours. The nurse keeps watching for post-ERCP pancreatitis and bleeding, and checks his sclerae each shift.

26.6 Acute and Chronic Pancreatitis

The pancreas makes digestive enzymes and hormones such as insulin (section 26.1). When it becomes inflamed, it can injure itself and trigger inflammation throughout the body. Diabetes after pancreatic disease is covered in Chapter 22.

Acute Pancreatitis

Acute pancreatitis is acute inflammation of the pancreas (Tenner et al., 2024). In most patients it is **interstitial edematous pancreatitis**, in which the gland swells. About 5% to 10% develop **necrotizing pancreatitis**, in which pancreatic tissue or the tissue around it dies (Banks et al., 2013).

Causes. Gallstones (about 40% to 70% of cases) and alcohol (about 25% to 35%) are the most common causes (Tenner et al., 2024). Other causes include (Tenner et al., 2024):

- very high triglycerides, usually above about 11.3 mmol/L (1,000 mg/dL), with a fasting level repeated about a month after discharge;
- ERCP (section 26.5);
- a small number of drugs, although blaming a drug is often wrong;
- in adults over 40 with no clear cause, a pancreatic tumour, which is looked for.

Alcohol is not judged to be the cause unless a person has drunk moderately or heavily for more than 5 years (Tenner et al., 2024). Canadian data on alcohol-related harm are in section 26.4 and Chapter 11.

Diagnosis. Acute pancreatitis is diagnosed when two of three features are present (Banks et al., 2013; Tenner et al., 2024):

- abdominal pain typical of the disease, usually epigastric and often spreading to the back;
- serum **lipase** (or amylase) at least three times the upper limit of normal; lipase is preferred;
- typical findings on imaging.

The onset is the time the pain began, not the time of admission (Banks et al., 2013). Every patient has an abdominal ultrasound to look for gallstones. A computed tomography (CT) scan is not used routinely to grade severity. It is kept for an unclear diagnosis or a patient who is not improving after 48 to 72 hours (Tenner et al., 2024). Triglyceride and calcium levels are part of the search for a cause (Tenner et al., 2024).

Cullen and Grey Turner signs. The **Cullen sign** is bruising around the umbilicus, and the **Grey Turner sign** is bruising of the flanks. Both form when blood from behind the peritoneum tracks into the abdominal wall. They are rare in acute pancreatitis (about 1% of patients each in older case series), usually appear a few days into the illness and point to serious disease (Wright, 2016). Neither is specific to pancreatitis; a ruptured ectopic pregnancy and other causes of internal bleeding can produce them (Wright, 2016). On light skin, the bruise may look blue-purple and turn green or yellow as it ages (Wright, 2016). On dark skin, a bruise may look only darker than the skin around it (Pusey-Reid et al., 2023). The nurse inspects both flanks and the umbilicus in natural or ambient light, compares one side with the other, and palpates for tenderness and swelling.

Severity. The **revised Atlanta classification** grades acute pancreatitis by organ failure and complications (Banks et al., 2013; Table 26.3). **Organ failure** means failure of the lungs, the circulation or the kidneys. It is **transient** if it resolves within 48 hours and **persistent** if it lasts longer (Banks et al., 2013). The early phase usually lasts about a week; a late phase of weeks to months occurs only in moderately severe or severe disease (Banks et al., 2013). No score or scan reliably predicts severity at the start, so the first 48 hours call for close watching (Tenner et al., 2024).

Table 26.3 Severity of acute pancreatitis (revised Atlanta classification) and what it means for care (Banks et al., 2013)

Severity	Definition (in own words)	Nursing focus

Severity	Definition (in own words)	Nursing focus
Mild	No organ failure and no local or body-wide complications; usually settles within the first week	Early oral feeding as tolerated, pain control, finding the cause, discharge teaching, and cholecystectomy before discharge if gallstones caused it
Moderately severe	Organ failure that resolves within 48 hours, or local complications (such as fluid collections or necrosis), or a flare of an existing illness such as heart or lung disease, without persistent organ failure	Close monitoring of vital signs, oxygen and urine output; enteral nutrition if eating is not possible; watching for collections, infection and worsening of chronic illness
Severe	Organ failure in one or more systems that lasts longer than 48 hours	Intensive care, organ support, careful fluid balance, enteral feeding and support for the patient and family

Early Care and Nursing Priorities

Most patients have mild disease and recover within days. The nurse's job in the first 48 hours is to support the circulation, control pain, feed early and recognize organ failure early.

IV fluids. The ACG guideline suggests moderately aggressive IV fluids, with extra boluses for hypovolemia, and prefers lactated Ringer's solution to normal saline (Tenner et al., 2024). Fluids matter most in the first 24 hours. Volume status is reassessed within 6 hours of arrival and repeatedly over the next 24 to 48 hours. The aim is a falling blood urea and a hematocrit that does not rise (Tenner et al., 2024). The guideline found too little evidence that strict goal-directed protocols improve outcomes, and it urges caution in patients with heart or kidney disease (Tenner et al., 2024). In a large trial, early aggressive fluids caused fluid overload in 20.5% of patients, compared with 6.3% given moderate fluids, without better outcomes (de-Madaria et al., 2022).

The nurse therefore watches both sides of the balance:

- **Too little fluid:** rising heart rate, falling blood pressure, low urine output, and rising urea, creatinine or hematocrit.
- **Too much fluid:** shortness of breath, crackles, falling oxygen saturation, rising weight and edema.

Accurate intake and output, daily weights and frequent vital signs make both visible (Chapter 3).

Pain. Pain is often severe and is a priority. The nurse gives analgesia as ordered, reassesses and watches for opioid sedation and slow breathing (Chapter 5).

Feeding. In mild disease, the guideline suggests eating by mouth within 24 to 48 hours as tolerated, starting with a low-fat solid diet rather than stepping up from clear fluids. Keeping the patient NPO for days is no longer standard (Tenner et al., 2024). In moderately severe or severe disease, enteral feeding, including by nasogastric tube, is preferred because it appears to prevent infection. Parenteral nutrition is used only when enteral feeding is not possible or not enough (Tenner et al., 2024; Chapter 24).

Monitoring and escalation. The nurse checks glucose, electrolytes and calcium as ordered (Chapter 3; Chapter 22). The nurse also watches the respiratory rate, work of breathing and oxygen saturation. A systolic blood pressure below 90 mm Hg, low oxygen levels, low urine output or rising creatinine can mean organ failure (Tenner et al., 2024). These findings call for immediate escalation, using the early warning score and the rapid response team (Chapter 6). Antibiotics are not given to prevent infection. They are used when infection is present, such as cholangitis or infected necrosis (Tenner et al., 2024).

Gallstone pancreatitis. In gallstone pancreatitis without cholangitis, the guideline favours medical care over early ERCP; with cholangitis, ERCP within 24 hours is advised (Tenner et al., 2024). After mild gallstone pancreatitis, cholecystectomy is done early, preferably before discharge, to prevent another attack (Tenner et al., 2024).

Alcohol. When alcohol is a cause, the nurse offers non-judgmental support, watches for withdrawal and connects the patient with treatment (Chapter 11).

> GOING DEEPER
>
> **Fluids and Organ Failure in Severe Acute Pancreatitis**
>
> *Required for RN students; optional for PN students.*

The revised Atlanta classification scores three organ systems (respiratory, cardiovascular and renal) with the modified Marshall score. Organ failure is a score of 2 or more in any one system (Banks et al., 2013). The ACG guideline gives practical markers: a systolic blood pressure below 90 mm Hg, a PaO_2 below 60 mm Hg, or a creatinine above about 177 µmol/L (2 mg/dL) after rehydration (Tenner et al., 2024). Persistent systemic inflammatory response syndrome (SIRS) is another warning: two or more of a heart rate above 90, a respiratory rate above 20, a temperature above 38 °C or below 36 °C, and an abnormal white cell count (Tenner et al., 2024).

Fluids cut both ways: leaking capillaries lower blood volume and organ perfusion, but extra fluid collects in the lungs and tissues. In the WATERFALL trial, aggressive goal-directed lactated Ringer's caused more fluid overload than a moderate approach (20.5% vs 6.3%) and did not reduce moderately severe or severe disease (de-Madaria et al., 2022). The RN therefore treats the fluid order as a hypothesis to test. The RN reassesses within hours, trends urea, hematocrit, urine output, lung sounds and oxygen needs, and reports early when the response is poor or overload appears. Patients with heart or kidney disease need the closest watch (Tenner et al., 2024).

Table 26.4 summarizes the gallbladder and pancreatic emergencies in this chapter and the nurse's first actions.

Table 26.4 Gallbladder and pancreatic emergencies at a glance (Aubin & Ball, 2018; Chandrasekhara et al., 2017; Kiriyama et al., 2012; Tenner et al., 2024)

Condition	Key signs	First nursing actions
Acute cholecystitis	RUQ pain lasting more than a few hours, fever, Murphy sign	NPO, IV access and fluids as ordered, analgesia, antibiotics as ordered; watch for sepsis; prepare for early surgery
Acute cholangitis	Fever, jaundice and abdominal pain (often not all three); confusion or low blood pressure in severe disease	Escalate at once; IV access, cultures and antibiotics as ordered; NPO; prepare for urgent ERCP
Acute pancreatitis	Epigastric pain often spreading to the back, vomiting, raised lipase; rising heart rate and falling urine output in early hypovolemia	IV fluids as ordered with reassessment within hours; analgesia; intake, output and weight; watch for organ failure and fluid overload
After ERCP	New or worse abdominal pain, vomiting, bleeding, severe pain with a rigid abdomen, fever	Assess vital signs and abdomen; report new pain promptly; keep NPO until assessed; escalate signs of perforation or bleeding

Chronic Pancreatitis

Chronic pancreatitis is a long-lasting fibroinflammatory disease. In people who are susceptible, repeated or ongoing injury leaves the pancreas scarred and slowly destroys its function (Gardner et al., 2020). Alcohol and smoking are the main toxic causes. Inherited, obstructive and autoimmune causes, and repeated attacks of acute pancreatitis, also lead to it (Gardner et al., 2020).

Abdominal pain is the main complaint. When enough enzyme-producing tissue is lost, fat is not digested and the person has **steatorrhea** (bulky, greasy, foul-smelling stools) and weight loss. Low levels of the fat-soluble vitamins, malnutrition and osteoporosis follow. Diabetes develops when insulin-producing cells are lost (Chapter 22), and the risk of pancreatic cancer is higher (Gardner et al., 2020). CT or magnetic resonance imaging (MRI) is the first imaging test, and a stool elastase test helps show poor enzyme output (Gardner et al., 2020).

Care focuses on four areas:

- **Stopping alcohol and tobacco:** the guideline's first step (Gardner et al., 2020; Chapter 11).
- **Pain:** managed with a long-term plan (Chapter 5). Endoscopic or surgical treatment helps some people with a blocked duct (Gardner et al., 2020).
- **Nutrition:** support with a dietitian (Chapter 24).
- **Pancreatic enzyme replacement therapy (PERT):** replaces the missing enzymes and treats malabsorption and malnutrition, but it is not a treatment for pain (Gardner et al., 2020).

In Canada, PERT is available as pancreatin capsules, for example Creon, made from pig pancreas (BGP Pharma ULC, 2024). The nurse discusses the porcine source with any patient for whom it matters.

LIFESPAN CONSIDERATIONS

Liver and Biliary Disease in Older Adults

- **Cholecystitis can be quieter and more dangerous.** Older adults are among the groups at higher risk of complicated cholecystitis, and advanced age raises the risk of a gangrenous gallbladder. Clinicians therefore keep a low threshold for suspecting it (Aubin & Ball, 2018). Because illness often presents atypically in older adults (Chapter 8), the nurse treats new confusion, poor intake or a fall in an older adult with gallstones as a possible cue.
- **Age alone does not rule out surgery.** Studies favour early laparoscopic cholecystectomy even after age 80, although the evidence is of low quality (Pisano et al., 2020).
- **Age counts in cholangitis grading.** Age 75 or older is one of the five Tokyo factors, any two of which make cholangitis moderate, a grade that calls for early drainage (Kiriyama et al., 2012).
- **Drugs act longer.** Many drugs are cleared by the liver (section 26.1). In liver disease, sedatives, opioids and benzodiazepines can build up and bring on hepatic encephalopathy, so the nurse watches older adults closely after each dose (Jophlin et al., 2024; Chapter 8).
- **Falls and delirium.** Hepatic encephalopathy, lactulose-driven trips to the toilet and diuretics combine to raise fall risk (section 26.3). The nurse uses a toileting schedule, a low bed and a bed alarm, and screens for delirium (Chapter 8).

Chapter 26 Summary

26.1 The Liver, Biliary Tree and Pancreas

- The liver receives portal blood from the gut and handles metabolism, albumin and clotting factor production, bilirubin and bile, and drug clearance; the pancreas makes digestive enzymes and, in its islets, insulin and glucagon.
- ALT and AST show liver cell injury, ALP and GGT show blocked bile flow, and albumin and the INR reflect synthetic function; reference ranges vary by laboratory.
- A cholestatic pattern (ALP higher than ALT) suggests blocked bile flow; an ALT above 1,000 U/L calls for an acetaminophen history.
- Jaundice may be prehepatic, hepatic or posthepatic; on darker skin, the nurse checks the sclerae and hard palate in natural or indirect light.
- Pruritus from cholestasis can disrupt sleep; skin care, short nails and reporting help.

26.2 Viral Hepatitis and Steatotic Liver Disease

- Hepatitis A spreads by the fecal-oral route and never becomes chronic; hepatitis B spreads through blood and body fluids and is prevented by vaccine; hepatitis C spreads mainly through blood and is curable.
- In 2021, an estimated 262,000 people in Canada were living with chronic hepatitis B and 214,000 with chronic hepatitis C, and about four in ten did not know it.
- CASL and AMMI Canada now recommend one-time hepatitis B screening for all adults; hepatitis C screening advice differs among the Canadian Task Force, CASL and PHAC.
- Direct-acting antivirals cure more than 90% of people with hepatitis C; Canada is committed to the WHO 2030 elimination targets.
- MASLD replaces NAFLD; it affects about one in five Canadians and most people with type 2 diabetes, and weight loss of 5% to 10% or more with exercise is the core of care.

26.3 Cirrhosis and Its Complications

- Cirrhosis causes portal hypertension and liver failure; decompensation is marked by overt ascites, variceal bleeding or overt hepatic encephalopathy.
- Ascites is managed with about 2 g of sodium a day, diuretics, avoidance of NSAIDs, daily weights and paracentesis with albumin when more than 5 L is removed; SBP may cause fever, pain, confusion or no symptoms.

- A variceal bleed is an emergency: protect the airway, call for help, use a restrictive transfusion strategy, start a vasoactive drug and antibiotics, and arrange endoscopy within 12 hours.
- Hepatic encephalopathy usually has a trigger; lactulose is titrated to two to three soft stools a day, rifaximin helps prevent recurrence, and safety and airway protection come first.
- Living with cirrhosis means no alcohol, no NSAIDs, cautious acetaminophen, a late-evening snack without protein restriction, vaccines, liver cancer surveillance every 6 months and early palliative care.

26.4 Alcohol-Related Liver Disease, Acute Liver Failure and Transplant

- Alcohol-related liver disease ranges from fatty liver through alcohol-associated hepatitis to cirrhosis; alcoholic liver disease led the rise in alcohol-attributable deaths and hospitalizations in Canada during the COVID-19 pandemic.
- Stopping alcohol is the key treatment; severe alcohol-associated hepatitis may be treated with corticosteroids, nutrition support and, for a few selected people, early transplant. The nurse uses person-first, non-judgmental language and links the person to treatment (Chapter 11).
- Acute liver failure is an INR of 1.5 or higher with any encephalopathy, in a person without cirrhosis, within 26 weeks; acetaminophen is the most common cause of liver failure in Canada.
- N-acetylcysteine is given whenever acetaminophen overdose is suspected, even if the timing is unknown; the Ontario Poison Centre (1-800-268-9017) gives advice at any hour.
- Patients with acute liver failure need frequent neurological and glucose checks, ICU care and early contact with a transplant centre.
- Liver transplant recipients take immunosuppressants for life, report fever, jaundice and other warning signs, and keep lifelong follow-up.

26.5 Gallbladder and Biliary Disease

- About 10% of people have gallstones; most never have symptoms. Biliary colic lasts about 30 minutes to 4 hours; longer pain suggests cholecystitis.
- Acute cholecystitis causes persistent RUQ pain, fever and a Murphy sign; ultrasound is the first test, and early laparoscopic cholecystectomy is preferred.
- After laparoscopic cholecystectomy, shoulder pain from the gas is common; worsening pain, fever, vomiting beyond 24 hours, jaundice and wound problems are reported.
- The Charcot triad (fever, jaundice, pain) is specific but appears in only about 1 in 4 patients with cholangitis; severe cholangitis needs urgent escalation, antibiotics and duct drainage.
- After ERCP, new or worse abdominal pain suggests post-ERCP pancreatitis, the most common serious complication; bleeding and perforation are also watched for.

26.6 Acute and Chronic Pancreatitis

- Gallstones and alcohol cause most acute pancreatitis; diagnosis needs two of typical pain, lipase at least three times the upper limit of normal, and typical imaging.
- The revised Atlanta classification grades severity by organ failure: transient (under 48 hours) or persistent (over 48 hours), plus local and systemic complications.
- Early care is moderately aggressive IV fluids (lactated Ringer's preferred) with reassessment within hours, watching for both hypovolemia and fluid overload.
- Patients with mild disease eat early, starting with a low-fat solid diet; enteral feeding is preferred over parenteral in more severe disease; prophylactic antibiotics are not used.
- Cullen and Grey Turner signs are rare signs of serious disease; on dark skin, bruising may look only darker than the surrounding skin.
- Chronic pancreatitis causes pain, steatorrhea, weight loss and diabetes; pancreatic enzymes are taken during or right after meals and snacks and swallowed whole.

Key Terms (49)

acute cholecystitis: Inflammation of the gallbladder, usually because a stone is stuck in its neck; the pain persists for longer than biliary colic and is often accompanied by fever and right upper quadrant tenderness.

acute liver failure (ALF): A sudden, severe loss of liver function in a person without cirrhosis, with an INR of 1.5 or higher and any degree of encephalopathy, arising within 26 weeks of the start of the illness.

acute pancreatitis: Acute inflammation of the pancreas, diagnosed when two of three features are present: typical pain, lipase or amylase at least three times the upper limit of normal, and typical imaging findings.

alcohol-associated hepatitis: The acute inflammatory stage of alcohol-related liver disease, typically with new jaundice in a person who has been drinking heavily.

alcohol-related liver disease (ALD): Liver injury caused by drinking alcohol over time, ranging from fatty liver through alcohol-associated hepatitis and fibrosis to cirrhosis and liver cancer.

ascites: A build-up of fluid in the peritoneal cavity, most often caused by portal hypertension in cirrhosis.

asterixis: A flapping movement of the outstretched hands with the wrists bent back, caused by brief loss of muscle tone; a sign of hepatic encephalopathy.

biliary colic: Pain, usually lasting about 30 minutes to 4 hours, caused when a gallstone briefly blocks the cystic duct; felt in the right upper quadrant or epigastrium, often after a meal.

bilirubin: A yellow pigment made when old red blood cells break down; the liver conjugates it and secretes it into bile.

Charcot triad: Fever, jaundice and abdominal pain; a highly specific but insensitive combination of signs of acute cholangitis.

cholangitis: Infection of the bile ducts behind a blockage, most often a stone; severe cases cause organ dysfunction and need urgent drainage.

choledocholithiasis: A stone in the common bile duct.

cholelithiasis: Stones in the biliary tract, most often in the gallbladder.

chronic pancreatitis: A long-lasting fibroinflammatory disease in which ongoing injury scars the pancreas and slowly destroys its digestive and hormone-producing function.

cirrhosis: Advanced scarring of the liver, with nodules of regenerating cells, that impairs blood flow through the liver and liver function.

compensated cirrhosis: Cirrhosis without overt ascites, variceal bleeding or overt hepatic encephalopathy.

Cullen sign: Bruising around the umbilicus caused by blood tracking from behind the peritoneum; rare and not specific to pancreatitis, but a sign of serious disease.

decompensated cirrhosis: Cirrhosis in which overt ascites, variceal bleeding or overt hepatic encephalopathy has developed.

direct-acting antiviral: A drug that blocks a step in hepatitis C virus replication; taken as tablets for 8 to 24 weeks, these drugs cure most people.

endoscopic retrograde cholangiopancreatography (ERCP): A procedure in which an endoscope passed through the mouth into the duodenum is used to image and treat the bile and pancreatic ducts, for example by removing stones.

esophageal varices: Enlarged, thin-walled veins in the lower esophagus caused by portal hypertension, which can bleed heavily.

Grey Turner sign: Bruising of the flanks caused by blood tracking from behind the peritoneum; rare and not specific to pancreatitis, but a sign of serious disease.

hepatic encephalopathy (HE): Brain dysfunction caused by liver failure, blood bypassing the liver, or both, ranging from subtle changes to coma.

hepatitis: Inflammation of the liver.

hepatitis A: A liver infection spread by the fecal-oral route that does not become chronic and is prevented by vaccine and hand hygiene.

hepatitis B: A liver infection spread through blood and body fluids that becomes chronic in a minority of infected adults and most infected infants; preventable by vaccine.

hepatitis C: A liver infection spread mainly through blood that often becomes chronic and is curable with direct-acting antivirals; no vaccine exists.

hepatocellular carcinoma: Cancer arising from liver cells, a long-term risk of cirrhosis and chronic hepatitis B.

hepatorenal syndrome: Acute kidney injury in a person with cirrhosis, caused by constriction of the kidneys' blood vessels rather than kidney damage, shock or nephrotoxic drugs.

jaundice: A yellow colour of the skin, sclerae and mucous membranes caused by a high blood level of bilirubin.

laparoscopic cholecystectomy: Removal of the gallbladder through small abdominal incisions using a camera and instruments.

lipase: A pancreatic digestive enzyme; a blood level at least three times the upper limit of normal is one of the diagnostic features of acute pancreatitis.

liver transplant: Replacement of a failing liver with a whole liver from a deceased donor or part of a liver from a living donor.

metabolic dysfunction-associated steatohepatitis (MASH): MASLD with inflammation and liver cell injury; formerly called nonalcoholic steatohepatitis (NASH).

metabolic dysfunction-associated steatotic liver disease (MASLD): Fat build-up in the liver with at least one cardiometabolic risk factor and no other cause; formerly called nonalcoholic fatty liver disease (NAFLD).

Murphy sign: A sudden stop in breathing in, caused by pain, when the examiner presses under the right rib margin; a local sign of acute cholecystitis.

N-acetylcysteine (NAC): The antidote for acetaminophen overdose (marketed in Canada as acetylcysteine), given whenever overdose is suspected, even if the timing is unknown.

palmar erythema: Redness of the palms, mostly at the base of the thumb and little finger, seen in advanced liver disease.

pancreatic enzyme replacement therapy (PERT): Capsules of pancreatic enzymes taken with meals and snacks to digest food when the pancreas no longer makes enough enzymes.

paracentesis: Drainage of ascitic fluid through a needle or catheter in the abdominal wall, for diagnosis or to relieve a large or tense ascites.

portal hypertension: Raised pressure in the portal vein system, usually caused by resistance to blood flow through a scarred liver.

portal vein: The vein that carries blood from the stomach, intestines, pancreas and spleen to the liver.

pruritus: Itching; in liver disease, often caused by cholestasis.

revised Atlanta classification: An international system that defines acute pancreatitis and grades it as mild, moderately severe or severe according to organ failure and complications.

spider angioma: A small red spot with fine vessels radiating outward that fades when the centre is pressed; seen in advanced liver disease.

spontaneous bacterial peritonitis (SBP): Infection of ascitic fluid without an obvious source, diagnosed by a fluid neutrophil count above 250/mm³.

steatorrhea: Bulky, greasy, foul-smelling stools caused by undigested fat.

steatotic liver disease: The umbrella term for fat build-up in the liver from any cause.

sustained virologic response: No hepatitis C virus found in the blood 12 weeks after treatment ends; considered a cure.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Lorraine Bouchard (Questions 1–4): Lorraine Bouchard, 63, has cirrhosis related to MASLD and type 2 diabetes and was admitted to a medical unit in Ontario with confusion; her daughter says that for three days Lorraine has slept most of the day, been awake at night and mixed up the days of the week, and that Lorraine cut back her lactulose because she was afraid of accidents while shopping.

1. [CORE] On admission, which finding best supports the nurse's concern that Ms. Bouchard's hepatic encephalopathy is worsening?

a. A soft, nontender abdomen with active bowel sounds in all four quadrants

b. Yellow sclerae that her daughter says have looked the same to her for several months now

c. A flapping movement of the hands when she holds her arms out with wrists bent back

d. A capillary blood glucose of 7.8 mmol/L taken one hour after she ate breakfast

Answer: c — Asterixis, a flapping of the outstretched hands caused by brief loss of muscle tone, appears at West Haven grade II and with day-night reversal signals overt HE (section 26.3, Hepatic Encephalopathy). A soft abdomen with bowel sounds is a normal finding. Long-standing scleral jaundice reflects her liver disease but does not show a change in brain function. A glucose of 7.8 mmol/L after a meal is not low; hypoglycemia, not this value, can mimic HE.

2. [CORE] The nurse looks for a trigger for Ms. Bouchard's encephalopathy. Which finding is most likely the trigger?

a. Only one hard bowel movement in the past two days since she reduced her lactulose

b. A serum sodium of 138 mmol/L on the admission blood work drawn this morning

c. A temperature of 36.8 °C, clear lungs on auscultation in all lobes, and no new cough

d. A potassium of 4.2 mmol/L with no change from her clinic visit last month

Answer: a — Constipation lets ammonia build up in the gut and is a common trigger of HE; cutting back lactulose explains it (section 26.3, Hepatic Encephalopathy). A sodium of 138 mmol/L and a potassium of 4.2 mmol/L are within usual ranges, so they do not point to an electrolyte trigger. A normal temperature and clear lungs make infection less likely, though the nurse still watches for it.

3. [CORE] On day 2, Ms. Bouchard is alert and oriented, and the nurse begins discharge teaching. Which statement shows that she understands her lactulose?

a. "I will take lactulose only on the days when I have not had a bowel movement."

b. "I will take it every day and aim for two or three soft bowel movements a day."

c. "If I have more than one soft stool, I will stop it until I feel constipated."

d. "I will add a stimulant laxative at bedtime every night to make sure the lactulose works."

Answer: b — Lactulose is taken daily and titrated to two to three soft bowel movements a day to prevent HE from returning (section 26.3, Patient Education box). Taking it only when constipated allows ammonia to build up again. Stopping it after one soft stool undertreats her. Other laxatives are avoided unless prescribed, because loose stools could hide whether the lactulose dose is right.

4. [CORE] That evening, Ms. Bouchard is hard to rouse, responds only to a loud voice and has vomited once. The RPN caring for her is due to give her oral lactulose. What is the RPN's priority?

a. Give the lactulose with a small amount of juice so she can swallow it more easily

b. Document the change and recheck her level of consciousness at the next scheduled round

c. Wake her fully with a cool cloth and then offer the lactulose and fluids by mouth

d. Hold the oral dose, turn her onto her side, and get help from the RN and team now

Answer: d — A patient who is hard to rouse and vomiting cannot protect her airway, so oral lactulose risks aspiration; positioning her on her side and escalating at once are the priorities (section 26.3, Hepatic Encephalopathy; Chapter 6). Any nurse who notices deterioration acts and escalates, and the RPN consults the RN as the patient's needs change. Giving the dose orally, with or without juice or after rousing her, ignores the aspiration risk. Waiting until the next round delays care for a patient who may need critical care.

5. [CORE] Which laboratory result best reflects the liver's ability to make proteins?

a. Alanine aminotransferase (ALT) activity

b. International normalized ratio (INR)

c. Gamma-glutamyl transferase (GGT)

d. Aspartate aminotransferase (AST)

Answer: b — The INR depends on clotting factors that the liver makes, so it reflects the liver's synthetic function and changes faster than albumin (section 26.1, Liver Tests the Nurse Sees). ALT and AST are enzymes released when liver cells are injured; they show injury, not function. GGT rises with blocked bile flow and helps show that a raised ALP comes from the liver.

6. [CORE] The nurse assesses a patient with dark skin for jaundice. Which approach is best?

a. Inspect the skin of the forearms under the room's overhead fluorescent lights

b. Press on the nail beds and watch how long the colour takes to return

c. Rely on the bilirubin result, because jaundice cannot be seen on dark skin

d. Inspect the sclerae and the hard palate in natural or indirect light

Answer: d — Jaundice is harder to see on darker skin, so the nurse looks at the sclerae and inside the mouth, especially the hard palate, in natural or indirect light (section 26.1, Jaundice). Fluorescent light casts a bluish tint and can hide true colour, and the forearms are a poor site. Capillary refill tests circulation, not bilirubin. Jaundice can be seen on any skin tone when the right sites and light are used; the blood test confirms it but does not replace assessment.

7. [CORE] A restaurant worker is diagnosed with acute hepatitis A. Which teaching is accurate?

a. Careful hand hygiene after using the toilet helps prevent spread to others

b. The infection often becomes chronic, so lifelong blood tests will be needed

c. The virus spreads mainly through sexual contact and shared drug equipment

d. Antiviral tablets taken for 8 to 12 weeks will cure the infection completely

Answer: a — Hepatitis A spreads by the fecal-oral route, so hand hygiene is central to preventing spread (section 26.2, Hepatitis A, B and C). Hepatitis A never becomes chronic. Spread by sex and shared drug equipment describes hepatitis B and C. Hepatitis A is treated with supportive care; direct-acting antivirals are for hepatitis C.

8. [CORE] A patient's anti-HCV (hepatitis C antibody) test is positive. What does the nurse explain?

a. The result proves that the patient has a current infection that needs treatment

b. The result shows that the patient is immune because of an earlier vaccination

c. A second test for HCV RNA is needed to show whether the virus is still present

d. The patient should repeat the same antibody test in one year to confirm it

Answer: c — A positive antibody test shows current or past infection; because some people clear the virus, an HCV RNA test confirms whether infection is current (section 26.2, Hepatitis A, B and C). There is no hepatitis C vaccine. Repeating the antibody test does not help, because antibodies stay positive after the virus clears.

9. [CORE] Which statement about hepatitis B in Canada is accurate?

a. Adults who are infected usually develop lifelong chronic infection

b. The 2025 CASL and AMMI Canada guideline recommends screening all adults once

c. Antiviral tablets cure chronic hepatitis B in 8 to 12 weeks in most people

d. Hepatitis B spreads mainly through contaminated food and water in Canada

Answer: b — The 2025 CASL and AMMI Canada guideline recommends one-time screening of all adults with HBsAg, anti-HBs and anti-HBc (section 26.2, Hepatitis A, B and C). Only 3% to 10% of infected adults develop chronic infection; infants are at far higher risk. Antivirals control the virus over the long term rather than curing it in weeks. Food and water spread hepatitis A, not hepatitis B.

10. [CORE] A patient with type 2 diabetes is told that she has MASLD. Which goal is most appropriate to discuss?

a. Avoiding all dietary fat until her next liver ultrasound

b. Stopping her statin, because statins are harmful in MASLD

c. Following a low-protein diet to reduce strain on her liver

d. Losing at least 5% to 10% of her body weight over time

Answer: d — Sustained weight loss of at least 5% to 10% is recommended for MASLD, with more than 10% preferred to reverse fibrosis, along with regular exercise (section 26.2, Metabolic Dysfunction-Associated Steatotic Liver Disease). Cutting out all fat is not the recommended approach. Diabetes Canada advises continuing statins unless cirrhosis becomes decompensated. Protein restriction is not advised in liver disease.

11. [CORE] The nurse cares for a patient with cirrhosis and ascites. Which actions are appropriate? Select all that apply.

a. Weigh the patient daily on the same scale

b. Measure abdominal girth at a marked site

c. Restrict fluid to 1 L a day for every patient with ascites

d. Offer ibuprofen for back discomfort from the tense abdomen

e. Track intake and output and watch sodium and creatinine

f. Encourage salty broth to replace salt lost through diuretics

Answer: a, b, e — Daily weights, girth at a marked site, and intake, output and laboratory monitoring track ascites and diuretic effects (section 26.3, Ascites and Spontaneous Bacterial Peritonitis). Fluid is restricted only when serum sodium becomes very low, at about 125 mmol/L or below. NSAIDs such as ibuprofen are avoided because they can cause low sodium, diuretic resistance and kidney injury. Salty broth works against the sodium restriction of about 2 g a day.

12. [CORE] A patient with cirrhosis and ascites develops a temperature of 38.1 °C, mild diffuse abdominal tenderness and new forgetfulness. What should the nurse suspect and do?

a. Spontaneous bacterial peritonitis; report promptly and prepare for a diagnostic paracentesis

b. Normal discomfort after a meal; offer a heating pad and reassess the abdomen again in four hours

c. Dehydration from diuretics; encourage oral fluids and recheck the temperature at bedtime

d. Constipation from reduced activity; give an extra dose of lactulose and document it

Answer: a — Fever, abdominal tenderness and new confusion in a patient with ascites suggest spontaneous bacterial peritonitis, which needs prompt reporting, a diagnostic paracentesis and IV antibiotics (section 26.3, Ascites and Spontaneous Bacterial Peritonitis). Fever and confusion are not normal after meals. Dehydration does not explain fever with abdominal tenderness. Changing lactulose without an order and without looking for infection delays treatment.

13. [CORE] A patient with cirrhosis suddenly vomits a large amount of bright red blood. What is the nurse's first action?

a. Insert a nasogastric tube to drain the stomach and measure the blood loss

b. Give the next scheduled dose of the nonselective beta-blocker by mouth

c. Turn the patient onto the side and call for help through rapid response

d. Ask the patient to describe when the bleeding started and how it felt

Answer: c — Protecting the airway by turning the patient to the side and calling for help at once come first in a variceal bleed (section 26.3, Varices and Variceal Bleeding). Inserting a tube is not a first action and may injure varices. Oral drugs are unsafe while the patient is vomiting blood. History can wait until the airway is protected and the team is coming.

14. [CORE] An RPN on a medical unit cares for a patient with cirrhosis who was stable. At 0300, the patient has black, tarry stool, a heart rate of 118 beats per minute and new restlessness. What should the RPN do?

a. Finish the rest of the assessment round, then report all findings to the RN in the morning

b. Act at once to stay with the patient, escalate per policy and consult the RN immediately

c. Ask the unregulated care provider to recheck the vital signs in an hour and report back

d. Call the patient's family to ask whether this has happened before during earlier stays

Answer: b — Melena, a rising heart rate and restlessness suggest GI bleeding with deterioration; every nurse who notices this acts at once and escalates, and the RPN consults the RN because the patient's needs have changed (section 26.3, Varices and Variceal Bleeding; Chapter 1, section 1.3). Waiting until morning or an hour delays care. Calling the family does not address the emergency.

15. [CORE] An RPN's patient with cirrhosis now has grade III hepatic encephalopathy, needs frequent neurological checks and may need transfer to critical care. Which response best reflects CNO's scope framework?

a. The RPN keeps the patient because RPNs may care only for stable, predictable patients

b. The RPN must transfer care at once because CNO bans RPNs from neurological checks

c. The RPN keeps the patient without discussion because the assignment is already set

d. The RPN consults the RN about authority, competence and context, including unit policy

Answer: d — CNO's Scope of Practice standard uses authority, competence and context (College of Nurses of Ontario, 2025); as the patient's needs change, the RPN consults the RN, and they decide together who is best placed to provide care, within employer policy (section 26.3; Chapter 1, section 1.3). Assigning RPNs to stable patients is a common employer practice, not a CNO rule. CNO does not ban RPNs from neurological checks. Keeping the assignment without discussion ignores the change in the patient's needs.

16. [CORE] A patient asks why rifaximin was added to the lactulose he takes for hepatic encephalopathy. What is the best response?

a. "Rifaximin is added to lactulose to lower the chance that confusion comes back."

b. "Rifaximin replaces lactulose, so you can stop the lactulose when you go home."

c. "Rifaximin treats the scarring in your liver and will slowly reverse your cirrhosis over time."

d. "Rifaximin is a sedative that will help you sleep through the night again."

Answer: a — Rifaximin is an antibiotic that stays mostly in the gut and is added to lactulose to prevent overt HE from coming back (section 26.3, Hepatic Encephalopathy). It does not replace lactulose. It does not reverse cirrhosis. It is not a sedative, and sedatives can worsen HE.

17. [CORE] A patient with compensated cirrhosis asks what to take for a headache. Which response is best?

a. "Ibuprofen is the safest choice, because it is not processed by the liver."

b. "Take any cold remedy you like, since these do not contain pain relievers."

c. "Avoid ibuprofen and naproxen, and ask your prescriber how much acetaminophen is safe."

d. "Take extra-strength acetaminophen as often as you need to until the headache has completely gone."

Answer: c — NSAIDs are avoided in cirrhosis, and people with liver disease may need a lower acetaminophen limit than the label states, so the patient checks with the prescriber or pharmacist (section 26.3, Living With Cirrhosis; Chapter 5). Ibuprofen can cause kidney injury and fluid retention in cirrhosis. Many cold remedies contain acetaminophen. Taking acetaminophen as often as needed risks liver injury.

18. [RN] A patient has jaundice, dark urine and pale stools. Results: ALT 95 U/L, ALP 620 U/L, GGT 540 U/L and a raised conjugated bilirubin. Which interpretation is most accurate?

a. A hepatocellular pattern that suggests acute viral hepatitis or acetaminophen injury

b. A cholestatic pattern that suggests blocked bile flow, such as a stone in the bile duct

c. A prehepatic pattern caused by rapid breakdown of red blood cells in the circulation

d. A normal pattern for an older adult that needs no further assessment or follow-up

Answer: b — ALP far above ALT, with a raised GGT confirming a liver source and a raised conjugated bilirubin, is a cholestatic pattern; with dark urine and pale stools, it suggests posthepatic obstruction (section 26.1, Liver Tests the Nurse Sees; Jaundice). A hepatocellular pattern would show ALT and AST raised more than ALP. Hemolysis raises unconjugated bilirubin without this enzyme pattern. These results are abnormal at any age.

19. [RN] A patient with cirrhosis arrives with hematemesis. Hemoglobin is 74 g/L and INR 1.8. Which plan matches Baveno VII?

a. Start a vasoactive drug now, give antibiotic prophylaxis, and plan endoscopy within 12 hours

b. Transfuse red cells until hemoglobin is above 100 g/L, then plan endoscopy within 72 hours

c. Give fresh frozen plasma first to bring the INR back to normal before any other treatment is started

d. Withhold antibiotics until a fever develops, to avoid antibiotic resistance on the unit

Answer: a — Baveno VII calls for a vasoactive drug as soon as possible, antibiotic prophylaxis and endoscopy within 12 hours (section 26.3, Varices and Variceal Bleeding). Transfusion is restrictive, targeting hemoglobin of 70 to 80 g/L, so transfusing to above 100 g/L goes against the guidance, and 72 hours is too late for endoscopy. Fresh frozen plasma is not recommended, because it does not correct the clotting problem. Antibiotics are part of treatment, not reserved for fever.

20. [RN] A patient with cirrhosis and ascites has a creatinine that rose from 88 to 150 µmol/L over 48 hours, with falling urine output, no shock and no nephrotoxic drugs. Which statement is accurate?

a. The rise is expected with ascites and needs no change in the plan of care

b. Diuretics should be increased to clear the ascites and restore urine output

c. The rise in creatinine raises the MELD score and signals higher 3-month mortality risk

d. MELD is calculated from albumin and the amount of ascites, so creatinine does not change the score

Answer: c — Creatinine is part of the MELD score, which predicts 3-month mortality; this picture fits hepatorenal syndrome, which calls for stopping diuretics, albumin with a vasoconstrictor and urgent transplant assessment (section 26.3, Going Deeper box). A creatinine rise of this size is acute kidney injury and is never expected. Increasing diuretics worsens kidney perfusion. MELD uses bilirubin, creatinine and INR, not albumin and ascites.

Case: Lorraine Bouchard (Questions 21–26): Lorraine Bouchard, 62, was admitted to a surgical unit at 0400 with epigastric pain that began 10 hours earlier after a large meal, spreads to her back and has caused vomiting four times; ultrasound shows gallstones with a common bile duct of normal size; her lipase is 2,400 U/L (laboratory upper limit 60 U/L) and her weight is 70 kg; at 0800 her temperature was 37.6 °C, heart rate 104, blood pressure 124/72 mm Hg, respiratory rate 20 and SpO_2 96% on room air, and at 1200 her temperature is 37.6 °C, heart rate 118, blood pressure 104/64 mm Hg, respiratory rate 22, SpO_2 95% on room air, urine output 60 mL over the past 4 hours, blood urea 9.8 mmol/L (7.1 mmol/L at 0400), creatinine 118 µmol/L (82 µmol/L at 0400) and total bilirubin 19 µmol/L.

21. [CORE] At 1200, which findings require immediate follow-up by the nurse? Select all that apply.

a. Heart rate of 118, up from 104 at 0800

b. Lipase of 2,400 U/L with a laboratory upper limit of 60 U/L

c. Urine output of 60 mL over the past 4 hours

d. Blood pressure of 104/64 mm Hg, down from 124/72 mm Hg at 0800

e. Temperature of 37.6 °C, unchanged since 0800

f. Blood urea of 9.8 mmol/L, up from 7.1 mmol/L at 0400

g. Gallstones on ultrasound with a common bile duct of normal size

Answer: a, c, d, f — A rising heart rate (a), a falling blood pressure (d), low urine output (c) and a rising urea (f) are cues of falling blood volume and reduced kidney perfusion. The ACG guideline aims for a falling, not rising, urea in the first 24 to 48 hours (section 26.6). The lipase level (b) confirms the diagnosis that has already been made; it does not call for new action now. A stable temperature of 37.6 °C (e) is not the urgent problem. The ultrasound result (g) explains the cause and shows no dilated duct; it does not need immediate follow-up.

22. [CORE] Which interpretation best fits Ms. Bouchard's findings at 1200?

a. Loss of fluid from the circulation, with early signs of reduced blood flow to her kidneys

b. Acute cholangitis from a stone lodged in the common bile duct, causing sepsis and a falling blood pressure

c. Urinary retention from opioid analgesia, causing low urine output and a rise in heart rate from discomfort

d. Fluid overload from the IV fluids she received in the emergency department, which is now straining her heart and lowering her blood pressure

Answer: a — Inflammation makes capillaries leak, and vomiting adds to the loss, so blood volume falls; the rising heart rate, falling blood pressure, low urine output and rising urea and creatinine fit this picture (section 26.6). Cholangitis (b) is unlikely with a normal-sized duct, no fever and a normal bilirubin (section 26.5). Urinary retention (c) would not explain the rising urea, creatinine and falling blood pressure, although a bladder scan is reasonable. Fluid overload (d) would show breathlessness, crackles and falling oxygen saturation, which she does not have.

23. [CORE] Which problem should the nurse address first?

a. Acute pain related to inflammation of the pancreas

b. Risk of malnutrition because she has vomited and is not eating

c. Hypovolemia that could progress to organ failure

d. Need for teaching about gallstones and a low-fat diet

Answer: c — Hypovolemia threatens perfusion of the kidneys and other organs and can progress to organ failure, which defines severe disease, so it comes first (section 26.6). Pain (a) is a high priority and is treated at the same time, but it is not the life-threatening problem. Nutrition (b) matters, and early feeding is planned once she can tolerate it. Teaching (d) belongs later in her stay.

24. [CORE] The physician reviews Ms. Bouchard at 1215. Which plan should the nurse expect?

a. A fixed 4 L of normal saline over the next 2 hours, with no further assessment until the morning blood work

b. Strict NPO for at least 5 days with clear fluids only after the lipase level returns to normal

c. IV antibiotics started now to prevent infected necrosis, and an ERCP this afternoon to clear stones from the common bile duct

d. A lactated Ringer's bolus, then a continuous infusion, with reassessment of vital signs, urine output and urea within hours

Answer: d — The ACG guideline suggests moderately aggressive fluids with boluses for hypovolemia, prefers lactated Ringer's, and calls for reassessment within 6 hours and over the next 24 to 48 hours (section 26.6). A large fixed volume without reassessment (a) risks fluid overload, which a large trial linked to aggressive fluids. Prolonged NPO (b) is no longer standard; early oral feeding is suggested in mild disease. Prophylactic antibiotics (c) are not recommended, and early ERCP is reserved for patients with cholangitis.

25. [CORE] On day 2, after several fluid boluses, Ms. Bouchard says she cannot catch her breath. Her respiratory rate is 28, SpO_2 89% on room air and heart rate 110. Crackles are heard at both lung bases, and her weight is 3 kg above her admission weight. What should the nurse do first?

a. Increase the IV rate, because a heart rate of 110 shows she still needs more fluid

b. Raise the head of the bed, apply oxygen as ordered and call the physician or rapid response team at once

c. Give her next ordered dose of opioid analgesic, because pain is making her breathe quickly

d. Encourage her to use the incentive spirometer every hour and recheck her oxygen saturation at the next scheduled vital signs

Answer: b — New breathlessness, crackles, low oxygen saturation and weight gain after boluses suggest fluid overload or a lung complication of pancreatitis. Both can mean respiratory organ failure, so the nurse supports breathing and escalates at once (section 26.6; Chapter 6). Increasing fluids (a) could worsen overload. An opioid (c) may slow breathing and does not treat the cause. Waiting for the next check (d) delays care for a patient with an SpO_2 of 89%.

26. [CORE] On day 4, the nurse evaluates Ms. Bouchard's response to care. Which set of findings best shows that her plan is meeting its goals?

a. Urea 6.0 mmol/L, hematocrit unchanged, respiratory rate 18, SpO_2 95% on room air, tolerating a low-fat solid diet

b. Lipase down to 300 U/L and pain well controlled with oral analgesia, but urea 11.4 mmol/L and hematocrit higher than on admission

c. Weight 4 kg above admission with crackles at both bases, IV fluids running at the day 1 rate, eating well

d. Urine output 15 mL/hour for 6 hours, SpO_2 93% on 2 L of oxygen, blood pressure 96/58 mm Hg, nausea settled

Answer: a — A falling urea and a hematocrit that is not rising are the guideline's markers that fluid therapy is working. Normal breathing on room air and tolerance of a low-fat solid diet show recovery (section 26.6). A falling lipase (b) does not show adequate fluid therapy, and the rising urea and hematocrit show that it is not working. Weight gain with crackles (c) shows fluid overload. Low urine output, a new oxygen need and low blood pressure (d) suggest ongoing organ dysfunction.

27. [CORE] A nurse is admitting a patient with alcohol-associated hepatitis. Which statement by the nurse best reflects non-judgmental, person-centred care?

a. "You need to understand that your drinking caused this, and you will die if you don't stop."

b. "Can you tell me about your alcohol use, so we can plan your care and the supports you would find helpful?"

c. "As an alcoholic, you should expect to be watched closely for withdrawal while you are here."

d. "We can't offer you much treatment for your liver until you have shown us that you can stay sober for several months."

Answer: b — An open, respectful question invites an honest history and partnership, and it fits the guideline's call for screening and brief intervention at every visit (section 26.4; Chapter 11). Threats and blame (a) increase shame and make honest talk less likely. Labelling a person an "alcoholic" (c) is stigmatizing; person-first language is used. Treatment is not withheld until sobriety is proven (d); stopping alcohol is a central goal, but care, including nutrition and treatment of severe disease, starts at once.

28. [CORE] A patient arrives in the emergency department and says she took "a lot of extra-strength acetaminophen" sometime yesterday but cannot say when. She feels well. Which statement about N-acetylcysteine is accurate?

a. It is not given, because the time of ingestion is unknown and a level cannot be interpreted

b. It is given only if her liver tests are already abnormal when they return from the laboratory

c. It is not useful once more than 24 hours have passed since the overdose was taken

d. It is given whenever acetaminophen overdose is suspected, even if the timing is unknown

Answer: d — Acute liver failure guidance recommends N-acetylcysteine for anyone who may have taken an acetaminophen overdose, even when the timing is unknown or the level is low, and notes that it can still be of value 2 days or more after ingestion (section 26.4). An unknown time (a) is a reason to give it, not to withhold it. Waiting for abnormal liver tests (b) delays an antidote that works best early. It can still help after 24 hours (c).

29. [CORE] A patient with acute liver failure from a drug reaction has become more confused over the past hour. Which assessment should the nurse complete first?

a. Check the INR result from this morning's blood work

b. Measure urine output for the last 4 hours

c. Check the capillary blood glucose

d. Weigh the patient to compare with yesterday

Answer: c — Hypoglycemia is common in acute liver failure and can be hidden by or mistaken for worsening encephalopathy. A glucose check is quick and the result is treatable at once (section 26.4). The INR (a) tracks liver function but does not explain a change in the last hour. Urine output (b) and weight (d) matter for kidney function and fluid balance but are not the first check for new confusion.

30. [CORE] Which statement by a patient preparing for discharge after a liver transplant shows that teaching has been effective?

a. "If I feel well, my anti-rejection pills are working, so a missed blood test doesn't matter."

b. "I can stop my anti-rejection medicine for a few days if my stomach is upset."

c. "I'll ask my pharmacist whether a cold remedy is safe, but I won't tell the transplant team."

d. "I'll call the transplant team if my eyes look yellow or I develop a fever."

Answer: d — Jaundice and fever can signal rejection or infection and need prompt reporting (section 26.4). Rejection may cause no symptoms and show only in blood work, so scheduled tests matter (a). Anti-rejection drugs are never stopped without the team's direction (b). The transplant team must know about any new prescription, over-the-counter or herbal product (c), because drug interactions can change immunosuppressant levels.

31. [CORE] An RPN is caring for a patient with cirrhosis who had 6 L of ascitic fluid removed 2 hours ago. The patient's blood pressure has dropped from 118/70 to 92/54 mm Hg, and he is newly drowsy. What should the RPN do?

a. Document the findings and recheck the vital signs in 1 hour, since some drop is expected after paracentesis

b. Assess the patient further, report the change to the RN and physician at once, and stay with the patient

c. Start the albumin infusion that is due to be given tomorrow, since albumin helps prevent this problem

d. Give the patient's scheduled diuretic and encourage oral fluids to raise his blood pressure

Answer: b — A falling blood pressure with new drowsiness after large-volume paracentesis is a change in condition. Every nurse acts at once and escalates, and the RPN consults the RN as the patient's needs change (section 26.3, Scope in Practice box; Chapter 6). Waiting an hour (a) delays care for a deteriorating patient. Giving a drug outside its order (c) is beyond the nurse's authority; albumin needs an order for the dose and time. A diuretic (d) would further lower his blood volume.

32. [CORE] A patient with RUQ pain is being assessed for acute cholecystitis. The physician presses under the right rib margin and asks the patient to breathe in deeply. The patient stops breathing in mid-breath because of pain. How should the nurse record this finding?

a. Positive Grey Turner sign

b. Positive Cullen sign

c. Charcot triad

d. Positive Murphy sign

Answer: d — A Murphy sign is the sudden stop in breathing in when the examiner presses over the gallbladder, a local sign of cholecystitis (section 26.5). The Grey Turner sign (a) and the Cullen sign (b) are bruising of the flanks and around the umbilicus from retroperitoneal bleeding (section 26.6). The Charcot triad (c) is fever, jaundice and abdominal pain in cholangitis.

33. [CORE] The day after a laparoscopic cholecystectomy, a patient calls the surgical unit worried about pain in her right shoulder. She has no fever, and her incisions look clean. What should the nurse explain?

a. Shoulder pain after this surgery usually means a stone has moved into the bile duct

b. She should go to the emergency department now, because shoulder pain signals bleeding

c. Gas used to inflate the abdomen often causes shoulder pain; lying flat and warmth to the shoulders may help

d. Shoulder pain shows that the incisions are infected, so she should begin applying warm, moist compresses directly to them

Answer: c — Carbon dioxide used during laparoscopy commonly causes shoulder or neck discomfort for about 48 hours; lying flat and warmth to the shoulders may help (section 26.5). A duct stone (a) causes worsening abdominal pain, jaundice or dark urine. Shoulder pain alone, without fever, worsening abdominal pain or other warning signs, does not mean bleeding (b). Incision infection (d) shows as redness, pus or drainage at the incisions.

34. [CORE] A patient admitted 2 days ago with biliary colic now has a temperature of 39.0 °C, yellow sclerae and abdominal pain. Her blood pressure is 94/56 mm Hg, down from 132/80 mm Hg. What is the nurse's priority?

a. Give acetaminophen for the fever and reassess her temperature in 1 hour

b. Escalate at once for suspected cholangitis with sepsis, and prepare for cultures, fluids and antibiotics

c. Check her sclerae again at the next shift to confirm that the jaundice is real

d. Encourage oral fluids and ask the dietitian to review her low-fat diet

Answer: b — Fever, jaundice and pain with a falling blood pressure suggest acute cholangitis with sepsis, which needs urgent escalation, antibiotics and drainage of the duct (section 26.5; Chapter 4; Chapter 6). Treating the fever alone (a) and waiting a shift (c) delay care for a deteriorating patient. Oral fluids and a diet review (d) do not address the cause, and she may need to be NPO for ERCP.

35. [CORE] Three hours after an ERCP with stone removal, a patient reports new, steady epigastric pain spreading to his back and has vomited once. What should the nurse suspect first?

a. Post-ERCP pancreatitis

b. A normal reaction to the sedation used during the procedure

c. Retained air from the procedure, which will pass without treatment

d. Biliary colic from a new stone forming in the gallbladder

Answer: a — Post-ERCP pancreatitis is the most common serious complication of ERCP, and new or worse abdominal pain is the key cue; the nurse assesses, keeps the patient NPO until assessed and reports promptly (section 26.5). Sedation (b) causes drowsiness or low oxygen levels, not new epigastric pain spreading to the back. Assuming the pain is harmless air (c) could miss pancreatitis or perforation. A new stone (d) does not form within hours.

36. [CORE] A patient with chronic pancreatitis is starting pancreatic enzyme replacement therapy. Which instruction should the nurse include?

a. Take the capsules at bedtime so the enzymes work overnight while the bowel is resting

b. Crush the capsules into a drink if they are hard to swallow, so the enzymes start working sooner

c. Take extra capsules whenever abdominal pain flares, because the enzymes calm the pancreas

d. Take the capsules during or right after meals and snacks, and swallow them whole with fluid

Answer: d — The Canadian monograph directs patients to take the enzymes during or right after meals and snacks and to swallow capsules whole with fluid (section 26.6). Bedtime dosing (a) misses the food the enzymes must digest. Crushing (b) damages the enteric coating, so the enzymes are released too early, and it can irritate the mouth; if swallowing is hard, the capsule can be opened and the granules sprinkled on acidic soft food such as applesauce. Enzymes are not a treatment for pain (c).

37. [CORE] The nurse is teaching a patient going home the day after a laparoscopic cholecystectomy. Which findings should the patient report to the surgeon or the emergency department? Select all that apply.

a. Yellow eyes or skin, with dark urine

b. Mild bloating on the first day after surgery

c. Abdominal pain that is getting worse instead of better

d. Nausea and vomiting lasting more than 24 hours

e. Shoulder discomfort that eases when lying flat

f. Pus or foul-smelling drainage from an incision

g. Persistent fever or chills

Answer: a, c, d, f, g — Jaundice with dark urine (a), worsening abdominal pain (c), vomiting beyond 24 hours (d), wound infection (f) and persistent fever (g) can signal a complication such as bleeding or infection, and need prompt review (section 26.5). Mild bloating on the first day (b) and shoulder discomfort from the gas used in surgery (e) are common and expected.

38. [RN] A patient with acute pancreatitis developed respiratory failure on admission that resolved after 30 hours of oxygen therapy. CT on day 5 shows an acute peripancreatic fluid collection. She has no other organ failure. How is her pancreatitis classified under the revised Atlanta classification?

a. Mild, because the respiratory failure has resolved and she is now improving

b. Severe, because she had organ failure and has a local complication

c. Moderately severe, because organ failure resolved within 48 hours and a local complication is present

d. It cannot be classified until the fluid collection has been drained

Answer: c — Moderately severe disease is defined by organ failure that clears within 48 hours, local or systemic complications, or both, without persistent organ failure (section 26.6, Table 26.3). Mild disease (a) has no organ failure and no complications. Severe disease (b) requires organ failure lasting longer than 48 hours. The classification does not depend on drainage (d).

39. [RN] An RN is caring for a 78-year-old patient with heart failure and acute pancreatitis who is receiving IV lactated Ringer's. Which finding should most concern the RN about the fluid plan?

a. Blood urea falling from 10.2 to 8.1 mmol/L over 12 hours

b. New crackles at both lung bases with a 2 kg weight gain since admission

c. Hematocrit unchanged from admission at 12 hours

d. Heart rate falling from 112 to 96 after the first bolus

Answer: b — New crackles and weight gain suggest fluid overload, the main risk of aggressive fluids. Patients with heart or kidney disease need the closest watch (section 26.6, Going Deeper box). A falling urea (a), an unchanged hematocrit (c) and a slowing heart rate (d) all suggest that fluids are restoring circulating volume as intended.

40. [RN] A patient is admitted to a community hospital with acute liver failure after an acetaminophen overdose. She is now mildly confused (grade 1 encephalopathy), and her INR is 2.8. Which action should the RN anticipate as the priority?

a. Early contact with the liver transplant centre and transfer to intensive care while she can still travel safely

b. Routine plasma transfusion to bring the INR below 1.5 before any other treatment

c. A sedative at bedtime so she can rest, with neurological checks every 8 hours

d. Holding N-acetylcysteine until her acetaminophen level can be compared with the time of ingestion

Answer: a — Any encephalopathy in acute liver failure calls for ICU care and early contact with a transplant centre. Transfer is advised even at grades 1 and 2, because deterioration can make transport unsafe later (section 26.4). Plasma (b) is kept for bleeding or procedures, because routine use hides the INR trend. Sedatives (c) are avoided, and neurological checks are frequent. N-acetylcysteine (d) is given whenever acetaminophen overdose is suspected, without waiting for timing.

VII Renal, Urologic & Reproductive Health Care

UNIT CLINICAL SCOPE & INTEGRATION

Grounds renal, urologic, and reproductive nursing in Canadian nephrology and SOGC guidance, spanning acute kidney injury (AKI), chronic kidney disease (CKD), hemodialysis and peritoneal dialysis access and exchanges, urinary tract infections, urolithiasis, benign prostatic hyperplasia (BPH), continuous bladder irrigation, and adult breast and reproductive health.

Contents of UNIT VII

Chapter	Chapter Title	Visual Assets	Page
Chapter 27	Acute Kidney Injury and Chronic Kidney Disease	6 Figs • 3 Tbls	p. 791
Chapter 28	Urinary Tract and Prostate Disorders	5 Figs • 4 Tbls	p. 822
Chapter 29	Reproductive and Breast Health in Adult Care	6 Figs • 3 Tbls	p. 852

27 Acute Kidney Injury and Chronic Kidney Disease

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain kidney function and interpret creatinine, eGFR, urea, urine albumin-to-creatinine ratio, urinalysis and urine output in SI units.
2. Recognize and stage acute kidney injury, identify its causes, and provide nursing care and escalation using the CJMM.
3. Describe chronic kidney disease staging and complications, and support measures that slow progression, including medication safety and diet.
4. Care for patients receiving hemodialysis and peritoneal dialysis, including vascular access protection and recognition of peritonitis.
5. Support patients before and after kidney transplant, and discuss conservative kidney management and advance care planning.
6. Describe kidney health in First Nations, Inuit and Métis communities and remote Canada with a distinctions-based, strengths-based lens.
7. Distinguish RN and RPN roles in kidney and dialysis care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4	Clinician; Scholar	Foundations of Practice
3, 5, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Collaborator	Legal Practice; Collaborative Practice

Introduction

Healthy kidneys do their work without being noticed. They clear wastes, balance water and salts, and help control blood pressure, red cell production and bone health. When they fail, every one of these jobs slips at once. Kidney disease is common in Canada. The Kidney Foundation of Canada reports that chronic kidney disease affects 1 in 10 Canadians, and that the number of people in Canada with it is projected to grow from 4.5 million in 2024 to more than 6.2 million by 2050 (Kidney Foundation of Canada, 2025). In 2024, more than 50,000 people in Canada had end-stage kidney disease (kidney failure), and 30,213 of them were on dialysis (Canadian Institute for Health Information [CIHI], 2025b).

Sudden loss of kidney function is just as common in acute care. In a study of two emergency departments in Vancouver, 10.7% of patients whose creatinine was measured had acute kidney injury, and their median age was 74 (Scheuermeyer et al., 2017). Nurses on every unit care for these patients. The nurse is often the first to notice a urine output that is falling, a weight that is climbing or a medication that should be questioned.

This chapter starts with what the kidneys do and how kidney tests are read in SI units (section 27.1). It then covers acute kidney injury (27.2) and chronic kidney disease (27.3). The second half turns to dialysis and vascular access (27.4), kidney transplant (27.5), and kidney health in Canada, including First Nations, Inuit and Métis communities and conservative kidney management (27.6).

The chapter builds on earlier ones. Scope of practice and the Clinical Judgment Measurement Model (CJMM) are taught in Chapter 1. Fluids, potassium, calcium, phosphate and acid–base balance, including emergency care for high potassium, are in Chapter 3. Sepsis is in Chapter 4, and recognizing deterioration in Chapter 6. Anemia is covered in section 20.2, and diabetes and sick-day medication guidance in Chapter 22. Urinary tract infection, urinary retention and catheters are in Chapter 28.

27.1 Kidney Function and Kidney Tests

What the Kidneys Do

Each kidney holds about a million tiny filtering units called **nephrons** (Figures 27.1 and 27.2). Each nephron has two parts. The **glomerulus** is a knot of capillaries that filters blood, letting water and small molecules pass while keeping blood cells and most proteins in the bloodstream. The **tubule** then reclaims what the body needs and adds wastes to what will leave as urine (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2018). Almost all of the filtered fluid returns to the blood; only a small fraction becomes urine.

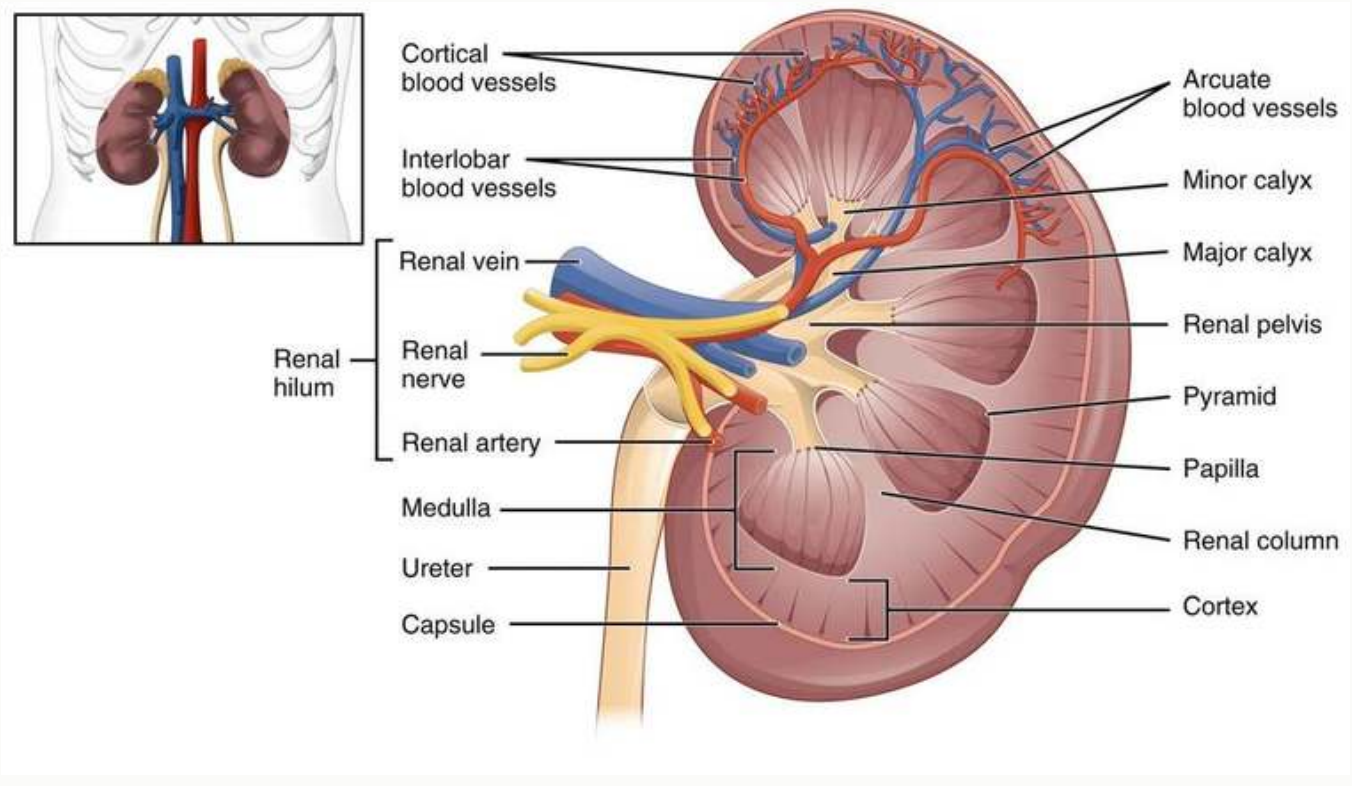

Figure 27.1 A frontal section of the left kidney: the outer cortex, the pyramids of the medulla, and the calyces and renal pelvis that collect urine into the ureter. (credit: Figure 25.8, "Left Kidney," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The **glomerular filtration rate (GFR)** is the volume of blood plasma the glomeruli filter each minute. It is the main measure of kidney function and is reported in millilitres per minute, adjusted to a standard body surface area (mL/min/1.73 m²) (Kidney Disease: Improving Global Outcomes [KDIGO] CKD Work Group, 2024). When the GFR falls, every job the kidneys do is affected:

- **Clearing wastes:** the kidneys remove urea, creatinine, acids and many drugs. When filtration falls, these build up, and drugs cleared by the kidneys can reach toxic levels.
- **Fluid and electrolytes:** the kidneys keep water, sodium, potassium, calcium and phosphate in balance (NIDDK, 2018). Chapter 3 covers these in depth.
- **Acid–base balance:** the kidneys remove the acid that cells produce every day (NIDDK, 2018), so failing kidneys lead to metabolic acidosis (section 3.7).
- **Blood pressure:** by controlling sodium and water and by releasing hormones, the kidneys help set blood pressure (NIDDK, 2018). Chapter 19 covers hypertension.
- **Red blood cells:** the kidneys release erythropoietin, the hormone that drives red cell production (section 20.1). Damaged kidneys make too little, causing anemia.

- **Bone health:** the kidneys make hormones that help keep bones strong (NIDDK, 2018), and they turn vitamin D into its active form, calcitriol, which bones need (NIDDK, 2021).

These links explain why kidney disease causes fluid overload, high potassium, acidosis, anemia and bone disease, the complications described in sections 27.2 and 27.3.

Kidney Tests

Results are reported in SI units. Reference ranges vary by laboratory, so the nurse compares each result with the range printed on the report and, above all, with the patient's own earlier results.

Creatinine is a waste product of normal muscle activity. The glomeruli filter it, so its blood level rises when the GFR falls. Typical adult ranges are about 35 to 88 µmol/L for females and 62 to 106 µmol/L for males (University of Ottawa, 2022). Because creatinine comes from muscle, a frail person with little muscle can have a "normal" creatinine even when kidney function is reduced (KDIGO CKD Work Group, 2024). A rise from the patient's own baseline matters more than a single value.

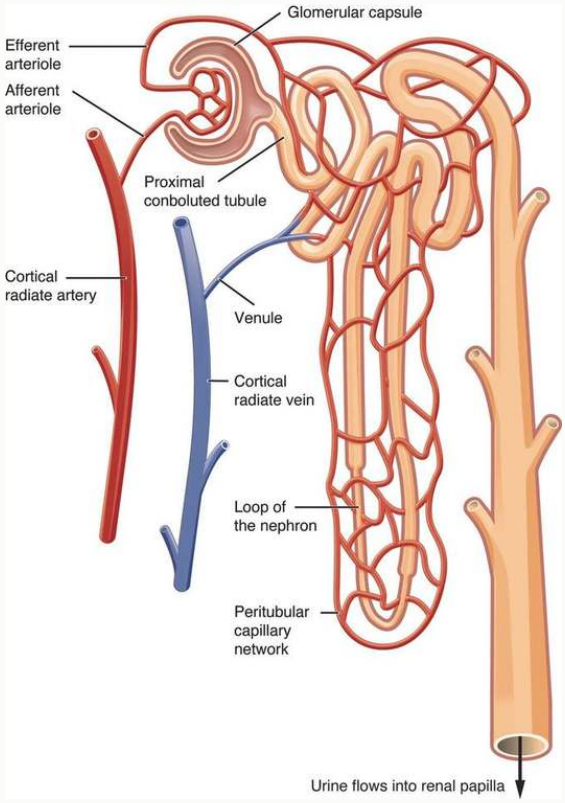

Figure 27.2 A nephron and its blood supply. Blood is filtered in the glomerulus, and the tubule then reclaims water and solutes into the peritubular capillaries; what remains flows on as urine. (credit: Figure 25.10, “Blood Flow in the Nephron,” in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The **estimated glomerular filtration rate (eGFR)** is calculated by the laboratory from serum creatinine, age and sex, and reported in mL/min/1.73 m² beside the creatinine. KDIGO advises using a validated equation, using the same equation across a region, and not using race in the calculation (KDIGO, 2024a; Levin et al., 2024). Canadian laboratories are moving to the 2021 CKD-EPI equation, which has no race term; Alberta Precision Laboratories, for example, began reporting it on January 20, 2026 (Alberta Precision Laboratories, 2026). Chapter 2, section 2.6, explains why the race term was removed.

Urea is a waste product of protein breakdown, with a typical adult range of about 2.5 to 8.0 mmol/L (University of Ottawa, 2022). It rises when filtration falls, and also with dehydration (section 3.2).

The **urine albumin-to-creatinine ratio (ACR)** measures albumin, a protein that healthy glomeruli hold back, in a random urine sample. It is reported in mg/mmol. Albumin in the urine is called **albuminuria**, and it is an early sign of kidney damage, often present while the eGFR is still normal. KDIGO considers an ACR below 3 mg/mmol normal to mildly increased and asks that a raised result be confirmed on repeat testing (Levin et al., 2024). For people with diabetes, Diabetes Canada uses a lower cut-off of 2.0 mg/mmol and diagnoses diabetic kidney disease from albuminuria only when at least two of three ACRs over at least three months are abnormal. Infection, recent exercise, menstruation and very high glucose or blood pressure can raise a single result (Tobe et al., 2025).

A **urinalysis** uses a dipstick (Figure 27.3) to screen for protein, blood, glucose and concentration, and **microscopy** looks for cells and casts in the urine sediment. Persistent blood or abnormal sediment can mark kidney damage (KDIGO CKD Work Group, 2024). Chapter 28 covers urine specimen collection and dipstick testing.

Urine output is the bedside measure of kidney function. KDIGO uses an output below 0.5 mL/kg per hour for 6 hours as one sign of acute kidney injury, and advises measuring both creatinine and urine output in patients at increased risk (KDIGO Acute Kidney Injury Work Group, 2012). To make that judgment, the nurse needs the patient's weight, an accurate start time and every millilitre recorded: urine measured in a graduated container, never estimated, and catheter drainage emptied and recorded on schedule.

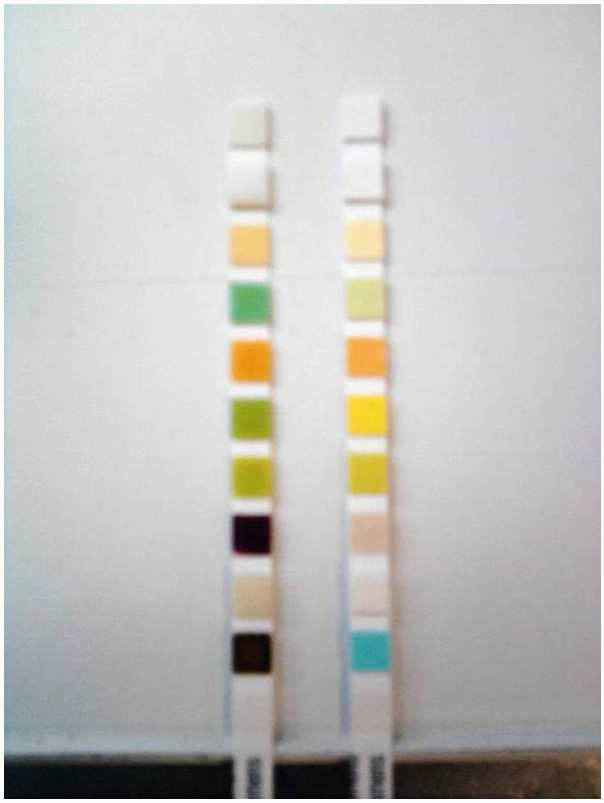

Figure 27.3 Two urine dipsticks: one with colour changes on several pads (left) beside one with little reaction (right). Each pad is compared with the colour chart on the container at the time stated. (credit: "Comp.Urine.Test.Strip" by J3D3/Wikimedia Commons, CC BY-SA 3.0)

Imaging, such as ultrasound, shows kidney size and structure and whether urine flow is blocked; structural abnormalities seen on imaging are one marker of kidney damage (KDIGO CKD Work Group, 2024).

GOING DEEPER

What eGFR Can and Cannot Tell You

Required for RN students; optional for PN students.

The 2021 CKD-EPI equations estimate GFR from creatinine, age and sex without a race term (Inker et al., 2021). An eGFR is still an estimate, and the nurse should know where it misleads.

- **Muscle mass:** creatinine-based eGFR overestimates true GFR in people with sarcopenia, which can lead to drug overdosing (KDIGO CKD Work Group, 2024). Very high muscle mass also makes the estimate less reliable (Tobe et al., 2025).
- **Rapid change:** during acute kidney injury, creatinine is still changing, so a single eGFR can misrepresent kidney function. KDIGO advises adapting drug doses when GFR is not in a steady state, and excluding acute kidney injury before calling a low eGFR chronic (Levin et al., 2024; KDIGO, 2024a).
- **Cystatin C:** this second blood marker is not affected by muscle mass (Parekh et al., 2022). KDIGO recommends an equation using both creatinine and cystatin C when creatinine-based eGFR is less accurate and the result will change care (Levin et al., 2024).
- **Drug dosing:** for most people, creatinine-based eGFR is adequate for dosing drugs cleared by the kidneys. When a drug has a narrow margin between effective and toxic levels, a more accurate measure may be needed (Levin et al., 2024). Some Canadian product monographs still state kidney limits as creatinine clearance, in mL/min (Nora Pharma, 2026), so the pharmacist confirms which measure the monograph uses.

27.2 Acute Kidney Injury

Acute kidney injury (AKI) is a sudden fall in kidney function, over hours to days. KDIGO defines AKI by any one of three findings (KDIGO Acute Kidney Injury Work Group, 2012):

- serum creatinine rises by 26.5 µmol/L or more within 48 hours;
- serum creatinine rises to 1.5 times baseline or more, known or presumed to have happened within the past 7 days;
- urine output stays below 0.5 mL/kg per hour for 6 hours.

Causes

AKI is grouped by where the problem starts (Table 27.1). KDIGO asks that the cause be found whenever possible and warns that labelling every case "prerenal" leads to wrong decisions (KDIGO Acute Kidney Injury Work Group, 2012).

Prerenal AKI means the kidneys are not getting enough blood flow. Causes include bleeding, vomiting, diarrhea, poor intake, low blood pressure, sepsis (Chapter 4) and heart failure (Chapter 18). Some drugs reduce filtration pressure when blood flow is already low. In a large study, people taking a diuretic, an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB), and a nonsteroidal anti-inflammatory drug (NSAID) together had more AKI, with the highest risk in the first 30 days of the combination (Lapi et al., 2013). In that study, an NSAID taken with only one of the other drugs was not linked to more AKI. Even so, a Canadian NSAID monograph lists dehydration, older age, heart failure and existing kidney disease as conditions that raise kidney risk on their own (Nora Pharma, 2026), so the nurse questions an NSAID in any patient who is volume depleted. Prerenal AKI often reverses when blood flow is restored, but if low flow lasts, the kidney tissue itself is injured.

Intrinsic AKI is damage within the kidney. A common form in hospital is **acute tubular injury**, in which tubule cells are harmed by prolonged low blood flow, sepsis or toxins. A **nephrotoxic** substance is one that can damage the kidneys. Examples include NSAIDs and aminoglycoside antibiotics; KDIGO suggests avoiding aminoglycosides when a less nephrotoxic alternative exists and recommends monitoring drug levels when they are given more than once a day for over 24 hours (KDIGO Acute Kidney Injury Work Group, 2012). Iodinated contrast for computed tomography (CT) is a risk mainly in people with poor kidney function. Canadian radiology guidance considers preventive measures, such as IV fluids, only when the eGFR is below 30 mL/min/1.73 m², says emergency scans should not be delayed while waiting for a creatinine result, and does not recommend routinely stopping drugs before contrast, apart from metformin when the eGFR is below 30 (Macdonald et al., 2022). Inflammation of the glomeruli or of the tissue between the tubules can also cause intrinsic AKI.

Postrenal AKI results from blocked urine flow. Causes include an enlarged prostate, stones, tumours, blood clots and a kinked or blocked catheter. Chapter 28 covers urinary retention and obstruction.

Table 27.1 Prerenal, intrinsic and postrenal acute kidney injury compared (KDIGO Acute Kidney Injury Work Group, 2012; Lapi et al., 2013; Macdonald et al., 2022; Nora Pharma, 2026)

Type	Common causes	Clues	Nursing focus
Prerenal (reduced blood flow to the kidneys)	Bleeding, vomiting, diarrhea, poor intake, low blood pressure, sepsis, heart failure; NSAIDs with ACE inhibitors or ARBs and diuretics	Signs of low fluid volume (section 3.2): falling blood pressure, fast heart rate, dry mouth, weight loss; low, concentrated urine	Report early; accurate intake, output and weight; fluids as prescribed; ask for review of drugs that lower kidney blood flow
Intrinsic (damage within the kidney, such as acute tubular injury)	Prolonged low blood flow or shock, sepsis, nephrotoxic drugs such as aminoglycosides and NSAIDs, contrast in people with very low eGFR, inflammation of the glomeruli or kidney tissue	Rising creatinine; abnormal cells or casts on urine microscopy; output may be low or normal	Prevent further harm: medication review, drug levels as prescribed; watch for fluid overload, high potassium and acidosis
Postrenal (blocked urine flow)	Enlarged prostate, stones, tumours, clots, blocked or kinked catheter, drugs that cause urinary retention	Little or no urine, full bladder on bladder scan, blockage seen on ultrasound	Check catheter and tubing; bladder scan; relieve the blockage as prescribed; measure output closely afterward (Chapter 28)

Recognizing and Staging AKI

KDIGO advises judging each patient's risk by their susceptibilities and exposures, and checking creatinine and urine output in those at higher risk (KDIGO Acute Kidney Injury Work Group, 2012). Susceptibilities include dehydration, older age, chronic kidney

disease, diabetes, cancer, anemia and chronic heart, lung or liver disease. Exposures include sepsis, critical illness, shock, burns, trauma, major surgery, nephrotoxic drugs and contrast. Older adults carry several of these at once; Chapter 8 discusses why.

Recognizing AKI depends on two habits. First, the nurse compares each creatinine with the patient's baseline, looking back through earlier results in the record, because a value inside the reference range can still be a large rise for that person. Second, the nurse converts urine output to mL/kg per hour. For a patient who weighs 70 kg, the KDIGO threshold of 0.5 mL/kg per hour is 35 mL per hour; three hours at 20 mL per hour is a trend worth reporting, even before the 6-hour mark.

Once AKI is present, KDIGO stages it by severity (Table 27.2). The patient is assigned the highest stage that either the creatinine or the urine output reaches.

Table 27.2 KDIGO stages of acute kidney injury in brief (KDIGO Acute Kidney Injury Work Group, 2012)

Stage	Serum creatinine	Urine output
1	1.5 to 1.9 times baseline, or a rise of 26.5 µmol/L or more	Below 0.5 mL/kg per hour for 6 to 12 hours
2	2.0 to 2.9 times baseline	Below 0.5 mL/kg per hour for 12 hours or more
3	3.0 times baseline; or a rise to 353.6 µmol/L or more; or the start of kidney replacement therapy (dialysis); or, in patients under 18, an eGFR below 35 mL/min/1.73 m²	Below 0.3 mL/kg per hour for 24 hours or more, or no urine for 12 hours or more

Oliguria is an abnormally low urine output; **anuria** is little or no urine. Urine output can also stay normal in AKI (KDIGO Acute Kidney Injury Work Group, 2012), so a rising creatinine may be the only early clue. As AKI progresses, the nurse watches for:

- **Fluid overload:** weight gain, swelling, crackles in the lungs, shortness of breath and falling oxygen saturation (Chapter 18).
- **High potassium:** weakness, palpitations or no symptoms before a dangerous rhythm. Section 3.5 covers ECG changes and emergency treatment.
- **Metabolic acidosis:** fast, deep breathing and a low serum bicarbonate (section 3.7).
- **Uremia:** the effects of retained wastes. Reduced appetite, nausea and tiredness are typical uremic symptoms (Levin et al., 2024); severe uremia can cause bleeding, confusion or a drop in alertness (encephalopathy), and inflammation of the sac around the heart (pericarditis) (Bagshaw et al., 2021).

Nursing Care

Nursing care aims to find and treat the cause, prevent further injury, and catch complications early.

Fluid status: the nurse measures intake and output accurately, weighs the patient daily on the same scale at the same time, and assesses blood pressure, heart rate, mucous membranes, edema and lung sounds. When volume is low and the patient is not in shock from bleeding, KDIGO suggests isotonic crystalloids rather than colloids such as albumin to restore volume. It recommends against diuretics to prevent AKI and suggests against them to treat AKI, except to manage fluid overload, and recommends vasopressors together with fluids in shock caused by widened blood vessels (vasomotor shock) (KDIGO Acute Kidney Injury Work Group, 2012; Chapter 6). Because 1 L of water weighs about 1 kg, a gain of more than 1 kg in a day mostly reflects fluid (section 3.2). Once output falls, fluid given can no longer be cleared, so the balance can swing from too little to too much within a day. The nurse totals intake and output at least every shift, compares the totals with the weight, and reports a growing positive balance, new crackles or rising oxygen needs. When overload develops, care may include a diuretic, a fluid limit and sitting the patient upright, each as prescribed.

Medication review: the nurse reviews every drug with the prescriber and pharmacist. Drugs that lower kidney blood flow or are cleared by the kidneys may be held or adjusted. KDIGO's CKD guideline suggests considering a planned, temporary stop of metformin, ACE inhibitors, ARBs and sodium-glucose cotransporter-2 (SGLT2) inhibitors before elective surgery or while an adverse effect is being managed, and warns that failing to restart them can cause harm; when drugs are stopped during an acute illness, a clear restart plan is given to the patient and documented (KDIGO, 2024b; Levin et al., 2024). The nurse holds a drug only as prescribed or as policy allows. Sick-day medication guidance is taught in section 22.6.

Bloodwork and monitoring: creatinine, urea, electrolytes and bicarbonate are repeated as prescribed, and the nurse looks for each new result rather than waiting for it to be called. A potassium that is rising is reported with the patient's heart rhythm and any symptoms; section 3.5 explains when an ECG and cardiac monitoring are needed.

Ruling out obstruction: when output falls, the nurse checks the catheter and tubing for kinks or clots, or uses a bladder scanner if the patient has no catheter (Chapter 28).

Escalation: a falling output, a rising creatinine or potassium, new crackles or new confusion are reported promptly using SBAR (Chapter 6). Any nurse who sees these changes acts and escalates at once. A registered practical nurse (RPN) consults the registered nurse (RN) as the patient's needs change, and calls the rapid response team when criteria are met (Chapter 1, section 1.3).

Urgent dialysis: KDIGO advises starting dialysis urgently when life-threatening fluid, electrolyte or acid–base changes are present, and judging the decision on the whole clinical picture rather than on a single creatinine or urea result (KDIGO Acute Kidney Injury Work Group, 2012). A Canadian-led review describes urgent indications as fluid overload affecting oxygenation, metabolic acidosis with a pH below 7.20 or bicarbonate below 12 mmol/L, potassium of 6.0 mmol/L or higher, and complications of uremia such as bleeding, encephalopathy and pericarditis (Bagshaw et al., 2021). These are weighed against the response to medical treatment: for high potassium, KDIGO notes that once treatment to shift potassium into the cells has been used, only dialysis can remove the excess. Dialysis can also help remove some poisons and drug overdoses that cause acidosis and AKI, such as salicylates, ethylene glycol, methanol and metformin (KDIGO Acute Kidney Injury Work Group, 2012). When dialysis is planned, the nurse prepares the patient as section 27.4 describes.

Recovery: as the kidneys recover, creatinine falls and urine output returns. After a blockage is relieved, some patients pass very large volumes of urine, more than 200 mL per hour for two hours in a row, which can cause dehydration and electrolyte loss; output, weight, blood pressure and electrolytes are checked closely (Khara et al., 2019). Recovery is not the end of the story. About 30% of people who recover from AKI remain at higher risk of chronic kidney disease, cardiovascular disease and death, so KDIGO advises checking kidney function three months after the episode (KDIGO Acute Kidney Injury Work Group, 2012). In the Vancouver study, only 4 of 31 patients sent home with AKI had kidney follow-up arranged in the emergency department (Scheuermeyer et al., 2017). The nurse makes sure the discharge plan says when to repeat bloodwork, which drugs to restart and when, and which over-the-counter products to avoid.

Patient and family teaching: the nurse explains in plain language that the kidneys were injured suddenly, that they often recover, and that the episode leaves them more sensitive. Teaching covers:

- avoiding NSAIDs such as ibuprofen unless the prescriber approves, and checking with a pharmacist before buying any pain, cold or herbal product;
- following the written sick-day plan when vomiting, diarrhea or fever make it hard to keep up fluids (section 22.6);
- keeping the follow-up blood test appointment and bringing an up-to-date medication list to every visit;
- reporting much less urine than usual, new swelling, rapid weight gain or shortness of breath.

CLINICAL SAFETY

Protecting the Kidneys From Medications

Many cases of AKI involve medications, and many are preventable. The nurse:

- **Questions NSAIDs:** a Canadian NSAID product monograph lists the highest kidney risk in people with existing kidney disease, dehydration, heart failure, liver disease or older age, and in those also taking ACE inhibitors, ARBs or diuretics (Nora Pharma, 2026). Choosing Wisely Canada advises against NSAIDs for people with hypertension, heart failure or CKD of any cause, including diabetes (Canadian Society of Nephrology, 2025).
- **Watches the combination:** an NSAID added to a diuretic plus an ACE inhibitor or ARB raises AKI risk most in the first month (Lapi et al., 2013).
- **Checks drug levels:** aminoglycoside levels are drawn on time and results reported before the next dose (KDIGO Acute Kidney Injury Work Group, 2012).
- **Knows the contrast plan:** preventive steps are considered when the eGFR is below 30 mL/min/1.73 m², and metformin may be held (Macdonald et al., 2022).

- **Asks about kidney dosing:** drugs cleared by the kidneys are dosed to kidney function (Levin et al., 2024); the pharmacist is a key partner.
- **Asks about home products:** over-the-counter, dietary and herbal products can harm the kidneys (Levin et al., 2024).
- **Plans the restart:** drugs held during illness need a documented restart plan (KDIGO, 2024b).

CLINICAL JUDGMENT

Only 60 mL in Four Hours

Names and details are fictional; this is a composite story.

Grace Mensah, 79, was admitted to a medical unit last night after three days of vomiting and diarrhea. She takes ramipril and furosemide for heart failure and has been taking ibuprofen from the pharmacy for knee pain. She weighs 60 kg. At 1200, the RPN caring for her totals her urine since 0800: 60 mL.

- **Recognize cues:** 60 mL in 4 hours is 15 mL per hour, or 0.25 mL/kg per hour. Blood pressure is 98/56 mm Hg (her usual is about 130/80), heart rate 108 beats/min, mouth dry. This morning's creatinine is 142 µmol/L (88 µmol/L two months ago), and potassium is 5.4 mmol/L.
- **Analyze cues:** her losses and poor intake point to low blood flow to the kidneys, made worse by three drugs that reduce filtration together. The creatinine is more than 1.5 times her baseline, which meets the definition of AKI.
- **Prioritize hypotheses:** prerenal AKI from volume loss is most likely. Retention must be ruled out, and her potassium could keep rising. The RPN does not wait for the 6-hour mark: the trend is already clear.
- **Generate solutions:** a bladder scan, repeat bloodwork, and a report to the RN and the physician asking for fluid orders and a review of all three drugs.
- **Take action:** the bladder scan shows 70 mL. Because her needs are changing, the RPN consults the RN (Chapter 1, section 1.3), then calls the physician using SBAR. An isotonic IV fluid is prescribed, ibuprofen is stopped, ramipril and furosemide are held, and potassium and creatinine are added to the next blood draw. The RPN starts hourly output and records a daily weight.
- **Evaluate outcomes:** over the next 4 hours, output rises to 40 to 50 mL per hour and blood pressure to 118/70 mm Hg. Potassium is 5.2 mmol/L. The next morning's creatinine is 110 µmol/L, and the team plans when to restart her heart failure drugs.

27.3 Chronic Kidney Disease

Defining and Staging CKD

Chronic kidney disease (CKD) is an abnormality of kidney structure or function that has lasted more than three months and has implications for health (KDIGO CKD Work Group, 2024). Either of the following, present for more than three months, meets the definition:

- **markers of kidney damage,** such as an ACR of 3 mg/mmol or more, abnormal urine sediment, persistent blood in the urine, imaging or biopsy abnormalities, or a past kidney transplant; or
- **a GFR below 60 mL/min/1.73 m².**

KDIGO classifies CKD by cause, GFR category and albuminuria category (KDIGO, 2024a). The GFR categories, in mL/min/1.73 m², are (KDIGO CKD Work Group, 2024):

- **G1:** 90 or more (normal or high)
- **G2:** 60 to 89 (mildly decreased)
- **G3a:** 45 to 59 (mildly to moderately decreased)
- **G3b:** 30 to 44 (moderately to severely decreased)
- **G4:** 15 to 29 (severely decreased)
- **G5:** below 15 (kidney failure)

The albuminuria categories, by ACR, are A1, below 3 mg/mmol (normal to mildly increased); A2, 3 to 30 mg/mmol (moderately increased); and A3, above 30 mg/mmol (severely increased). G1 and G2 count as CKD only when a marker of damage is also

present.

Before a low eGFR or a raised ACR is called chronic, AKI must be ruled out and the finding confirmed after three months (KDIGO, 2024a). A single low result during an acute illness may reflect AKI rather than CKD, which is why repeat testing matters. KDIGO also notes that point-of-care tests for creatinine and urine albumin, once quality-assured, are accurate enough to guide care where laboratory access is limited (KDIGO, 2024a), which matters for rural and remote communities (section 27.6).

The two scales work together. Risk of kidney failure, AKI, heart disease and death climbs as the GFR falls and as albuminuria rises, so a person in G3a with heavy albuminuria may face more risk than a person in G3b with none. KDIGO shows this as a coloured grid from low to very high risk, and notes that the grid shows relative risk; individual risk is estimated with validated tools (KDIGO CKD Work Group, 2024). Diabetes Canada recommends the Kidney Failure Risk Equation and suggests referral to a nephrologist when the five-year risk of kidney failure is 5% or more (Tobe et al., 2025).

Causes in Canada: the Kidney Foundation of Canada reports diabetes as the leading cause of kidney failure, at 36%, based on Canadian registry data for 2011 to 2020 that exclude Quebec (Kidney Foundation of Canada, 2022). It names an aging population and rising rates of diabetes and high blood pressure as drivers of CKD in Canada, and notes that Indigenous peoples in Canada have a higher prevalence of CKD, with faster progression and poorer outcomes at younger ages (Kidney Foundation of Canada, 2025). Section 27.6 discusses the structural causes behind these differences. Other causes include glomerular diseases, which damage the glomeruli, and inherited diseases such as polycystic kidney disease (NIDDK, 2025). Diabetes Canada recommends yearly screening of people with diabetes with an eGFR and an ACR (Tobe et al., 2025).

Complications

As GFR falls, complications build up:

- **Anemia:** failing kidneys make too little erythropoietin (section 20.2). Treatment may include iron and an erythropoiesis-stimulating agent. The aim is not a normal hemoglobin, because using these agents to normalize hemoglobin has not improved survival or cardiovascular outcomes and may cause harm (Canadian Society of Nephrology, 2025). On every skin tone, the nurse looks for pallor where pigment does not hide it, such as the conjunctiva and the lining of the mouth (Pusey-Reid et al., 2023; section 20.2).
- **CKD–mineral and bone disorder (CKD–MBD):** damaged kidneys cannot clear phosphate or make enough active vitamin D (calcitriol). Blood calcium falls, the parathyroid glands release extra parathyroid hormone that draws calcium out of bone, and bones become thin and weak; high phosphate can also harden (calcify) blood vessels (NIDDK, 2021). Section 3.6 covers calcium and phosphate.
- **Metabolic acidosis:** KDIGO suggests considering drug treatment, with or without diet changes, to prevent acidosis in CKD (Levin et al., 2024).
- **High potassium:** reduced excretion and drugs such as ACE inhibitors, ARBs and mineralocorticoid receptor antagonists raise potassium, so potassium is checked when these drugs are started or increased (Tobe et al., 2025). KDIGO notes that a high potassium caused by these drugs can often be managed by lowering the potassium rather than stopping the kidney-protecting drug (Levin et al., 2024).
- **Fluid overload:** edema (Figure 3.1 shows pitting edema), weight gain, high blood pressure and shortness of breath (Chapter 18).
- **Cardiovascular disease:** people with diabetes and CKD have a high risk of heart attack, stroke and heart failure (Tobe et al., 2025).
- **Uremic symptoms:** KDIGO lists fatigue (about 70%) and itch (about 46%) among the most common symptoms in CKD (KDIGO, 2024b), and asks clinicians to check for reduced appetite, nausea and tiredness at each visit (Levin et al., 2024). The nurse asks about symptoms directly, because assessing them can change care, and inspects the skin for dryness and scratch marks (Figure 27.4).

Slowing Progression and Living With CKD

Blood pressure: KDIGO suggests a systolic target below 120 mm Hg, when tolerated, measured with standardized office readings (Levin et al., 2024). Targets are individualized for people who are frail, prone to falls, have dizziness on standing or have a very

limited life expectancy (KDIGO, 2024b). Chapter 19 covers hypertension and accurate measurement.

Kidney-protecting drugs: an ACE inhibitor or an ARB, not both, is started for people with albuminuria, and both KDIGO and Diabetes Canada advise against combining them (Levin et al., 2024; Tobe et al., 2025). SGLT2 inhibitors are recommended for people with type 2 diabetes and CKD with an eGFR of 20 mL/min/1.73 m² or more, and for other adults with CKD who have heavier albuminuria or heart failure (Levin et al., 2024). Diabetes Canada notes that their kidney and heart protection persists at low eGFR, even though their glucose-lowering effect is weaker there (Tobe et al., 2025). For people with type 2 diabetes and persistent albuminuria despite an ACE inhibitor or ARB, a nonsteroidal mineralocorticoid receptor antagonist (finerenone) is suggested when potassium is normal and the eGFR is above 25 (Levin et al., 2024). Diabetes Canada also lists glucagon-like peptide-1 (GLP-1) receptor agonists among kidney-protecting therapies (Tobe et al., 2025; Chapter 22). The Medications box summarizes the nursing points.

Figure 27.4 Uremic frost on the forehead and scalp of a young Black man: fine white crystals left on the skin as sweat evaporates. It is a rare sign of severe, untreated uremia. (credit: "Uremic frost on forehead and scalp of young Afro-Caribbean male" by Fythrion/Wikimedia Commons, CC BY-SA 3.0)

A small early dip in eGFR is expected after an ACE inhibitor, ARB or SGLT2 inhibitor is started. A fall of 30% or more from baseline is larger than expected and calls for a search for causes such as volume depletion, AKI or NSAID use (KDIGO, 2024b). Once started, an SGLT2 inhibitor can usually continue when the eGFR later drops under 20, unless it is not tolerated or dialysis begins (Levin et al., 2024). The nurse reports a large drop rather than stopping a drug on their own.

Lifestyle: KDIGO encourages people with CKD not to use tobacco and to build up to at least 150 minutes of moderate activity a week (Levin et al., 2024). Good glucose management for people with diabetes is covered in Chapter 22.

Diet: a dietitian tailors the plan. KDIGO suggests protein of 0.8 g/kg of body weight per day for adults in G3 to G5, and advises avoiding more than 1.3 g/kg per day in people at risk of progression. It suggests limiting sodium to less than 2 g per day (Levin et al., 2024). KDIGO favours a diet built more on plant foods than on animal foods, with fewer ultra-processed foods, which may help with acidosis, high potassium and high phosphate (KDIGO, 2024b). People with G3 to G5 who have had high potassium may be advised to limit foods rich in readily absorbed potassium, such as processed foods (Levin et al., 2024). Food insecurity can make these changes hard; the nurse asks about access rather than assuming a choice (Chapter 2).

Vaccines: the Canadian Immunization Guide recommends that people with CKD or on dialysis receive all routine vaccines, yearly influenza and COVID-19 vaccines, and hepatitis B and pneumococcal conjugate vaccines. A higher-dose hepatitis B vaccine is used, and antibody levels are checked afterward. For people aged 65 years or over with kidney disease, a respiratory syncytial virus (RSV) vaccine is a particular priority (Public Health Agency of Canada [PHAC], 2026).

Medication safety: people with CKD are more vulnerable to the kidney-damaging effects of drugs. Medications are reviewed at every transition of care, doses are matched to kidney function, and over-the-counter and herbal products are limited (Levin et al., 2024). The nurse teaches the patient to avoid NSAIDs unless the prescriber approves, to tell every pharmacist and prescriber about their kidney disease, and to follow a written sick-day plan (section 22.6).

Self-management and planning ahead: KDIGO describes CKD care as a combined strategy of education, lifestyle, diet and medications (KDIGO, 2024b). The nurse helps the person learn their own numbers (eGFR, ACR and blood pressure), keep a current medication list, and know when to call. As CKD progresses, plans for future care, including the choice between dialysis, transplant and conservative kidney management, should be discussed early and shared with everyone involved (KDIGO, 2024b; sections 27.4 to 27.6). Chapter 10 covers advance care planning.

MEDICATIONS

Drugs Used in Chronic Kidney Disease

No doses are given here; follow the current Canadian product monograph and the prescription.

- **ACE inhibitors (ramipril) and ARBs (candesartan):** check blood pressure, creatinine and potassium within 2 to 4 weeks of starting or increasing the dose. A small creatinine rise is expected; KDIGO advises continuing unless creatinine climbs more than 30% within 4 weeks (Levin et al., 2024). Held on sick days (section 22.6).
- **SGLT2 inhibitors (dapagliflozin, empagliflozin):** teach genital hygiene and to report genital itching or discharge; ketoacidosis is rare but serious (Tobe et al., 2025), and Chapter 22 explains why glucose may be only mildly raised. Held on sick days.
- **Finerenone:** monitor potassium, the main risk (Tobe et al., 2025).
- **Erythropoiesis-stimulating agents (darbepoetin alfa) and iron (iron sucrose IV):** follow hemoglobin and iron results and blood pressure; the aim is not a normal hemoglobin (Canadian Society of Nephrology, 2025).
- **Phosphate binders (sevelamer):** bind phosphate from food, so they are taken with meals; some other oral drugs are given at least 1 hour before or 3 hours after them (Sanofi-aventis Canada, 2026). Monitor phosphate and calcium.
- **Active vitamin D (calcitriol):** monitor calcium and phosphate.
- **Treatment for metabolic acidosis:** when prescribed, monitor bicarbonate so that it does not rise above the normal range (Levin et al., 2024), along with blood pressure and edema.
- **Potassium binders (sodium zirconium cyclosilicate):** lower potassium so that kidney-protecting drugs can often continue (Levin et al., 2024).
- **Diuretics (furosemide):** for fluid overload; monitor weight, blood pressure, potassium and output.

LIFESPAN CONSIDERATIONS

Kidney Disease in Older Adults

- **Older adults:** creatinine-based eGFR overestimates kidney function when muscle mass is low, which can lead to overdosing (KDIGO CKD Work Group, 2024). The nurse treats a "normal" creatinine in a frail older adult with caution and asks the pharmacist to check kidney dosing. KDIGO keeps the same GFR threshold, 60 mL/min/1.73 m², for diagnosing CKD in older adults as in younger adults (KDIGO, 2024a).
- **Drug accumulation:** many drugs cleared by the kidneys, including some opioids and sedatives, build up and can cause confusion and falls (Chapter 8, section 8.5).
- **Blood pressure:** strict lowering can cause dizziness, falls and fractures, so targets are individualized (KDIGO CKD Work Group, 2024). The nurse checks for a drop in blood pressure on standing.
- **AKI risk:** older age is a susceptibility for AKI (KDIGO Acute Kidney Injury Work Group, 2012), and older adults often carry several exposures at once, such as surgery, new drugs and poor intake.
- **Choices about treatment:** for some older adults with kidney failure, conservative kidney management, without dialysis, fits their priorities better (section 27.6). Choices about kidney replacement therapy or conservative care should reflect the person's own priorities (KDIGO CKD Work Group, 2024).
- **Younger adults:** CKD in younger adults can affect school, work and family planning, so referral and education start early.

27.4 Dialysis

When chronic kidney disease reaches kidney failure (section 27.3), the kidneys can no longer clear wastes and extra fluid well enough to sustain life. **Kidney replacement therapy (KRT)** is the term for treatments that take over this work: dialysis or a kidney transplant. Dialysis can also be needed for a short time in acute kidney injury (section 27.2). This section covers how each type of dialysis works, access care and the complications that need quick action.

Choosing Kidney Replacement Therapy

People approaching kidney failure in Canada may be offered several paths:

- **In-centre hemodialysis:** treatment in a hospital or community dialysis unit, usually several times a week.
- **Home hemodialysis:** the patient or a family member, after training, runs the machine at home.

- **Peritoneal dialysis:** treatment at home that uses the lining of the abdomen as the filter.
- **Kidney transplant:** from a living or deceased donor (section 27.5). A **pre-emptive transplant** is done before dialysis is ever needed.
- **Conservative kidney management:** active, planned care without dialysis or transplant (section 27.6).

In-centre hemodialysis is by far the most common choice. The Canadian Organ Replacement Register (CORR), kept by the Canadian Institute for Health Information (CIHI), counted 30,213 people receiving dialysis at the end of 2024 and 19,940 living with a functioning kidney transplant (CIHI, 2025a). These CORR figures exclude Quebec. Of the people on dialysis, 77.7% had in-centre hemodialysis, 11.4% automated peritoneal dialysis, 6.8% continuous ambulatory peritoneal dialysis and 4.1% home hemodialysis. Among people who started KRT in 2024, 76.8% began with in-centre hemodialysis, 19.7% with peritoneal dialysis, 3.1% with a pre-emptive transplant and 0.5% with home hemodialysis (CIHI, 2025a).

Planning ahead matters. In 2024, 28.6% of people who started dialysis had first seen a nephrologist less than 90 days earlier, which CIHI calls late referral (CIHI, 2025a). Late referral leaves little time to weigh options, train for home therapy or create a fistula.

The choice of therapy is a **shared decision**. The kidney team explains what each option involves and what the evidence shows. The patient weighs the options against their own values, health, work, family and home. Written or online decision aids help people compare options side by side (Kidney Supportive Care Research Group [KSCRG], n.d.). Distance matters too, because people in remote communities may have to move to reach dialysis (see the Canadian Context box in section 27.6). The nurse supports these decisions by checking what the patient understands, answering questions within their competence and referring others to the kidney team. Consent and capacity are discussed in Chapter 1, section 1.5.

Hemodialysis and Vascular Access

In **hemodialysis**, blood leaves the body through a vascular access, passes through a filter called a **dialyzer** in the dialysis machine (Figure 27.5), and returns to the body cleaned of wastes and extra fluid (Peterborough Regional Health Centre [PRHC], 2024). Inside the dialyzer, wastes such as urea and potassium move across a thin membrane from the blood into a cleansing fluid called dialysate. Extra water is pulled out of the blood by pressure, a process called **ultrafiltration**. Most people on in-centre hemodialysis have three or more treatments a week, each lasting about 4 hours or longer (PRHC, 2024). Many feel tired afterward, and blood pressure can swing (PRHC, 2024).

Hemodialysis needs a high blood flow, which an ordinary vein cannot supply. There are three types of access (Kidney Foundation of Canada, 2020; Lok et al., 2020):

- **Arteriovenous fistula (AV fistula):** a surgeon joins an artery to a vein, usually in the arm. The extra flow makes the vein larger and thicker so it can take dialysis needles. A fistula uses the person's own vessels, so it has lower rates of infection and clotting and tends to last longer. It usually needs 4 to 6 weeks or more to mature before use.
- **Arteriovenous graft (AV graft):** a tube of synthetic or biological material joins an artery to a vein. Needles are placed in the graft.
- **Central venous catheter (CVC) for dialysis:** a large catheter in a central vein, usually in the neck, that allows high flow. A tunnelled catheter, which travels under the skin before entering the vein, carries a lower infection risk than a non-tunnelled one.

Guidelines favour an AV fistula or graft over a catheter for most people because of the lower infection risk (Lok et al., 2020). Yet most Canadians still start hemodialysis with a catheter: 88.4% in 2024, up from 82.4% in 2015, while fistula use at the start fell from 15.9% to 10.6% (CIHI, 2025a). Because a future fistula depends on healthy arm veins, guidelines advise protecting the veins of people with CKD categories G3 to G5 and avoiding peripherally inserted central catheters (PICCs) and unnecessary blood draws (Lok et al., 2020). The nurse raises this with the team before a PICC is placed in a patient with advanced CKD.

Assessing an AV fistula or graft. Examining the access means looking, feeling and listening (Lok et al., 2020; Salman & Beathard, 2013):

- **Look:** at the access, arm and hand. Swelling, redness, warmth, pus or thin, shiny or ulcerated skin over a bulge are warning signs. A hand that is pale, bluish, cold, numb or painful may mean the access is "stealing" blood from the hand. Colour changes

can look different on darker skin, so the nurse uses natural or other good ambient light rather than fluorescent light, feels for warmth, swelling and tenderness, and compares with the other arm (Pusey-Reid et al., 2023).

- **Feel:** a **thrill** is the buzzing vibration of blood flowing through the access. A normal thrill is soft and continuous. A thrill that is strong in only one spot, or one that has changed, can mean narrowing.
- **Listen:** a **bruit** is the sound of that flow heard with a stethoscope. A normal bruit is low-pitched and continuous, like a soft whoosh. A high-pitched bruit, or one heard only in pulses, suggests narrowing.
- **No thrill and no bruit** suggests the access has clotted. The nurse reports this to the dialysis team or prescriber at once, because a clotted access may be saved if treated quickly.

Figure 27.5 A hemodialysis machine beside a treatment chair. The blood pump moves blood through the dialyzer, and the screen shows pressures, flow and fluid removal. (credit: "Hemodialysis machine INNOVA" by Vitaly Pospelov (Виталий Поспелов) at Russian Wikipedia/Wikimedia Commons, CC BY-SA 3.0)

Protecting the access arm. No blood pressure readings, blood draws or IV starts are done in the arm with a fistula (Health PEI, 2022; Kidney Foundation of Canada, 2020). The same protection applies to a graft arm. The nurse also avoids tight sleeves, tight watches and anything that compresses the arm. Many patients carry a wallet card describing their access. The nurse asks for it, documents the location of the access and makes sure the whole team knows. After two incidents in which an IV was placed in a fistula arm, Health PEI (2022) reminded staff that a dialysis access is for dialysis only, except in a life-threatening emergency.

Caring for a dialysis catheter. A dialysis catheter is a direct line to the heart. Misuse can cause severe bleeding, infection, clots or air embolism (Health PEI, 2022). For this reason, only staff trained and authorized in hemodialysis open or use it, and it is not used for blood work or IV medications on the ward except in a life-threatening emergency. The nurse keeps the dressing dry and intact and does not get the site wet. Fever, chills, or redness, tenderness or drainage at the exit site are reported promptly. Infection prevention for central lines is covered in Chapter 4.

Before and after dialysis. Before a treatment, the nurse weighs the patient on the same scale each time, measures blood pressure on the non-access arm and reports laboratory results as ordered, such as potassium (hyperkalemia is covered in Chapter 3). The nurse confirms with the prescriber or dialysis unit which medications to give or hold before the treatment. Blood pressure drugs taken just before dialysis add to the risk of low blood pressure during treatment (Chou et al., 2017). After the treatment, the nurse:

- weighs the patient and compares the result with the pre-dialysis weight;
- checks blood pressure, including for dizziness on standing, and helps the patient up slowly to prevent a fall;
- checks the needle sites. If a site bleeds, light, direct pressure is held for about 10 minutes. Bleeding that does not stop is reported at once (Kidney Foundation of Canada, 2020);
- watches for headache, nausea or vomiting, dizziness, confusion or agitation during or soon after early treatments. These can signal **dialysis disequilibrium syndrome**, brain swelling caused by rapid removal of urea, which is most likely in a patient's first treatments (Mistry, 2019).

Peritoneal Dialysis

Peritoneal dialysis (PD) uses the **peritoneum**, the thin membrane lining the abdomen, as the filter. A soft catheter is placed through the abdominal wall. Dialysate runs into the abdomen, stays there for a set time (the dwell), and is then drained out along with wastes

and extra fluid. The drained fluid is called **effluent**. Each fill, dwell and drain cycle is an exchange. There are two main methods: (Figure 27.6)

- **Continuous ambulatory peritoneal dialysis (CAPD):** the patient does several manual exchanges by hand through the day.
- **Automated peritoneal dialysis (APD):** a machine called a cycler does exchanges overnight while the patient sleeps.

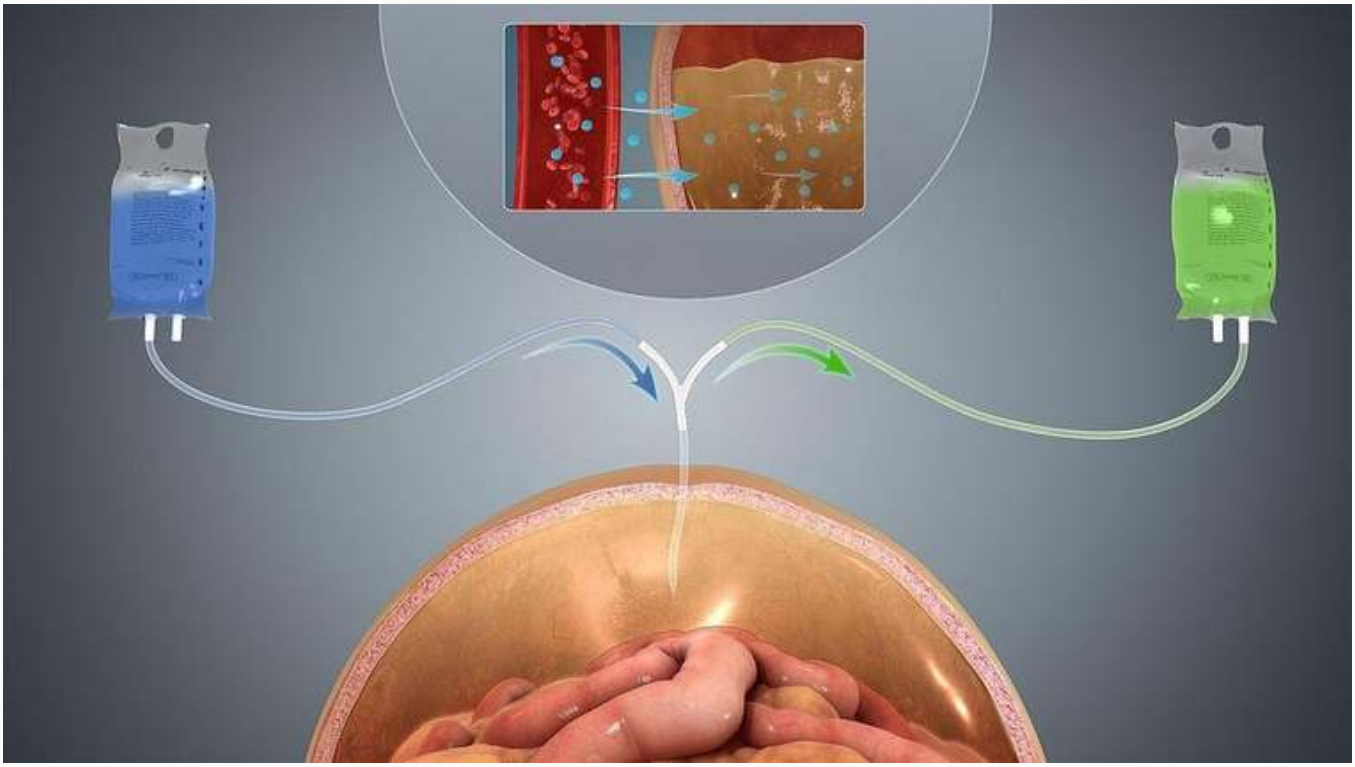

Figure 27.6 Peritoneal dialysis: sterile dialysate flows through an indwelling catheter into the peritoneal cavity, where water and uremic solutes diffuse across the semipermeable peritoneal membrane before the effluent is drained. (credit: "Peritoneal dialysis" by Manu5 [Scientific Animations]/Wikimedia Commons, CC BY-SA 4.0)

Most dialysate contains glucose to draw water out of the blood. Some of this glucose is absorbed. In one study, people on PD had increases in fat mass and blood sugar measures over time (Law & Davenport, 2021). The nurse therefore watches blood glucose closely in a patient with diabetes, and the dietitian plans energy and protein intake with the patient.

Exit-site care and infection prevention. The catheter's exit site is a door for bacteria. Patients and nurses wash hands thoroughly before and after every exchange (Li et al., 2022). The nurse checks that the dressing is dry and intact each shift, cleans the site as the program directs and applies the prescribed antibiotic cream to the skin around the exit site (Li et al., 2022; The Ottawa Hospital [TOH], 2015). Scabs are left in place, and the catheter is secured against tugging. Patients should not soak the exit site in a bath, because this can cause an exit-site infection and peritonitis (TOH, 2015). Any drainage from the exit site is reported and swabbed. If sterile technique breaks during an exchange, the patient contacts the PD unit right away (Li et al., 2022).

Recognizing peritonitis. PD-related peritonitis is infection of the peritoneum. It is the complication the nurse must not miss. The International Society for Peritoneal Dialysis (ISPD) guideline diagnoses peritonitis when at least two of three criteria are present: abdominal pain or cloudy effluent; an effluent white cell count above 100 per microlitre (0.1×10^9/L) after a dwell of at least 2 hours, with more than half neutrophils; and a positive effluent culture (Li et al., 2022). Fever, chills, nausea, vomiting or diarrhea may also occur (TOH, 2015).

First actions follow the ISPD guideline (Li et al., 2022):

- **Treat cloudy effluent as peritonitis** until it is proven otherwise.

- **Notify the PD unit or nephrologist at once,** and follow the unit's directions for getting an effluent sample to the laboratory quickly. ISPD advises that specimens reach the laboratory within 6 hours.
- **Send effluent** for a Gram stain, a cell count with differential and a culture, with the culture in blood culture bottles.
- **Start antibiotics as soon as specimens are collected,** without waiting for results. Antibiotics are often given into the peritoneal fluid (intraperitoneal), and a patient with mild pain may be treated at home if this can be arranged.
- **Consider peritonitis even if the effluent is clear** when a PD patient has abdominal pain.

Fluid balance on PD. The nurse tracks weight, blood pressure, edema and the volume drained compared with the volume instilled, as the PD program directs. A drain that is much smaller than expected, or rising weight with edema, means fluid is building up and is reported (fluid overload is covered in Chapter 18).

Table 27.3 compares hemodialysis and peritoneal dialysis.

Table 27.3 Hemodialysis and peritoneal dialysis compared (CIHI, 2025a; Kidney Foundation of Canada, 2020; Li et al., 2022; PRHC, 2024; TOH, 2015)

Feature	Hemodialysis	Peritoneal dialysis
How it works	Blood passes through a dialyzer outside the body	Dialysate fills the abdomen; the peritoneum acts as the filter
Access	AV fistula, AV graft or central venous catheter	Soft catheter through the abdominal wall
Where and how often	Most often in a dialysis unit, three or more sessions a week of about 4 hours or longer; home hemodialysis for some	At home every day, by hand through the day (CAPD) or by cycler overnight (APD)
Share of people on dialysis, 2024 (excluding Quebec)	77.7% in-centre and 4.1% home	11.4% APD and 6.8% CAPD
Main infection risk	Catheter-related bloodstream infection; infection at needle sites	Peritonitis; exit-site infection
Key nursing checks	Thrill and bruit; no blood pressure, blood draws or IVs in the access arm; weight and blood pressure before and after	Cloudy effluent and abdominal pain; exit site; drain volumes; blood glucose

PATIENT EDUCATION

Caring for Your Fistula

Your fistula is your lifeline. These steps help it last (Health PEI, 2022; Kidney Foundation of Canada, 2020):

- **Check it every day.** Feel for the buzz (thrill) over your fistula. Tell your kidney team right away if the buzz is gone or feels different.
- **Check your hand.** Report a hand that is cold, a different colour, numb, tingling, swollen or painful.
- **Watch the site.** Report redness, warmth, swelling, pain or bleeding.
- **Protect your arm.** Do not let anyone take your blood pressure, draw blood or start an IV in that arm. Carry your wallet card and show it in every hospital, clinic and lab.
- **Avoid pressure.** Skip tight sleeves and watches. Do not sleep on the arm or keep it bent for long periods.
- **After dialysis,** hold light pressure on each needle site for about 10 minutes, or as your team teaches you. If a site bleeds again at home, hold light pressure for 20 minutes. If it still bleeds, go to the nearest emergency department and tell your kidney team.
- **Speak up.** You are an important member of your own safety team.

GOING DEEPER

Fluid and Electrolyte Shifts During Dialysis

Required for RN students; optional for PN students.

Between hemodialysis sessions, most patients make little or no urine, so the fluid they drink builds up. The weight gained between sessions is called **interdialytic weight gain**. During the next session, ultrafiltration must remove this fluid in a few hours. The faster fluid is pulled from the blood, the harder it is for fluid in the tissues to refill the blood vessels.

When refilling cannot keep up, blood pressure falls. **Intradialytic hypotension** has been defined in research as a lowest systolic pressure below 90 mm Hg in more than 30% of treatments. It is linked with poorer survival and with harmful effects on the heart, brain and gut (Chou et al., 2017). Risk rises with large interdialytic weight gains, high ultrafiltration rates and blood pressure drugs taken before treatment (Chou et al., 2017). This is why teaching about fluid and sodium limits matters, and why the prescriber decides which antihypertensives to hold or time on dialysis days.

Electrolytes shift too. Potassium moves from the blood into dialysate that contains less potassium, so the blood potassium level falls during treatment. Rapid removal of urea can also draw water into the brain, which causes dialysis disequilibrium syndrome (Mistry, 2019).

27.5 Kidney Transplant

For many people with kidney failure, a transplant offers the most freedom from dialysis. Kidney transplants are very successful for most recipients (TOH, n.d.). This section describes how donation works in Canada and what nurses teach and watch for after a transplant.

Donation and Transplant in Canada

A kidney can come from a **living donor**, who gives one of their two kidneys, or a **deceased donor**. Living donors may be related to the recipient, such as a sibling, or unrelated, such as a spouse or friend. In 2020, 26% of kidney transplants in Canada came from living donors, and more than 45% of living donors were not related to the recipient (Kidney Foundation of Canada, 2022). A transplant from a living donor can sometimes be done before dialysis starts, which is a pre-emptive transplant. In 2024, 3.1% of Canadians starting KRT received a pre-emptive transplant (CIHI, 2025a).

Kidneys are the organ transplanted most often in Canada. CIHI reported 3,174 organ transplants of all types in 2025, and 59% of them were kidney transplants (CIHI, 2026). Across all organs, 81% of transplants used organs from deceased donors and 19% from living donors. The 888 deceased donors in 2025 donated after neurological determination of death (62%), after circulatory death not related to medical assistance in dying (MAID) (30%) or after MAID (8%) (CIHI, 2026). MAID is discussed in Chapter 10.

The need is greater than the supply. On December 31, 2025, 4,344 Canadians were on transplant wait-lists for any organ. Of the 678 people removed from wait-lists during 2025, 31% had died while waiting (CIHI, 2026). For adults on dialysis, CIHI reported a median wait of 3.4 years for a deceased-donor kidney in 2023, down from 3.8 years in 2014 (CIHI, 2024). Waits vary widely by province: in 2020, the median ranged from 2 years and 8 months in British Columbia to 7 years and 2 months in Manitoba (Kidney Foundation of Canada, 2022).

Each province and territory has an organ donation organization. In Ontario, Ontario Health (Trillium Gift of Life Network) coordinates organ and tissue donation and transplant services (Ontario Health [Trillium Gift of Life Network], 2026). Ontarians aged 16 or older can register their consent online with their health card in a few minutes. Nurses can encourage people to register and to share their wishes with their families.

Care After Transplant

After surgery, the recipient takes **immunosuppressants** for as long as the kidney works. These drugs lower the immune response so the body does not attack the new kidney. How they work, their adverse effects and the safety precautions they require are covered in section 21.3. Nursing care after transplant centres on five areas.

Watching for rejection. Rejection is an immune attack on the new kidney, which the body sees as foreign tissue (TOH, n.d.). Acute rejection can occur at any time but is most common in the first year. It may or may not cause symptoms and is often found on routine blood work, so keeping every laboratory appointment matters. Chronic rejection develops slowly over time. The Ottawa Hospital (n.d.) teaches recipients to report these possible signs:

- a temperature of 38 °C or above, or symptoms like the flu;
- less urine, darker urine or blood in the urine;
- shortness of breath, sudden weight gain or swelling of the legs or around the eyes;
- pain or tenderness over the new kidney;

- high blood pressure or a rising creatinine.

Small changes in creatinine are normal and can reflect hydration, medications or the timing of the test. The transplant team decides whether a change matters (TOH, n.d.). The nurse reports any of these signs promptly rather than waiting for the next clinic visit. Rejection found early can often be treated, which helps save kidney function.

Preventing and recognizing infection. Immunosuppression raises the risk of infection, and it can also blunt the usual signs, such as fever (section 21.3). The nurse uses strict hand hygiene, assesses wounds and lines closely and teaches the patient to report fever or new symptoms early. Infection prevention is covered in Chapter 4.

Supporting adherence. Missed doses of immunosuppressant raise the risk of rejection. Recipients are taught to take every dose as prescribed, to never run out and to bring a current medication list to every clinic visit (TOH, n.d.). The nurse asks about barriers such as cost, side effects, complex schedules and low mood, and refers to the transplant pharmacist or social worker. Before the patient starts any new drug, including over-the-counter and natural health products, the transplant team or pharmacist checks it for interactions with immunosuppressants (section 21.3).

Lowering cancer risk. Kidney transplant recipients have a much higher rate of skin cancer than the general population (Kidney Disease: Improving Global Outcomes [KDIGO] Transplant Work Group, 2009). The nurse teaches the recipient to limit sun exposure for life, use sunscreen and protective clothing, check their skin and lips regularly and report any new spot.

Lifelong follow-up and emotional care. A transplant is a treatment, not a cure. On average, a kidney from a living donor works for up to about 18 years and one from a deceased donor for up to about 12 years (TOH, n.d.). Recipients need regular blood work and clinic visits for life. Fear of rejection, grief and worry are common. The nurse asks about them and offers the support of the team, including the social worker (TOH, n.d.).

27.6 Kidney Health in Canada and Living Well With CKD

Kidney disease does not affect all communities equally, and kidney care is not equally easy to reach. This section looks at kidney health in First Nations, Inuit and Métis communities and in remote Canada. It then turns to conservative kidney management for people who choose not to have dialysis.

Kidney Disease in First Nations, Inuit and Métis Communities

A distinctions-based approach recognizes that First Nations, Inuit and Métis peoples have their own histories, governance and health priorities (Chapter 2). Findings for one group are not assumed to apply to the others.

The strongest Canadian kidney data describe First Nations adults. In a population-based study in Alberta, adults tested from 2002 to 2008 who were First Nations reached kidney failure at rates two to three times higher than other adults with the same eGFR and albuminuria category (Samuel et al., 2014). First Nations adults in the study were also less likely to have had their urine albumin measured: 53.8% had no measure, compared with 38.5% of other adults. The authors point to gaps in the quality of care and in access to kidney specialists. These patterns are not explained by biology. They reflect structural causes:

- **Diabetes burden,** itself shaped by colonial policies and loss of traditional food systems (Chapter 22).
- **Water and food insecurity** in some communities (Chapter 2).
- **Distance** from kidney specialists, laboratories and dialysis units.
- **Colonialism and systemic racism** in health care, which make relocation for dialysis especially harmful (Trachtenberg & Goldberg, 2021).

Inuit and Métis kidney health deserves its own distinctions-based data. When this chapter cites First Nations data, it does not apply them to Inuit or Métis patients. The nurse asks each patient about their own community and needs.

Community-led work shows what is possible. In Manitoba, the FINISHED project brought point-of-care screening to rural and remote First Nations communities in two Tribal Councils. It was designed with Indigenous leaders and organizations, approved by Band Council Resolutions and run under the First Nations principles of OCAP® (ownership, control, access and possession)

(Harasemiw et al., 2021). Mobile teams measured blood chemistry, glycated hemoglobin (HbA1c), the urine albumin-to-creatinine ratio and blood pressure, and shared the results with each person during counselling the same day. Among the 1,353 adults studied, 44% had a risk of kidney failure at screening. After screening, complete laboratory testing, diabetes treatment and nephrology visits all increased compared with a matched group that was not screened (Harasemiw et al., 2021). Any use of First Nations data follows OCAP® (Chapter 2).

What this means for nursing practice:

- **Test early.** Adults with diabetes or high blood pressure need both eGFR and urine albumin checked (section 27.1). The nurse makes sure the urine test is not the one that gets missed.
- **Explain results.** The nurse explains in plain language what a result means and what happens next, and offers an interpreter when one is wanted.
- **Plan around distance.** The nurse asks where the patient lives, how they travel and who supports them, and links them with Indigenous patient navigators or liaison services where they exist (Chapter 2).
- **Name the barrier, not the person.** A missed appointment often reflects distance, cost or past harm in health care, not a lack of interest.

Culturally safe kidney care means building trust, inviting family and community supports, offering interpreters, including traditional foods in diet planning and respecting traditional healing alongside dialysis or transplant care (Chapter 2).

Conservative Kidney Management and Advance Care Planning

Not everyone with kidney failure chooses dialysis. **Conservative kidney management (CKM)** is planned, comprehensive, person-centred care for kidney failure that does not include dialysis (KSCRG, n.d.). It is an active treatment choice, not a withdrawal of care (Kidney Foundation of Canada, n.d.). The KDIGO 2024 CKD guideline advises telling people with CKD about both kidney replacement therapy and comprehensive conservative care, and supporting conservative management for those who choose not to have kidney replacement therapy (Kidney Disease: Improving Global Outcomes [KDIGO] CKD Work Group, 2024). People may choose CKM because they have other life-limiting illnesses, are not transplant candidates or feel that the burden of dialysis would outweigh its benefits. A nephrologist may raise the option when dialysis is unlikely to help, especially for frail older adults (section 27.3). Age shapes the trade-offs. Among people aged 75 or older on dialysis, CIHI reported unadjusted survival of 72.9% at 1 year and 24.6% at 5 years (CIHI, 2025a). Numbers like these help older adults and families weigh time spent travelling to and receiving dialysis against what matters most to them.

CKM combines kidney care with palliative care principles (KSCRG, n.d.). It includes:

- slowing the loss of kidney function with medications and diet;
- preventing and managing complications;
- treating symptoms such as itch, breathlessness, nausea and fatigue;
- psychosocial, spiritual and family support, and screening for depression;
- advance care planning, including a plan for crises and for the last weeks of life.

The CKM team works with the person's primary care provider and with palliative care services (KSCRG, n.d.). The nurse's part is to ask regularly about symptoms, mood and sleep, to report symptoms that are not controlled, and to make sure the person and family know whom to call in a crisis. The decision belongs to the person, who can change their mind at any time (Kidney Foundation of Canada, n.d.). Some people already on dialysis decide later to stop. That decision follows the same informed, shared process and moves the focus to comfort. The nurse confirms that the person understands the choice and has capacity, or involves the substitute decision-maker (Chapter 1, section 1.5). Advance care planning and end-of-life care are covered in Chapter 10.

CANADIAN CONTEXT

Dialysis Far From Home

Hemodialysis needs a machine, treated water and trained staff several times a week. Many rural and remote communities have no local dialysis unit. People who live there often must move to a city to survive (Trachtenberg & Goldberg, 2021). Moving can split

families, end jobs and cause money problems. It can also leave people far from their community and culture (Trachtenberg & Goldberg, 2021).

In an Alberta survey, 121 people on hemodialysis who lived in remote areas were asked to compare two futures. One was a shorter life at home with their usual supports. The other was a longer life at a referral centre without those supports. On average (median), 6 years of life at home with supports was valued the same as 10 years at the referral centre without them, so participants would give up about 4 years of life to stay where they were. Older participants would give up even more (Tonelli et al., 2015).

Ways to shrink the distance include:

- home dialysis, especially peritoneal dialysis, with training and remote support;
- satellite dialysis units closer to home;
- early referral, so a home option and access can be ready in time;
- considering priority for transplant when local dialysis is not possible (Trachtenberg & Goldberg, 2021).

Nurses help by asking where home is, what matters there and who will support the patient through the change.

SCOPE IN PRACTICE

Dialysis Care and Who Does What

In Ontario, the College of Nurses of Ontario (CNO) frames every nursing activity by authority, competence and context (CNO, 2025; Chapter 1, section 1.3).

- **Authority:** an activity must be within the nurse's legal scope, with an order where one is required.
- **Competence:** dialysis nursing needs education beyond entry to practice. In Ontario, for example, Confederation College's nephrology nursing program admits both registered nurses (RNs) and registered practical nurses (RPNs) and covers hemodialysis and peritoneal dialysis care (Confederation College, n.d.). Without the education a role requires, a nurse does not cannulate an access or run a treatment.
- **Context:** employer policy sets who may start and run hemodialysis, cannulate a fistula or graft and access a dialysis catheter. These tasks are usually limited to staff trained and authorized for hemodialysis (Health PEI, 2022). Employers decide how RNs and RPNs share work in dialysis units, home dialysis programs and medical units. On a medical unit, a nurse who has been taught and is authorized by the employer may do PD exchanges for an admitted patient. A nurse who has not been taught asks for help and makes sure the exchange is not missed.

Some duties belong to every nurse:

- protecting the access arm and assessing the thrill and bruit;
- recognizing cloudy effluent, a lost thrill, bleeding or signs of infection, and escalating at once;
- teaching and supporting the patient.

An RPN who sees a change in the patient's condition consults the RN. Employer policy and the rules of each province or territory shape these roles.

PRACTICE STORY

The Arm With the Thrill

Names and details are fictional; this is a composite story.

Nurse: Teresa Bouchard, RPN. Years in practice: 4. Setting: medical unit, Ontario.

Mr. Lucien Arsenault was 71 and had been admitted with pneumonia. He went to hemodialysis three times a week. At handover I heard "left forearm fistula," and I wrote it at the top of my sheet.

At 0800 a new staff member wheeled the vital signs machine in and reached for his left arm. Mr. Arsenault was drowsy and didn't say a word. I asked her to stop and use his right arm. Then I put my fingers on his left forearm and felt that steady buzz. The thrill was there, and so was the soft whoosh when I listened.

At 1000 his IV came out. The nurse who came to restart it had tried his right arm twice without success, and she began looking at his left hand. I told her about the fistula and showed her the thrill. She hadn't known. Together we called the charge nurse, who arranged for the IV team to try again on the right side.

None of this was anyone's bad intention. The information just wasn't where people looked. I asked Mr. Arsenault for his wallet card, and his wife found it in his coat. I documented the access location and put up the arm sign our unit uses. I added it to the whiteboard and the handover tool, and I told the charge nurse that the fistula needed to be raised at safety huddle.

When Mr. Arsenault was more awake, we talked. He said that at the dialysis unit everyone knows, so he had stopped mentioning it. I asked him to tell every nurse, lab worker and doctor who touched that arm. I also showed his wife how to check the buzz each day. He laughed and said he'd been "promoted to safety officer."

At the huddle the next day, I showed two new staff members how to feel a thrill. It took less than a minute each.

Reflect: What parts of protecting a fistula arm fall within every nurse's scope, and which dialysis tasks need further education and employer authorization? What would you do if a colleague insisted on using the fistula arm in a non-emergency?

Chapter 27 Summary

Introduction

- Chronic kidney disease affects 1 in 10 Canadians, and in 2024 more than 50,000 people in Canada had kidney failure.
- Acute kidney injury is common in acute care, and nurses are often first to notice falling urine output or a medication that should be questioned.

27.1 Kidney Function and Kidney Tests

- Nephrons filter blood and adjust its contents; the GFR is the main measure of kidney function.
- The kidneys clear wastes and drugs, balance fluid, electrolytes and acid, help set blood pressure, and support red cell production and bone health.
- Creatinine depends on muscle mass, so trends from the patient's baseline matter more than single values; eGFR is calculated from creatinine, increasingly with the race-free 2021 CKD-EPI equation.
- The urine ACR detects albuminuria early; Diabetes Canada uses 2.0 mg/mmol for people with diabetes and needs two of three abnormal samples.
- Accurate, timed urine output related to body weight is essential to recognizing AKI.

27.2 Acute Kidney Injury

- KDIGO defines AKI by a creatinine rise of 26.5 µmol/L in 48 hours, a rise to 1.5 times baseline within 7 days, or output below 0.5 mL/kg per hour for 6 hours, and stages it 1 to 3.
- Causes are prerenal (low blood flow), intrinsic (such as acute tubular injury) and postrenal (obstruction); NSAIDs combined with diuretics and ACE inhibitors or ARBs raise risk.
- Nursing care includes accurate intake, output and weights, medication review with the team, ruling out obstruction, and prompt escalation of falling output, high potassium or fluid overload.
- Urgent dialysis is considered for life-threatening fluid overload, acidosis, high potassium or uremic complications, weighed against the response to medical treatment, and for some poisonings.
- Recovery needs a follow-up plan, because many people remain at higher risk of CKD.

27.3 Chronic Kidney Disease

- CKD is an abnormality of kidney structure or function for more than three months, classified by cause, GFR category (G1 to G5) and albuminuria category (A1 to A3).
- Diabetes is the leading cause of kidney failure in Canada; Indigenous peoples face higher rates and worse outcomes for structural reasons (section 27.6).
- Complications include anemia, mineral and bone disorder, acidosis, high potassium, fluid overload, cardiovascular disease, fatigue and itch.
- Progression is slowed with blood pressure control, an ACE inhibitor or ARB, SGLT2 inhibitors and other kidney-protecting drugs, no tobacco, activity, and a dietitian-guided diet lower in sodium.
- People with CKD need vaccines, medication review at every transition, kidney-adjusted doses and avoidance of NSAIDs.

27.4 Dialysis

- Kidney replacement therapy includes in-centre or home hemodialysis, peritoneal dialysis and transplant. Conservative kidney management is another option. Choices are shared decisions.
- At the end of 2024, 30,213 people were on dialysis in Canada outside Quebec, and 77.7% of them had in-centre hemodialysis (CIHI, CORR). Most people still start hemodialysis with a catheter.
- Assess a fistula or graft by looking, feeling for the thrill and listening for the bruit. Loss of both suggests clotting and is reported at once.
- No blood pressure, blood draws or IV starts in the access arm. Dialysis catheters are for dialysis staff only, except in a life-threatening emergency.
- Before and after hemodialysis, check weight and blood pressure, confirm which medications to hold, watch needle sites for bleeding and watch for dialysis disequilibrium.
- In PD, cloudy effluent is treated as peritonitis. Notify the PD unit, send effluent for testing and start antibiotics once specimens are taken.

27.5 Kidney Transplant

- Kidneys made up 59% of the 3,174 organ transplants in Canada in 2025. In 2025, 31% of people removed from wait-lists for any organ had died while waiting.
- Donors may be living (related or unrelated) or deceased. In Ontario, Ontario Health (Trillium Gift of Life Network) coordinates donation, and people aged 16 or older can register online.
- Lifelong immunosuppression prevents rejection (section 21.3). Missed doses raise the risk of rejection, which may cause no symptoms.
- Report fever, less urine, swelling, sudden weight gain, tenderness over the graft or a rising creatinine.
- Teach infection prevention, careful checking of new drugs and lifelong sun protection, because skin cancer is much more common after transplant.

27.6 Kidney Health in Canada and Living Well With CKD

- In Alberta, First Nations adults progressed to kidney failure at two to three times the rate of other adults. The causes are structural: quality of care, access, diabetes burden, water and food insecurity, distance and racism.
- Distinctions-based care does not apply First Nations data to Inuit or Métis people. Use of First Nations data follows OCAP®.
- Community-led screening in Manitoba, under OCAP®, improved testing and specialist care.
- Relocating for dialysis harms people and communities. Home dialysis, satellite units and early referral help.
- Conservative kidney management is active, person-centred care without dialysis. It includes symptom care and advance care planning, and the person can change their mind (Chapter 10).

Key Terms (35)

acute kidney injury (AKI): a sudden fall in kidney function over hours to days, defined by KDIGO by a rise in creatinine or a fall in urine output

acute tubular injury: damage to the kidney tubule cells from prolonged low blood flow, sepsis or toxins; a common form of intrinsic AKI in hospital

albuminuria: albumin in the urine, an early marker of kidney damage; classified by KDIGO as A1, A2 or A3

arteriovenous fistula (AV fistula): a surgical joining of an artery and a vein, usually in the arm, that creates a large, strong vein for hemodialysis needles.

arteriovenous graft (AV graft): a tube of synthetic or biological material that joins an artery to a vein and is used for hemodialysis needles.

bruit: the sound of blood flow through a fistula or graft heard with a stethoscope; normally low-pitched and continuous.

central venous catheter for dialysis: a large catheter in a central vein, usually in the neck, used for hemodialysis and reserved for dialysis staff.

chronic kidney disease (CKD): an abnormality of kidney structure or function lasting more than three months with implications for health, classified by cause, GFR category and albuminuria category

CKD–mineral and bone disorder (CKD–MBD): imbalance of calcium, phosphate, parathyroid hormone and vitamin D in CKD that affects bone and blood vessels

conservative kidney management (CKM): planned, active, person-centred care for kidney failure that does not include dialysis, combining kidney care with palliative care principles.

creatinine: a waste product of muscle activity, filtered by the kidneys; its blood level rises as GFR falls and depends on muscle mass

dialysis disequilibrium syndrome: headache, vomiting, confusion and, in severe cases, seizures caused by brain swelling when urea is removed quickly, most often in early treatments.

dialyzer: the filter in a hemodialysis machine, in which wastes move from the blood across a membrane into dialysate.

effluent: the fluid drained out of the abdomen at the end of a peritoneal dialysis dwell.

erythropoiesis-stimulating agent: a drug that acts like erythropoietin to raise red blood cell production in anemia of CKD

estimated glomerular filtration rate (eGFR): a GFR calculated by the laboratory from serum creatinine, age and sex; in Canada increasingly with the race-free 2021 CKD-EPI equation

glomerular filtration rate (GFR): the volume of plasma filtered by the glomeruli each minute; the main measure of kidney function, reported in mL/min/1.73 m^2

hemodialysis: dialysis in which blood passes through a filter (dialyzer) outside the body to remove wastes and extra fluid, then returns to the body.

interdialytic weight gain: weight gained from fluid between hemodialysis sessions.

intradialytic hypotension: a fall in blood pressure during hemodialysis, linked with rapid fluid removal and with poorer outcomes.

kidney replacement therapy (KRT): treatment that takes over the work of failed kidneys: hemodialysis, peritoneal dialysis or a kidney transplant.

kidney transplant: surgery to place a healthy kidney from a living or deceased donor into a person with kidney failure.

nephron: one of about a million filtering units in each kidney, made up of a glomerulus and a tubule

nephrotoxic: able to damage the kidneys, as some drugs and contrast agents can

oliguria: an abnormally low urine output

peritoneal dialysis (PD): dialysis at home that uses the peritoneum as the filter, with dialysate drained in and out through an abdominal catheter.

peritonitis (PD-related): infection of the peritoneum in a person on peritoneal dialysis, signalled by cloudy effluent and abdominal pain.

postrenal acute kidney injury: AKI caused by blocked outflow of urine

pre-emptive transplant: a kidney transplant done before dialysis has started.

prerenal acute kidney injury: AKI caused by reduced blood flow to the kidneys

rejection: an immune attack on a transplanted organ; acute rejection is most common in the first year and may cause no symptoms.

thrill: the vibration felt over a working fistula or graft; normally soft and continuous.

ultrafiltration: removal of extra water from the blood by pressure during dialysis.

uremia: the effects of wastes retained when the kidneys fail, such as reduced appetite, nausea, fatigue and itch, and in severe cases bleeding, encephalopathy and pericarditis

urine albumin-to-creatinine ratio (ACR): a random urine test, reported in mg/mmol, that measures albumin in the urine and is used to detect and classify kidney damage

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Harjit Gill (Questions 1–6): Mr. Harjit Gill, 81, is on day 2 after surgical repair of a hip fracture on an orthopedic unit. His home medications include ramipril, and ibuprofen was added after surgery for pain. He weighs 70 kg. He has been nauseated and drinking little. Over the last 12 hours his urine output was 300 mL. Blood pressure 102/60 mm Hg (usually about 138/82 mm Hg), heart rate 102 beats/min, respiratory rate 20 breaths/min, temperature 37.4 °C, SpO2 95% on room air. A bladder scan shows 70 mL. Today's results: creatinine 168 µmol/L (82 µmol/L before surgery), potassium 6.1 mmol/L, urea 14.2 mmol/L. His incision is dry, and he rates his pain 3 out of 10 when turning.

1. [CORE] Which findings are most important for the nurse to follow up? Select all that apply.

a. Urine output of 300 mL over the last 12 hours
b. Creatinine of 168 µmol/L, up from 82 µmol/L before surgery
c. Potassium of 6.1 mmol/L
d. Blood pressure of 102/60 mm Hg when his usual reading is about 138/82 mm Hg
e. Pain rated 3 out of 10 when he turns in bed
f. Bladder scan volume of 70 mL
g. Temperature of 37.4 °C

Answer: a, b, c, d — His output is about 0.36 mL/kg per hour, his creatinine has doubled from baseline, his potassium is high and his blood pressure is well below his usual, all cues of acute kidney injury and its complications (a, b, c, d) (section 27.2). Pain of 3 out of 10 on turning (e) is expected and controlled. A bladder scan of 70 mL (f) shows that retention is not the cause. A temperature of 37.4 °C (g) is not a fever and does not change the priority.

2. [CORE] Which explanation best fits Mr. Gill's findings?

a. Urinary retention caused by opioid analgesia, with urine backing up from the bladder into both kidneys
b. Low kidney blood flow from poor intake and a lower blood pressure, worsened by ibuprofen and ramipril
c. Fluid overload from IV fluids given during surgery, diluting his blood and lowering his blood pressure
d. Kidney damage from the iodinated contrast dye that was given for his hip imaging before surgery

Answer: b — Poor intake, a lower blood pressure and two drugs that reduce filtration pressure point to prerenal acute kidney injury (b) (section 27.2). The small bladder scan volume rules out retention (a). Fluid overload (c) would raise weight and cause edema or crackles, not low blood pressure with poor intake. Plain X-ray imaging of a hip fracture does not use iodinated contrast, and nothing in the case suggests he received any (d).

3. [CORE] Which problem should the nurse treat as the highest priority?

a. Risk of a pressure injury from limited movement after hip surgery
b. Risk of constipation from opioid analgesia and reduced activity
c. Risk of delirium related to age, surgery and an unfamiliar setting
d. Risk of a dangerous heart rhythm from the high potassium level

Answer: d — A potassium of 6.1 mmol/L with worsening kidney function can cause a life-threatening rhythm without warning, so it comes first (d) (sections 27.2 and 3.5). Pressure injury (a), constipation (b) and delirium (c) are real risks for an older adult after hip surgery, but none threatens life as quickly.

4. [CORE] Which plan should the nurse propose when reporting to the surgical team?

a. Encourage 3 L of oral fluid today, continue his current medications and repeat the creatinine at his follow-up visit
b. Give the next scheduled ibuprofen dose for pain control and ask the team to review all medications on morning rounds
c. Ask for review of ibuprofen and ramipril, an ECG, repeat electrolytes and creatinine, and hourly urine output monitoring
d. Insert an indwelling urinary catheter now, before calling, so that an exact hourly output is available to report to the team

Answer: c — The plan addresses the likely cause (drugs that reduce kidney blood flow), checks the heart for effects of high potassium and tracks the trend (c) (section 27.2). Forcing a large volume of oral fluid in a nauseated older adult and waiting days (a) delays care. Giving more ibuprofen (b) adds to the injury. A catheter needs a prescription and is not a reason to delay reporting (d).

5. [RN] An ECG shows tall, peaked T waves. The prescriber orders IV calcium gluconate, IV insulin with dextrose, oral sodium zirconium cyclosilicate and IV furosemide. Which should the RN give first?

a. IV calcium gluconate
b. IV insulin with dextrose
c. Oral sodium zirconium cyclosilicate
d. IV furosemide

Answer: a — When high potassium causes ECG changes, IV calcium is given first to protect the heart, although it does not lower the potassium (a) (sections 27.2 and 3.5). Insulin with dextrose (b) shifts potassium into cells and follows calcium. A potassium binder (c) removes potassium more slowly. Furosemide (d) is not a first-line treatment for hyperkalemia and could worsen volume depletion in prerenal kidney injury.

6. [CORE] Which findings 24 hours later best show that Mr. Gill's treatment is working?

a. Urine output 20 mL/h, creatinine 175 µmol/L, potassium 5.6 mmol/L and much less nausea than yesterday
b. Urine output 45 mL/h, creatinine 131 µmol/L, potassium 4.9 mmol/L and blood pressure 126/74 mm Hg
c. Blood pressure 106/62 mm Hg, weight up 2.5 kg since yesterday and new crackles at both lung bases
d. Pain 2 out of 10, potassium 6.0 mmol/L, urine output 25 mL/h and a dry incision

Answer: b — Output above 0.5 mL/kg per hour, a falling creatinine, a normal potassium and a restored blood pressure show recovery (b) (section 27.2). Option a shows worsening kidney function despite less nausea. Weight gain with crackles (c) suggests fluid overload. Better pain control (d) does not offset an unchanged potassium and low output.

7. [CORE] An 88-year-old woman who weighs 44 kg has a serum creatinine of 70 µmol/L. How should the nurse interpret this result?

a. Her kidney function must be normal, because the result is inside the laboratory's reference range

b. Her creatinine is low because she is overhydrated, and her fluid intake should be restricted

c. Low muscle mass can keep creatinine low, so her kidney function may be worse than the result suggests

d. Creatinine does not depend on body size, so the result can be compared directly with a younger adult's

Answer: c — Creatinine comes from muscle, so in a frail person with little muscle a "normal" result can hide reduced kidney function, and eGFR can overestimate it (c) (section 27.1). A result in range (a) does not prove normal function in this case. Nothing suggests overhydration (b). Creatinine does depend on muscle mass (d).

8. [CORE] A patient's urine albumin-to-creatinine ratio is 12 mg/mmol on two tests taken four months apart. How is this albuminuria classified by KDIGO?

a. A1, normal to mildly increased

b. A2, moderately increased

c. A3, severely increased

d. Not albuminuria, because the eGFR has not been reported

Answer: b — An ACR of 3 to 30 mg/mmol is category A2, moderately increased (b) (section 27.3). A1 (a) is below 3 mg/mmol, and A3 (c) is above 30 mg/mmol. Albuminuria is classified on its own, whatever the eGFR (d).

9. [CORE] Which action by the nurse supports an accurate assessment of urine output in a patient at risk of acute kidney injury?

a. Measuring each voiding in a graduated container, noting the time, and relating output to current weight

b. Estimating the volume in the urinal by eye and recording a rounded total to the nearest 100 mL at shift end

c. Recording only the voidings that the patient reports, so that the patient is not disturbed overnight

d. Emptying the catheter bag only when it is full, so that one large volume can be recorded for the shift

Answer: a — AKI is judged by output per kilogram per hour over time, so each volume must be measured, timed and related to the patient's weight (a) (section 27.1). Estimating by eye (b), relying on reports (c) and emptying the bag only when full (d) all make the hourly trend impossible to judge.

10. [CORE] A 76-year-old man has passed no urine for 8 hours. He has lower abdominal discomfort, and the bladder scan shows 850 mL. Which type of acute kidney injury is most likely if his creatinine is rising?

a. Prerenal, from reduced blood flow to the kidneys

b. Intrinsic, from acute tubular injury

c. Intrinsic, from inflammation of the glomeruli

d. Postrenal, from blocked outflow of urine

Answer: d — A full bladder with no urine passed points to obstruction below the kidneys (d) (section 27.2). Prerenal injury (a) comes from low blood flow and would not fill the bladder. Acute tubular injury (b) and glomerular inflammation (c) are causes within the kidney, and neither explains 850 mL of retained urine.

11. [CORE] Which finding meets the KDIGO definition of acute kidney injury?

a. Creatinine rising from 80 to 98 µmol/L over 2 weeks in an outpatient

b. Urine output of 0.6 mL/kg per hour for 8 hours after surgery

c. Creatinine rising from 80 to 110 µmol/L within 36 hours

d. Urea of 9.0 mmol/L in a patient with a normal creatinine

Answer: c — A rise of 26.5 µmol/L or more within 48 hours meets the definition; this rise is 30 µmol/L in 36 hours (c) (section 27.2). Option a is an 18 µmol/L rise, about 1.2 times baseline, over two weeks, which meets neither creatinine criterion. An output of 0.6 mL/kg per hour (b) is above the 0.5 threshold. Urea alone (d) is not a KDIGO criterion.

12. [CORE] An RPN is caring for a patient on day 1 after bowel surgery. Urine output has been 10 mL per hour for 3 hours, and a new potassium result is 6.3 mmol/L. What should the RPN do?

a. Assess the patient, then report at once to the RN and the surgical team using SBAR

b. Wait until 6 hours of low output have passed so that the KDIGO definition is met before reporting

c. Document the findings and pass them on at the end of the shift, because the patient was stable this morning

d. Encourage the patient to drink more fluids and recheck the output in 4 hours before reporting anyone

Answer: a — Every nurse who notices deterioration acts at once and escalates; the RPN assesses, reports using SBAR and consults the RN as the patient's needs change (a) (section 27.2; Chapter 1, section 1.3). Waiting for a definition (b) or until shift end (c) delays treatment of a dangerous potassium. Oral fluids (d) may be unsafe after bowel surgery and do not address the risk.

13. [CORE] A patient with an eGFR of 25 mL/min/1.73 m² is booked for an elective CT scan with IV iodinated contrast. Which statement is consistent with Canadian radiology guidance?

a. Contrast must never be given to anyone whose eGFR is below 60 mL/min/1.73 m², even in an emergency

b. All of the patient's ACE inhibitors and diuretics must be stopped before any contrast scan

c. Creatinine must be rechecked routinely after every contrast scan, for every patient, whatever their eGFR

d. The team considers preventive steps, such as IV fluids, because the eGFR is below 30 mL/min/1.73 m²

Answer: d — Canadian guidance considers prevention only when the eGFR is below 30 mL/min/1.73 m², which applies here (d) (section 27.2). It does not forbid contrast at an eGFR below 60 (a), does not recommend routinely stopping drugs other than metformin at an eGFR below 30 (b), and does not require routine follow-up creatinine tests (c).

14. [CORE] Which patients have a higher risk of acute kidney injury? Select all that apply.

a. A 70-year-old taking furosemide and ramipril who starts ibuprofen for back pain

b. A patient receiving an aminoglycoside antibiotic for several days

c. A patient with severe diarrhea and poor intake for three days

d. A healthy 30-year-old who takes acetaminophen at the recommended dose for a headache

e. A patient with sepsis and low blood pressure

f. A patient with chronic kidney disease scheduled for major surgery

Answer: a, b, c, e, f — An NSAID added to a diuretic and an ACE inhibitor (a), aminoglycosides (b), volume loss (c), sepsis with low blood pressure (e) and chronic kidney disease with major surgery (f) are all KDIGO exposures or susceptibilities (section 27.2). A healthy young adult taking acetaminophen as directed (d) has no added kidney risk from the evidence presented.

15. [CORE] A patient has an eGFR of 52 mL/min/1.73 m² on two tests taken four months apart. How is this GFR category classified?

a. G2, mildly decreased

b. G3a, mildly to moderately decreased

c. G3b, moderately to severely decreased

d. Acute kidney injury, because the eGFR is below 60

Answer: b — An eGFR of 45 to 59 mL/min/1.73 m² for more than three months is category G3a (b) (section 27.3). G2 (a) is 60 to 89, and G3b (c) is 30 to 44. A stable result over four months is chronic, not acute (d).

16. [CORE] Two weeks after starting ramipril, a patient's creatinine has risen from 120 to 138 µmol/L, and potassium is 5.0 mmol/L. What does the nurse understand about this result?

a. The drug must be stopped at once, because any rise in creatinine after starting it means kidney injury

b. The patient should double the dose to protect the kidneys more strongly

c. A small rise is expected; ramipril usually continues unless creatinine rises more than 30% in 4 weeks

d. The potassium result means a potassium binder must be started before the next ramipril dose is given

Answer: c — The rise is 15%, an expected effect of ACE inhibitors; KDIGO advises continuing unless the rise exceeds 30% within 4 weeks (c) (section 27.3). Stopping (a) would lose the kidney protection. Patients never change a dose on their own (b). A potassium of 5.0 mmol/L does not on its own call for a binder (d).

17. [CORE] The nurse teaches a patient with CKD G3b about diet. Which statement shows understanding?

a. "I'll keep my sodium under 2 g a day and choose more plant foods and fewer processed foods."

b. "I should eat as much protein as I can every day, because extra protein helps my kidneys heal."

c. "I need to avoid all fruits and vegetables, because every one of them is high in potassium."

d. "I can use as much table salt as I like, as long as I drink extra water every day."

Answer: a — KDIGO suggests sodium below 2 g a day, plant-based foods and fewer ultra-processed foods, and a dietitian tailors the plan (a) (section 27.3). High protein intake (b) is avoided in people at risk of progression. Plant foods are not banned (c); potassium advice is individualized. KDIGO suggests limiting sodium to below 2 g a day whatever the fluid intake, so drinking extra water does not make unlimited salt safe (d).

18. [CORE] An RPN on a medical unit is caring for a patient with CKD G4. The patient becomes short of breath, with crackles in both lungs, SpO2 89% on room air and a weight 3 kg higher than yesterday. What should the RPN do first?

a. Give the next scheduled diuretic dose early, because the patient clearly has fluid overload and needs it now

b. Restrict the patient's fluids for the rest of the day and reassess the breathing at the end of the shift

c. Document the weight gain and ask the dietitian to review the patient's sodium intake tomorrow

d. Stay with the patient, sit them upright, and call the RN and the physician or rapid response team

Answer: d — Acute shortness of breath with low saturation is deterioration; the RPN acts at once, supports breathing and escalates, and the RPN consults the RN as the patient's needs change (d) (section 27.3; Chapter 6). Giving a dose early (a) needs a prescriber's direction. Fluid restriction alone with delayed reassessment (b) and a dietitian referral (c) do not address an emergency.

19. [RN] A patient's baseline creatinine is 90 µmol/L. Three days after a cardiac arrest, it is 280 µmol/L, and urine output has been 0.4 mL/kg per hour for the last 10 hours. What is the KDIGO stage?

a. Stage 1, because the urine output has been low for less than 12 hours

b. Stage 2, because the creatinine is about twice the baseline value

c. Stage 3, because the creatinine is more than 3.0 times baseline

d. The stage cannot be assigned until 24 hours of urine output are available

Answer: c — 280 ÷ 90 is about 3.1 times baseline, which meets stage 3; the patient is assigned the highest stage reached by either criterion (c) (section 27.2). The urine output alone meets stage 1 (a), but the creatinine criterion is higher. Option b miscalculates the ratio. Staging does not require 24 hours of output (d).

20. [RN] Which finding in a patient with acute kidney injury is an urgent indication to discuss starting dialysis?

a. Potassium of 6.4 mmol/L that persists after shifting treatment and a potassium binder

b. Creatinine of 410 µmol/L in an alert patient with good urine output, clear lungs and normal electrolytes

c. Urea of 22 mmol/L with mild nausea that settles with an antiemetic

d. Urine output of 0.4 mL/kg per hour for 7 hours with stable vital signs, clear lungs and normal potassium

Answer: a — Potassium of 6.0 mmol/L or higher that persists despite medical treatment, including shifting treatment and a binder, is an urgent indication (a) (section 27.2). KDIGO advises against starting dialysis on a single creatinine (b) or urea (c) value alone, and low output (d) without fluid overload, acidosis or uremic complications is not an urgent indication.

Case: Daniel Osei (Questions 21–24): Daniel Osei, 58, has done continuous ambulatory peritoneal dialysis (CAPD) at home for 14 months. He has type 2 diabetes. A practical nurse (PN) from home care visits for a scheduled diabetes check. Daniel says his belly has ached since last night, and the bag he drained this morning looks "milky, like you can't read through it." His temperature is 37.9 °C, heart rate 96, blood pressure 132/78 mm Hg. His capillary blood glucose is 11.2 mmol/L. He says that four days ago his cat jumped onto the table during an exchange and brushed the tubing, but "nothing seemed wrong," so he did not call anyone. The exit site is dry, with no drainage.

21. [CORE] Which finding should the nurse recognize as the most important cue?

a. A capillary blood glucose of 11.2 mmol/L in a person who has type 2 diabetes and uses glucose-containing dialysate

b. A heart rate of 96 and a blood pressure of 132/78 mm Hg measured while he is sitting at home

c. Cloudy drained fluid together with abdominal pain that began last night

d. A dry exit site with no drainage and no change since the home care nurse's last visit

Answer: c — Cloudy effluent with abdominal pain meets the clinical criterion for PD-related peritonitis, and the ISPD guideline says cloudy effluent is treated as peritonitis until proven otherwise (section 27.4, Peritoneal Dialysis). A glucose of 11.2 mmol/L (a) is worth noting, because dialysate glucose is absorbed and infection raises glucose, but it is not the main cue. A heart rate of 96 (b) is a little high and fits infection, but on its own it does not identify the problem. A dry exit site (d) is reassuring and makes an exit-site infection less likely. It does not rule out peritonitis.

22. [CORE] What should the nurse do first?

a. Call the PD unit or nephrologist now, and keep the drained fluid for testing as the unit directs

b. Have him drain and discard the cloudy bag, do a fresh exchange and phone the clinic if the next bag is also cloudy

c. Encourage oral fluids and rest, give acetaminophen for the pain and recheck the effluent at tomorrow's visit

d. Teach him to clean the exit site twice a day and arrange for the home care team to check it again in 2 days

Answer: a — Cloudy effluent is presumed to be peritonitis. The PD team is notified at once so effluent can be sent for a Gram stain, a cell count with differential and a culture, and antibiotics can start (section 27.4). Discarding the bag and waiting for the next one (b) delays diagnosis and loses the specimen. Fluids, rest and acetaminophen with a recheck tomorrow (c) let a serious infection progress and can mask fever. Exit-site cleaning (d) does not treat infection of the peritoneum, and the exit site looks healthy.

23. [CORE] The PD nurse arranges for testing. Which statement by Daniel shows he understands the plan?

a. "I'll hold off on antibiotics until the lab confirms which germ is growing, so I get the right one."

b. "Because the fluid is cloudy, they'll probably need to take my catheter out today to clear the infection."

c. "The fluid will clear up once my blood sugar is back under control, so I need to watch my diet."

d. "Once they take a sample of my drained fluid, the antibiotics start right away, before the results are back."

Answer: d — The ISPD guideline starts antibiotics as soon as effluent specimens are collected, without waiting for results (section 27.4). Waiting for culture results (a) delays treatment of a serious infection. Catheter removal (b) is not the first step; it is considered when peritonitis does not respond to appropriate antibiotics. Blood glucose control (c) matters but does not clear an infection.

24. [CORE] Daniel asks how to prevent another episode. Which teaching should the nurse give?

a. "Soak in a warm bath each evening to keep the skin around the exit site clean and soft."

b. "Wash your hands before and after each exchange and after touching your cat, and call the PD unit at once if the tubing is touched."

c. "Gently pull off any crust at the exit site each day so bacteria cannot hide underneath it."

d. "You only need to call the PD unit if your temperature goes above 39 °C, because a little cloudiness in the drained bag is common and usually clears on its own."

Answer: b — The ISPD guideline stresses careful hand washing before and after exchanges and after handling pets, and tells patients to contact their dialysis centre right away after a possible contamination (section 27.4). Soaking the exit site in a bath (a) can cause exit-site infection and peritonitis. Crusts are not pulled off (c). Cloudy effluent is never normal and needs a call whether or not there is fever (d).

25. [CORE] The nurse assesses a newly admitted patient's right forearm AV fistula, which was used for dialysis yesterday. Which finding is expected?

a. A high-pitched bruit heard only in short pulses, with a strong thrill felt in a single small spot

b. A low-pitched, continuous whooshing bruit with a soft vibration felt along the access

c. No vibration over the access, with a firm, cord-like vein and a faint pulse below the fistula

d. A cool, pale right hand with numb fingertips that improves when the arm hangs down

Answer: b — A normal fistula has a soft, continuous thrill and a low-pitched, continuous bruit (section 27.4, Hemodialysis and Vascular Access). A high-pitched, pulsing bruit and a localized strong thrill (a) suggest narrowing. A missing thrill with a firm vein (c) suggests clotting. A cool, pale, numb hand (d) suggests the access is stealing blood from the hand and is reported.

26. [CORE] A patient has a left forearm AV fistula. A student nurse plans to take the patient's blood pressure on the left arm because the right arm is bruised from yesterday's blood work. What should the nurse tell the student?

a. "The left arm is fine today, because the fistula is in the forearm and the cuff goes on the upper arm."

b. "Use the left arm, but inflate the cuff slowly and only partly so that the fistula is not damaged."

c. "Use the right arm with the cuff away from the bruise, or another limb as policy allows. Never use the fistula arm."

d. "Ask the patient which arm they prefer, because both arms are equally safe for a single reading."

Answer: c — No blood pressure readings, blood draws or IV starts are done in the arm with a fistula (section 27.4). Bruising is not a reason to use the access arm; the nurse uses the other arm or another suitable limb as agency policy allows. Using the fistula arm (a, b), whatever the cuff position or speed of inflation, risks damaging or clotting the access. The patient's preference (d) does not override access protection.

27. [CORE] At 0600, the nurse cannot feel a thrill or hear a bruit over a patient's left arm AV graft. Both were present at 2200. What should the nurse do?

a. Report the finding to the dialysis team or prescriber now, because the graft may have clotted

b. Apply a warm compress for 20 minutes and recheck the thrill at the next scheduled assessment

c. Gently massage along the graft for several minutes to restart the flow, then document the result in the chart

d. Raise the arm on a pillow and recheck at 1000, before the scheduled dialysis run

Answer: a — Loss of thrill and bruit suggests the access has clotted. Prompt reporting gives the best chance of restoring flow before the next treatment (section 27.4). Warm compresses (b), massage (c) and waiting until a later check (d) delay treatment, and massage could dislodge a clot.

28. [CORE] A patient returns to the medical unit after hemodialysis. Which finding needs the nurse's action first?

a. The patient feels tired and wants to sleep until lunch

b. The patient's weight is 2.1 kg less than before the treatment

c. The patient asks when the dietitian will visit to talk about fluid limits

d. Bright red blood is soaking through the dressing over a needle site

Answer: d — Bleeding from a needle site needs light, direct pressure right away, and bleeding that does not stop is reported (section 27.4). Fatigue after dialysis (a) is common. A weight loss after treatment (b) reflects fluid removed by ultrafiltration and is expected. The dietitian question (c) is important but not urgent.

29. [CORE] A patient receives hemodialysis at 0900. At 0800 the nurse is due to give an antihypertensive medication. What should the nurse do?

a. Give the medication on time, because skipping a dose could make blood pressure rise during dialysis

b. Give half the dose now and the rest after dialysis to balance the risks

c. Check with the prescriber or dialysis unit whether to give or hold the medication before dialysis

d. Hold the medication without telling anyone, because all medications are held on dialysis days

Answer: c — Blood pressure drugs taken just before dialysis add to the risk of low blood pressure during treatment. The prescriber decides which drugs to give or hold on dialysis days (section 27.4). Giving it automatically (a) ignores this risk. The nurse never changes a dose without an order (b). Holding it without a prescriber decision or communication (d) is unsafe, and not every medication is held.

30. [CORE] A patient with kidney failure asks how peritoneal dialysis differs from hemodialysis. Which response is accurate?

a. "Peritoneal dialysis is done at home every day. The lining of your abdomen is the filter, and fluid flows in and out through a catheter."

b. "Peritoneal dialysis cleans your blood through a machine at the hospital two times a week, using needles placed in a fistula in your arm."

c. "Peritoneal dialysis removes fluid only. You would still need hemodialysis once a week to clear wastes."

d. "Peritoneal dialysis is only used for a few weeks after acute kidney injury. It is not a long-term option."

Answer: a — PD uses the peritoneum as the filter. Exchanges are done at home every day, by hand (CAPD) or by cycler overnight (APD) (section 27.4). In-centre treatment through a fistula (b) describes hemodialysis. PD removes both wastes and fluid (c). PD is a long-term home therapy, used by about 18% of people on dialysis in 2024 (CORR figures excluding Quebec) (d).

31. [CORE] A patient with a tunnelled dialysis catheter in the right internal jugular vein needs blood work and an IV antibiotic. The peripheral veins are difficult. Which action is appropriate?

a. Draw the blood and connect the antibiotic through the dialysis catheter, using sterile technique

b. Flush the dialysis catheter with saline before and after each use so it can serve as the main IV line

c. Ask the dialysis unit to remove the catheter so a peripherally inserted central catheter can be placed in the arm

d. Seek peripheral access or other help, following agency policy, and leave the dialysis catheter for dialysis staff only

Answer: d — A dialysis catheter is for dialysis only and is used only by trained, authorized staff, except in a life-threatening emergency, because of the risk of infection, bleeding, clots and air embolism (section 27.4). Using it for routine care (a, b) breaks this rule. Removing the dialysis access (c) is not appropriate, and PICCs are avoided in people with advanced CKD to protect veins for a future fistula.

32. [CORE] A patient had a kidney transplant 1 year ago. Which teaching about skin protection should the nurse give?

a. "Your skin cancer risk returns to normal after the first year, so using sunscreen on summer holidays is enough from now on."

b. "Limit sun exposure for life, use sunscreen and protective clothing, and report any new spot on your skin or lips."

c. "Tanning beds are safer than the sun, so use one if you want a tan before your trip."

d. "Skin checks are needed only if a family member has had skin cancer in the past."

Answer: b — Kidney transplant recipients have a much higher rate of skin cancer than the general population. They are taught to limit sun exposure for life, use ultraviolet protection, check their skin and lips and report new lesions (section 27.5). The risk does not return to normal after a year (a). Tanning beds are another source of ultraviolet light (c). The risk applies to every recipient, not just those with a family history (d).

33. [CORE] A man who had a kidney transplant 6 months ago says, "I feel great, so sometimes I skip my evening immunosuppressant." Which response is best?

a. "That's fine as long as you never miss your morning dose."

b. "Ask your family doctor to switch you to once-a-month dosing."

c. "Feeling well means your new kidney has fully accepted your body, so you can stop the medication after talking to your pharmacist."

d. "Missing doses can trigger rejection even when you feel well. What makes the evening dose hard to take?"

Answer: d — Rejection may cause no symptoms. Missed immunosuppressant doses can trigger it, so the nurse explains the risk and explores barriers to adherence (section 27.5). Skipping evening doses (a) and stopping the medication (c) both risk rejection. Dosing decisions belong to the transplant team, and the suggested change (b) is not an option.

34. [CORE] Which statement about conservative kidney management (CKM) is accurate?

a. CKM is active, planned care that treats symptoms and slows kidney decline without dialysis, and the person can change their decision

b. CKM means stopping all kidney care, blood work and medications so that the person can be discharged home with comfort measures only

c. CKM is offered only to people who have been on dialysis for at least a year and are no longer benefiting

d. CKM is chosen by the nephrologist when dialysis is unavailable, and the family cannot ask to change the plan

Answer: a — CKM is an active treatment choice. It includes slowing kidney decline, managing complications and symptoms, psychosocial support and advance care planning, and the person can change their mind (section 27.6). It is not a withdrawal of care (b). It can be chosen by people who have never had dialysis (c). It is a shared, person-centred decision, not one imposed by the nephrologist (d).

35. [CORE] Which statement best reflects a distinctions-based, structural understanding of kidney failure among First Nations adults?

a. First Nations people have a genetic tendency toward kidney failure, so screening and earlier treatment in the community are not likely to change outcomes.

b. In Alberta, First Nations adults had more kidney failure and less urine albumin testing, which the authors linked to quality of care and specialist access.

c. Kidney data from First Nations studies can be applied directly to Inuit and Métis patients, because the causes and the health systems involved are the same.

d. Higher rates of kidney failure in First Nations communities are mainly due to people choosing not to attend clinic visits or follow treatment plans.

Answer: b — The Alberta study found progression rates two to three times higher and less albumin testing among First Nations adults, and the authors point to quality of care and specialist access. These are structural causes, not biology (section 27.6). A genetic explanation (a) treats race as biology. Distinctions-based care does not apply First Nations data to Inuit or Métis people (c). Blaming individual choices (d) ignores structural causes such as distance and systemic racism.

36. [CORE] An RPN on a medical unit is assigned a patient on peritoneal dialysis who needs an exchange at 1400. The RPN has never been taught to do PD exchanges. What should the RPN do?

a. Do the exchange by following the steps printed on the dialysate bag, then document it

b. Ask the patient to do the exchange alone, because patients on home PD are trained to do their own exchanges every day

c. Tell the charge nurse now and ask for a nurse who is competent and authorized to do the exchange on time

d. Skip the 1400 exchange and ask the night nurse to add extra dialysate time to make up for it

Answer: c — Under CNO's framework, the nurse needs competence as well as authority. An RPN who has not been taught does not do the exchange alone. The RPN asks for help in good time and makes sure the treatment is not missed (section 27.6, Scope in Practice). Following printed steps (a) does not give competence. A patient who is acutely ill may not be able to do their own exchange safely, and agency policy decides whether they can (b). Skipping an exchange or changing the prescription (d) is unsafe.

37. [CORE] The nurse is teaching a patient who has a new AV fistula how to care for it. Which instructions should the nurse include? Select all that apply.

a. Check for the buzz (thrill) over the fistula every day

b. Do not wear tight watches or sleeves on the fistula arm

c. Allow blood to be drawn from the fistula arm if the veins in the other arm are hard to find

d. Avoid sleeping on the fistula arm

e. Report redness, warmth, swelling, pain, bleeding or a change in the thrill

f. After dialysis, hold light pressure on each needle site for about 10 minutes, or as your team teaches

g. Keep the fistula arm bent for long periods to rest the vessels

Answer: a, b, d, e, f — Daily thrill checks (a), avoiding tight clothing or watches (b), not sleeping on the arm (d), reporting warning signs (e) and holding light pressure after dialysis (f) all protect the fistula (section 27.4, Patient Education box). Blood draws in the fistula arm (c) are not allowed. Keeping the arm bent for long periods (g) is to be avoided.

38. [RN] A patient on hemodialysis gained 4.5 kg since the last treatment and took his usual antihypertensive before arriving. Ninety minutes into dialysis, his blood pressure falls from 148/86 to 84/50 mm Hg, and he has leg cramps and nausea. Which explanation best fits these findings?

a. Fluid is being removed from the blood faster than it can refill from the tissues, made worse by the antihypertensive

b. Potassium is rising quickly as it moves from the dialysate into the blood, which lowers blood pressure

c. Urea is moving from the dialysate into the blood, which pulls fluid into the brain and lowers pressure

d. The dialyzer is removing red blood cells with the fluid, which causes sudden anemia and a drop in pressure

Answer: a — A large interdialytic weight gain requires fast ultrafiltration. When refilling of the blood vessels cannot keep up, blood pressure falls, and antihypertensives taken before treatment add to the risk (section 27.4, Going Deeper box). Potassium moves out of the blood into dialysate, so its level falls (b). Urea moves out of the blood, not in (c), and dialysis disequilibrium causes neurologic symptoms, not this picture. The dialyzer membrane does not remove red blood cells (d).

39. [RN] Which group of findings 5 months after a kidney transplant most strongly suggests rejection and needs prompt reporting to the transplant team?

a. Mild hand tremor, a craving for sweets and a small increase in appetite since the last clinic visit

b. A runny nose and sneezing for 2 days, with normal temperature, urine output and blood pressure

c. Rising creatinine, less urine, a 2 kg weight gain over 3 days and tenderness over the transplanted kidney

d. A creatinine that is 3 micromol/L higher than last week, with no other change in symptoms or output

Answer: c — Rising creatinine, less urine, sudden weight gain and tenderness over the graft are signs the Ottawa Hospital teaches recipients to report as possible rejection (section 27.5). Tremor and appetite changes (a) may be drug adverse effects (section 21.3) but do not suggest rejection. Cold symptoms with normal findings (b) are less concerning, although infection is still watched closely. A very small change in creatinine (d) can reflect hydration, medications or test timing, and the transplant team judges its meaning.

40. [RN] An 86-year-old woman with kidney failure, heart failure and frailty chooses conservative kidney management. Her son says, "So we're just giving up on her." Which response by the nurse is best?

a. "Dialysis would not help her at her age, so there is nothing else the team can offer."

b. "This is active care. We will keep treating her symptoms, slow her kidney decline, plan ahead with her and support you. She can change her mind."

c. "I understand how you feel. I will ask the nephrologist to arrange dialysis for tomorrow so that the whole family can feel better about the plan."

d. "She has made her decision, so the family will not be part of her care planning from now on."

Answer: b — CKM is planned, active, person-centred care. It continues measures to slow decline, manages symptoms, includes advance care planning and family support, and the person may change the decision (section 27.6). Saying nothing more can be offered (a) is inaccurate and takes away hope. Starting dialysis against the patient's informed choice (c) ignores her autonomy and capacity (Chapter 1, section 1.5). Excluding the family (d) contradicts the supportive, family-centred nature of CKM, within the limits of the patient's privacy wishes.

28 Urinary Tract and Prostate Disorders

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Recognize and care for adults with urinary tract infection, collect urine specimens correctly, and distinguish asymptomatic bacteriuria from infection.
2. Use urinary catheters only when indicated, insert and maintain them safely, and prevent catheter-associated urinary tract infection.
3. Assess and manage urinary retention and the main types of urinary incontinence, with attention to dignity and older adults.
4. Care for adults with kidney stones, including recognizing an obstructed, infected kidney as an emergency.
5. Care for patients with benign prostatic hyperplasia and after prostate surgery, including continuous bladder irrigation and TUR syndrome, using the CJMM.
6. Support patients with prostate and bladder cancer, including informed discussion of PSA screening and urostomy care.
7. Distinguish RN and RPN roles in catheter, bladder and prostate care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5	Clinician; Scholar	Foundations of Practice
3, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Problems of the bladder and urinary tract are among the most common reasons adults need nursing care, and among the most private. A person with burning on urination, leakage when they cough, a bladder that will not empty or blood in the urine may feel embarrassed to say so. A calm, matter-of-fact approach from the nurse makes it easier for the person to describe what is happening and to accept care. These problems are common: about 3.3 million Canadians, roughly 10% of the population, experience urinary incontinence (Bettez et al., 2012).

Much of the nursing work in this area is about doing less, wisely. Urine tests sent without symptoms lead to antibiotics that do not help and can harm, and urinary catheters left in without a reason cause infection and injury (Choosing Wisely Canada, n.d.; Leis & Soong, 2019). Nurses decide when to collect specimens, notice catheters that are no longer needed and check that the bladder still empties after a catheter comes out.

This chapter is the book's home for the lower urinary tract and the prostate. Section 28.1 covers urinary tract infection, urine specimens and asymptomatic bacteriuria. Section 28.2 covers urinary catheters and the prevention of catheter-associated infection, and section 28.3 covers urinary retention and incontinence. The second half of the chapter turns to kidney stones (28.4), benign prostatic hyperplasia and prostate surgery (28.5), and prostate and bladder cancer (28.6).

The chapter builds on earlier ones. Scope of practice and the Clinical Judgment Measurement Model (CJMM) are taught in Chapter 1 (sections 1.3 and 1.4), and dignity and cultural safety in Chapter 2. Kidney tests, including the basic urinalysis, are in section 27.1. Specimen collection, infection prevention and control (IPAC), antimicrobial stewardship and sepsis are in Chapter 4, pain in Chapter 5, postoperative urinary retention in section 7.6, delirium in section 8.2 and skin care for incontinence in Chapter 35.

28.1 Urinary Tract Infection

Cystitis, Pyelonephritis and Urosepsis

A **urinary tract infection (UTI)** is an infection anywhere from the urethra to the kidneys. Most begin when bacteria from the skin around the urethra travel up into the bladder. **Cystitis** is infection limited to the bladder. **Pyelonephritis** is infection that has reached the kidney, and it is more serious. When a UTI triggers a dysregulated body-wide response with organ dysfunction, the result is **urosepsis**, sepsis that starts in the urinary tract (section 4.6).

Women have a short urethra that opens near the vagina and anus, so bacteria reach the bladder more easily. Other risks the nurse looks for are an indwelling catheter, for which the length of time it stays in is the most important risk factor (Patel et al., 2023); a bladder that does not empty fully, which is linked with repeated UTIs and pyelonephritis (Stoffel et al., 2016); a blockage such as a kidney stone (section 28.4); and recent urologic procedures.

Cystitis usually causes new **dysuria** (pain or burning on urination), urgency, frequency, pain above the pubic bone, and sometimes visible blood in the urine or new incontinence (Choosing Wisely Canada, n.d.). Pyelonephritis adds signs that infection has moved beyond the bladder: fever, shaking chills (rigors) and pain in the flank or tenderness at the **costovertebral angle**, the angle between the lowest rib and the spine. A 2025 guideline from the Infectious Diseases Society of America (IDSA) now classes a UTI as complicated mainly by bedside signs that infection has spread beyond the bladder, especially fever (Trautner et al., 2025).

Fever with rigors, a rising heart rate or breathing rate, low blood pressure, new confusion or falling urine output in a patient with a suspected UTI may signal urosepsis. Any nurse who notices these changes acts at once and escalates through the early warning and rapid response process (sections 6.1 and 6.2) while sepsis care begins (section 4.6). Fever and flank pain in a person with a known kidney stone may mean an obstructed, infected kidney, which needs urgent drainage (section 28.4).

Specimens and Urinalysis

A **midstream clean-catch specimen** is urine collected from the middle of the stream after the genital area has been cleaned, so that the first urine flushes skin bacteria away. The nurse teaches the person to wash their hands, open the sterile container without touching the inside and clean the area with the towelettes provided. A person with a vulva sits well back on the toilet, holds the labia apart throughout and wipes with downward strokes. A person with a penis retracts the foreskin, if present, and wipes the head of the penis. The person starts to void into the toilet, moves the container into the stream without stopping, fills it one-half to three-quarters full and finishes in the toilet. The specimen is labelled with two identifiers and the date and time, and reaches the laboratory within 2 hours or is refrigerated (Alberta Precision Laboratories [APL], 2020).

For a patient with an indwelling catheter, the nurse disinfects the sampling port, briefly clamps the tubing below it and withdraws urine with a sterile syringe. Urine for culture is never taken from the drainage bag, and the closed system is not opened (APL, n.d.; Centers for Disease Control and Prevention [CDC], 2009). Section 4.2 shows the steps.

A urine dipstick gives quick results for several chemicals; two relate to infection. **Leukocyte esterase** is an enzyme from white blood cells, so a positive result suggests **pyuria**, white blood cells in the urine. **Nitrites** form when certain bacteria convert nitrate in the urine. A dipstick is better at ruling infection out than in: in adults without added risk factors, negative nitrite and leukocyte esterase results reliably exclude UTI (Corcos et al., 2017). A positive result proves little, because pyuria and bacteria are also common without infection (Nicolle et al., 2019). Choosing Wisely Canada advises against using a dipstick or urinalysis to diagnose UTI in long-term care, and its clinician leads recommend that dipsticks not be used for adults older than 65 in any setting (Choosing Wisely Canada, n.d.; Leis et al., n.d.).

A **urine culture** identifies the organism, counts it and tests which antibiotics work against it (susceptibility). It is collected before the first antibiotic dose. Choosing Wisely Canada advises against sending a culture routinely on admission or at a check-up, or because urine looks dark, cloudy or smells strong, or because behaviour has changed. A culture is sent when minimum criteria for UTI are met. For a long-term care resident without a catheter, these are new dysuria alone, or two or more new findings from a short list: fever, urgency, frequency, suprapubic pain, flank pain, visible blood in the urine or new incontinence (Choosing Wisely Canada, n.d.; Leis et al., n.d.).

GOING DEEPER

Reading a Urinalysis and Urine Culture

Required for RN students; optional for PN students.

Reference ranges vary by laboratory. One Canadian laboratory lists nitrite and leukocyte esterase as normally negative, specific gravity as 1.005 to 1.030 and pH as 5.0 to 8.0 (University Health Network [UHN], n.d.).

- **Nitrite:** Some gram-negative bacteria convert nitrate from the diet into nitrite, but only if urine has stayed in the bladder for about 4 hours or more. *Enterococcus* and some other organisms do not make nitrite, so a negative result does not exclude bacteriuria (Beaumont Hospital, 2023).
- **Leukocyte esterase:** a marker of pyuria. Pyuria occurs with both infection and asymptomatic bacteriuria, so it cannot tell them apart (Nicolle et al., 2019).
- **Colony count:** Growth of 10^8 colony-forming units (CFU) per litre (10^5 CFU/mL) or more is the usual threshold for significant bacteriuria, in voided and catheter specimens alike. In women without symptoms, the IDSA asks for two consecutive specimens before calling it asymptomatic bacteriuria, because many first results do not persist (Nicolle et al., 2019).
- **Number of organisms:** Surveillance definitions of catheter infection count only cultures with one or two organisms (Patel et al., 2023).
- **Susceptibility:** The nurse checks that the ordered antibiotic matches the report and tells the prescriber when it does not, or when the culture is negative (Choosing Wisely Canada, n.d.).

Asymptomatic Bacteriuria

Asymptomatic bacteriuria (ASB) is bacteria in the urine, at the threshold above, in a person without signs or symptoms of UTI. It applies whether or not pyuria is present (Nicolle et al., 2019). It is common, especially in older adults: as many as half of long-term care residents have it (Choosing Wisely Canada, n.d.).

ASB is not an infection that needs treatment. The IDSA guideline recommends against screening for or treating it in healthy non-pregnant women, older adults with functional impairment living in the community, older adults in long-term care, people with diabetes or spinal cord injury, people with short- or long-term indwelling catheters, kidney transplant recipients after the first month, and patients having non-urologic surgery (Nicolle et al., 2019). Antibiotics given for ASB do not help the person and can cause harm, including adverse drug effects, *Clostridioides difficile* infection and antimicrobial resistance (Choosing Wisely Canada, n.d.; section 4.4). The two main exceptions are pregnancy (Chapter 29) and urologic procedures that break the lining of the urinary tract, before which ASB is screened for and treated (Nicolle et al., 2019).

The hardest case is the older adult who becomes confused or falls and has a positive urine test. When there are no urinary or systemic signs such as fever or low blood pressure, the IDSA recommends looking for other causes and observing carefully rather than giving antibiotics. If fever or other signs of sepsis appear without a clear source, broad antibiotics that cover urinary and other sources are started (Nicolle et al., 2019). The Lifespan box and section 8.2 describe the approach.

LIFESPAN CONSIDERATIONS

Older Adults, Confusion and the Urine Test

Many older adults, especially in long-term care, have bacteria in the urine without infection (Choosing Wisely Canada, n.d.). A positive dipstick or culture is therefore expected in many and does not explain a change in health. Bacteriuria and delirium often occur together, but a causal link has not been shown, and treating bacteriuria in delirium without sepsis has not improved mental status (Leis et al., n.d.).

When an older adult becomes newly confused, sleepy or agitated, or falls, the nurse:

- screens for delirium and looks for other causes: dehydration, constipation, urinary retention, pain, new or changed medications, poor sleep and infection elsewhere (section 8.2);
- examines the perineal skin and offers fluids if urine is dark or strong-smelling, then reassesses (Choosing Wisely Canada, n.d.);
- sends a urine culture only when minimum criteria for UTI are met;
- listens to family concerns, explains the possible causes and why a urine test may not help (Choosing Wisely Canada, n.d.).

> Fever with a rising heart rate, falling blood pressure or other signs of sepsis is a different situation: the nurse escalates at once (section 4.6).

Treatment and Teaching

Antibiotic choice depends on the type of UTI, local resistance patterns, allergies, kidney function and culture results. For acute uncomplicated cystitis in women, the IDSA guideline names nitrofurantoin, fosfomycin and, where local resistance is low, trimethoprim-sulfamethoxazole as appropriate choices. Fluoroquinolones such as ciprofloxacin work well but are reserved for more important uses, and beta-lactam antibiotics are alternatives when the preferred drugs cannot be used (Gupta et al., 2011). The four conditions in this section are compared side by side (Table 28.1).

For pyelonephritis, a urine culture with susceptibility testing is always done (Gupta et al., 2011). Patients well enough to stay home may take an oral antibiotic such as ciprofloxacin when local resistance allows; patients admitted to hospital start with intravenous (IV) therapy (Gupta et al., 2011). The 2025 IDSA guideline suggests switching to an oral antibiotic once the patient is improving and can take one, notes that options such as first-generation cephalosporins (for example, cephalexin) are less well studied but may suit some patients, and favours about 7 days of treatment for many patients rather than 10 to 14 (Trautner et al., 2025). All of these drugs are marketed in Canada (Health Canada, 2026).

Nursing care with the CJMM. For a patient admitted with pyelonephritis, the nurse *recognizes cues* such as temperature, heart rate, blood pressure, mental status, flank pain and urine output, and *analyzes* them against the patient's baseline and kidney tests (section 27.1). When cues point that way, the nurse *prioritizes* the hypotheses of sepsis or an obstructed kidney over simple infection. The nurse *generates solutions* and *takes action* with the team: antibiotics, fluids and pain relief as ordered, and early escalation. In *evaluating outcomes*, the nurse expects fever, pain and appetite to improve as treatment works, and reports a patient who is not improving, because a complication such as obstruction may need imaging and drainage (section 28.4).

The nurse gives antibiotics on time, checks culture results and helps the team reassess treatment within about 3 days, stopping it if the culture taken before treatment is negative (Choosing Wisely Canada, n.d.). These are core stewardship actions (section 4.5). The nurse also encourages fluids unless restricted, offers pain relief (Chapter 5) and monitors temperature, vital signs and intake and output.

Teaching covers how to take the antibiotic exactly as prescribed, not to save or share leftover tablets, and to seek care if fever, flank pain or vomiting develop or symptoms are not improving. Many people ask about cranberry products. A 2023 Cochrane review found that they probably reduce symptomatic, culture-confirmed UTIs in women with recurrent UTIs, but the evidence does not support them for older adults in institutions, people with bladder-emptying problems or pregnant people. Products and doses varied widely (Williams et al., 2023).

Table 28.1 Asymptomatic bacteriuria, cystitis, pyelonephritis and urosepsis compared (Nicolle et al., 2019; Gupta et al., 2011; Trautner et al., 2025; Choosing Wisely Canada, n.d.)

Condition	Typical findings	Culture or antibiotics?	Nursing focus
Asymptomatic bacteriuria	Bacteria in urine with no urinary symptoms, fever or systemic signs; pyuria may be present	No screening and no antibiotics, except in pregnancy and before urologic procedures that break the mucosa	Look for other causes of any change in health; avoid dipsticks and routine cultures; explain to families
Cystitis	New dysuria, urgency, frequency, suprapubic pain, visible blood or new incontinence; no fever or flank pain	Antibiotics such as nitrofurantoin, fosfomycin or trimethoprim-sulfamethoxazole as ordered; culture as ordered, and before treatment in long-term care	Correct specimen technique; fluids; antibiotic teaching; reassess within about 3 days
Pyelonephritis	Fever, rigors, flank pain or costovertebral angle tenderness, with or without bladder symptoms	Culture and susceptibility always; oral or IV antibiotics depending on severity; often about 7 days	Vital signs, intake and output; antibiotics on time; watch for sepsis; report fever with a known stone at once

Condition	Typical findings	Culture or antibiotics?	Nursing focus
Urosepsis	UTI with signs of organ dysfunction such as new confusion, low blood pressure, fast breathing or low urine output	Cultures, then IV antibiotics without delay	Escalate at once; sepsis care (section 4.6); team looks for an obstruction that needs drainage

28.2 Urinary Catheters and CAUTI Prevention

Indwelling Catheters

An **indwelling urinary catheter** is a flexible tube passed through the urethra (or, for a suprapubic catheter, through the lower abdominal wall) into the bladder and held in place by an inflated balloon (Figure 7.3 shows a catheter being prepared for insertion). It drains urine continuously into a closed bag. Catheters are useful but carry real harm. UTIs are among the most common health care-associated infections, and the length of time a catheter stays in is the strongest single risk factor for infection (Patel et al., 2023). Catheters also tether patients to the bed, which adds to functional decline and delirium in older adults (sections 8.2 and 8.4).

Catheters are often used without a good reason. A review of inpatients at Sunnybrook Health Sciences Centre, a Toronto hospital, found that 18% had a urinary catheter, and 69% of them had no appropriate guideline-based reason (Leis & Soong, 2019). Studies cited in the same toolkit found that physicians did not know their patient had a catheter in as many as 40% of cases.

Appropriate indications. The United States Centers for Disease Control and Prevention (CDC) guideline, which Canadian programs draw on, gives these examples (CDC, 2009):

- sudden inability to void (acute retention) or a blockage at the bladder outlet;
- accurate measurement of urine output in critically ill patients;
- selected surgical procedures, with removal as soon as possible afterward, preferably within 24 hours;
- helping open sacral or perineal wounds heal in patients with incontinence;
- prolonged immobilization, such as after trauma;
- comfort at the end of life.

The Choosing Wisely Canada toolkit adds continuous bladder irrigation for visible blood in the urine (section 28.5), a long-term catheter already in place before admission, spinal cord injury and some pelvic cancer surgery (Leis & Soong, 2019).

Inappropriate uses include managing incontinence in place of nursing care, collecting urine from a patient who can void, measuring a post-void residual, continuing a catheter after surgery without a reason, and convenience (CDC, 2009; Leis & Soong, 2019). Delirium, dementia and being confined to bed are not indications on their own.

Insertion. In Ontario, inserting a catheter is a controlled act authorized to registered nurses (RNs) and registered practical nurses (RPNs); it needs an order or medical directive unless the nurse has authority to initiate it (College of Nurses of Ontario [CNO], 2025c; section 28.6, Scope in Practice box). The nurse explains the procedure, gains consent and protects privacy (Chapter 1; Chapter 2). In acute care, the nurse performs hand hygiene and uses aseptic technique with sterile equipment, including a single-use lubricant, and a new sterile kit for each attempt (CDC, 2009; Leis & Soong, 2019). The smallest catheter that drains well limits urethral injury, and the catheter is secured after insertion to prevent movement and pulling on the urethra (CDC, 2009).

Maintenance. The CDC (2009) and the Society for Healthcare Epidemiology of America compendium (Patel et al., 2023) set out these practices:

- Keep the drainage system closed. If it is opened, disconnected or leaking, replace the catheter and bag using aseptic technique.
- Keep urine flowing: no kinks or loops in the tubing.
- Keep the bag lower than the bladder throughout, including during transfers and walks, and never rest it on the floor.
- Empty the bag regularly into a separate clean container for each patient, without letting the spout touch the container (Figure 28.1).

- Clean the meatus during routine bathing; antiseptic cleaning around the catheter does not prevent infection.
- Do not change catheters or bags at fixed intervals, and do not use routine bladder irrigation or preventive antibiotics.

Review and removal. Every day, the nurse asks whether each catheter still has an indication, and the team reviews it on rounds (Patel et al., 2023). Many hospitals use a **nurse-driven catheter removal protocol**, often a medical directive, that lets nurses remove a catheter when no listed indication remains, and the compendium recommends considering one (Patel et al., 2023). Other tools are reminders and orders that expire unless renewed (Leis & Soong, 2019). After removal, the nurse checks that the patient voids and that the bladder empties (section 28.3).

Going home with a catheter. Some patients leave hospital with an indwelling catheter, for example after prostate surgery or with chronic retention. The nurse teaches hand hygiene before and after touching the catheter or bag, keeping the bag below the bladder and the tubing free of kinks, securing the catheter, cleaning the meatus during daily washing and emptying the bag regularly (CDC, 2009). The patient also learns how to change between a daytime leg bag and a larger night bag, and to report fever, flank pain, no drainage for several hours or leaking around the catheter. Home and community care nurses often continue this teaching (section 1.7).

Figure 28.1 Emptying a urinary drainage bag: the spout drains into a separate measuring container without touching it, and the bag stays below the level of the bladder. (credit: "Empty the Urinary Drainage Bag" by BruceBlaus/Wikimedia Commons, CC BY-SA 4.0)

CLINICAL SAFETY

Lose the Tube

Lose the Tube is a Choosing Wisely Canada toolkit for appropriate urinary catheter use in hospitals, written by physicians at Sunnybrook Health Sciences Centre and Sinai Health in Toronto (Leis & Soong, 2019). It grew from a finding that most catheters in Sunnybrook's inpatients had no appropriate reason and were often put back at the first sign of retention.

The team agreed on criteria for appropriate use, wrote a medical directive that let nurses remove catheters without a listed indication, trained nurses with practice cases in about 30 minutes, and added an algorithm for checking the bladder after removal. Catheter use on the medical wards fell by half for more than a year, and no inappropriate removals were found (Leis & Soong, 2019).

For the bedside nurse, the lessons are:

- Ask every day whether each catheter still has an indication.
- Remove it when it does not, under a directive or by asking the prescriber.
- After removal, follow the unit's algorithm to confirm the bladder empties, using intermittent catheterization when needed rather than reinserting an indwelling catheter.
- Offer alternatives first: toileting help, a commode, a urinal or bedpan, or an external catheter.

Intermittent and External Catheters

Intermittent catheterization means passing a catheter into the bladder to drain it and then removing it. For patients whose bladder does not empty, the CDC (2009) prefers it to an indwelling catheter. In hospital, the nurse uses sterile technique; at home, a clean technique is an acceptable, practical alternative (CDC, 2009). For long-term retention, clean intermittent self-catheterization, done by the patient or a caregiver, is the preferred approach when it is possible (Stoffel et al., 2016). The nurse teaches the technique, a schedule set with the care team, hand hygiene and the signs of infection to report.

An **external catheter** collects urine from outside the body, so nothing enters the bladder. A male external catheter fits over the penis like a sheath; external devices for female anatomy sit against the vulva and carry urine away to a collection container. The CDC (2009) suggests male external catheters for cooperative patients without retention or obstruction. A more recent compendium recommends keeping both male and female external catheters on every unit, but notes that evidence on their skin injury and infection risks, especially for female devices, is still developing (Patel et al., 2023). The nurse checks the skin under and around the device regularly and follows the manufacturer's instructions for fit and changes (Chapter 35).

Recognizing CAUTI

A **catheter-associated urinary tract infection (CAUTI)** is a UTI in a person who has, or recently had, a urinary catheter. Because the catheter drains the bladder continuously, the usual urgency and frequency are absent, so recognition rests on other signs. Surveillance definitions require significant bacteriuria plus at least one clinical finding such as fever, suprapubic tenderness or costovertebral angle pain or tenderness (Patel et al., 2023). In long-term care, minimum criteria for a resident with a catheter are any one of fever, new flank tenderness, rigors or new delirium, after other causes have been considered (Leis et al., n.d.).

Cloudy, dark or foul-smelling urine alone is not a reason to send a culture (Patel et al., 2023). Bacteria in the urine of a catheterized patient without signs of infection is asymptomatic bacteriuria and is neither screened for nor treated (Nicolle et al., 2019). When the nurse suspects CAUTI, the nurse assesses vital signs and the catheter, reports to the prescriber, collects the specimen from the sampling port, and asks whether the catheter can be removed. Signs of sepsis call for immediate escalation (section 4.6).

28.3 Urinary Retention and Incontinence

Urinary Retention

Urinary retention is the inability to empty the bladder completely or at all. **Acute urinary retention** comes on suddenly. The person may have lower abdominal discomfort and an urge they cannot act on, although after anesthesia or with sedation many people feel no urge at all (section 7.6). Chronic retention develops slowly and is often painless. A consensus statement from the American Urological Association defines chronic urinary retention as a post-void residual above 300 mL on two or more occasions that persists for at least 6 months (Stoffel et al., 2016).

Common causes include:

- an enlarged prostate blocking outflow (section 28.5);
- drugs with anticholinergic effects, which weaken bladder contraction, and opioids (Serlin et al., 2018; Chapter 5; section 8.5);
- anesthesia and surgery, especially pelvic surgery and spinal anesthesia (section 7.6);
- constipation or stool impaction (Serlin et al., 2018; Leis & Soong, 2019);
- neurologic disease or injury, such as spinal cord injury.

The nurse suspects retention when a patient has not voided for several hours, passes small amounts often, has fullness or discomfort above the pubic bone, leaks small amounts (overflow), or becomes restless or newly confused.

The **post-void residual (PVR)** is the volume of urine left in the bladder right after voiding. It can be measured with a catheter or with a **bladder scanner**, a portable ultrasound device that estimates bladder volume without entering the body (Stoffel et al., 2016). Where scanners are used, indications must be clear, staff must be trained, and the device is disinfected between patients (CDC, 2009). The nurse scans soon after the patient voids, follows the device instructions and employer policy, and documents the voided volume and the scan result together.

No single PVR threshold fits every setting. One infection prevention compendium defines postoperative retention as a PVR over 500 mL in a patient without symptoms, or over 300 mL in a patient who has symptoms (Patel et al., 2023). The Canadian Urological Association's overactive bladder guideline says a PVR above 250 to 300 mL needs attention before an antimuscarinic drug is started (Corcos et al., 2017). The nurse uses the thresholds and actions in the unit's protocol or medical directive and reports results outside them.

For retention after catheter removal or surgery, intermittent catheterization is preferred to reinserting an indwelling catheter, and the nurse also treats constipation and helps the patient walk (CDC, 2009; Leis & Soong, 2019). Acute retention from an obstruction is an indication for an indwelling catheter (CDC, 2009). For chronic retention, patients with high-risk features such as hydronephrosis or recurrent infections need treatment, while low-risk patients without symptoms are not offered catheterization just to lower the PVR (Stoffel et al., 2016).

When a large volume is drained, nurses were long taught to empty the bladder gradually to prevent bleeding, low blood pressure and a sudden large urine output. A 2022 meta-analysis of four studies found that rapid, complete drainage did not increase bleeding and reported no circulatory collapse, but the evidence was of very low certainty (Wu et al., 2022). The nurse follows the order and policy and monitors vital signs, urine colour and urine output after drainage.

Retention that comes with fever, flank pain, a rising creatinine or very low urine output needs prompt reporting. A blocked outflow can damage the kidneys, and chronic retention with hydronephrosis, reduced kidney function or repeated infections is considered high risk (Stoffel et al., 2016; Chapter 27).

Urinary Incontinence

Urinary incontinence is any involuntary leakage of urine (Bettez et al., 2012). It affects about 30% to 60% of people over 65, and more in frail older adults, yet it is not a normal or inevitable part of aging and can often be cured or improved (Bettez et al., 2012; Health Canada, 2006). Many people do not mention it, so the nurse asks directly and privately.

The main types are compared side by side (Table 28.2). **Stress incontinence** is leakage with coughing, sneezing or exertion. **Urgency (urge) incontinence** is leakage with or right after a sudden, strong need to void; it is part of overactive bladder, which affects an estimated 14% to 18% of Canadians (Corcos et al., 2017). Mixed incontinence combines the two. **Overflow incontinence** is leakage from a bladder that overfills because it cannot empty. **Functional incontinence** is leakage because a person cannot reach or use the toilet in time, for example because of limited mobility, dementia or poor vision (Bettez et al., 2012; Health Canada, 2006).

Table 28.2 Types of urinary incontinence (Bettez et al., 2012; Corcos et al., 2017; Health Canada, 2006)

Type	What happens	Common causes	Nursing and treatment focus
Stress	Small leaks when pressure in the abdomen rises: coughing, sneezing, laughing, lifting	Weak pelvic floor, for example after childbirth; prostate surgery	Pelvic floor muscle training first; weight loss and constipation control; pessary or surgery if needed
Urgency	Leaks with or right after a sudden, strong urge that is hard to delay; often frequency and night-time voiding	Overactive bladder; caffeine; stroke, Parkinson disease or multiple sclerosis	Bladder training, pelvic floor training and less caffeine; antimuscarinic or beta-3 agonist if needed
Mixed	Both stress and urgency leaks	A combination of the above; common in older women	Combine the approaches for both types
Overflow	Frequent small leaks from a bladder that cannot empty, often without a feeling of fullness	Blockage such as an enlarged prostate; weak bladder muscle	Measure the PVR; restore emptying first by treating the cause or using intermittent catheterization
Functional	Leaks because the person cannot get to or use the toilet in time	Limited mobility, dementia, poor vision, mental health conditions, barriers in the room	Toileting help and prompted voiding; call bell in reach; raised seat, grab bars and easy clothing

Assessment. The nurse asks about the type, amount and timing of leakage, how much it bothers the person, fluid and caffeine intake, bowel habits and medications such as diuretics. The team also considers mobility, dexterity, cognition and access to a toilet. A urinalysis and a **bladder diary**, a record of fluid intake, voids, urgency and leaks over 3 or more days, are part of the first assessment (Bettez et al., 2012; Corcos et al., 2017). A PVR is measured when there are voiding symptoms or concern about emptying. Temporary, treatable causes are looked for first, including delirium, infection, medications, high urine output, restricted mobility and stool impaction (Bettez et al., 2012).

Because incontinence is common and often hidden in frail older adults, the CUA guideline recommends screening them for it every year. Their assessment includes medications, cognition, fluid intake, access to a toilet and support from caregivers (Bettez et al.,

2012). Nurse continence advisors and continence physiotherapists can help, and simple changes such as a raised toilet seat, grab bars and clothing that is easy to remove support people with functional incontinence (Health Canada, 2006).

Conservative treatment comes first, and a fair trial takes 8 to 12 weeks (Bettez et al., 2012; Corcos et al., 2017):

- **Lifestyle:** less caffeine, weight loss when relevant, constipation control, sensible fluid intake (less in the hours before bed for night-time voiding) and stopping smoking.
- **Pelvic floor muscle training (PFMT):** repeated, correctly performed contractions of the pelvic floor muscles. It is first-line for stress incontinence and also helps urgency incontinence; intensive, supervised training is preferred where available.
- **Bladder training:** a voiding schedule with intervals lengthened gradually, by about 15 to 30 minutes a week, combined with urge-suppression techniques.
- **Scheduled and prompted voiding:** recommended for frail people (Bettez et al., 2012). In **prompted voiding**, staff regularly prompt the person to use the toilet, help them there and praise success (Eustice et al., 2000).

Medications. For urgency incontinence that persists, the prescriber may add an antimuscarinic such as oxybutynin, or the beta-3 agonist mirabegron, both marketed in Canada (Corcos et al., 2017; Health Canada, 2026). Antimuscarinics cause dry mouth, constipation and central nervous system effects, add to anticholinergic burden and are linked with cognitive impairment. They are considered potentially inappropriate for frail older adults and are contraindicated in uncontrolled narrow-angle glaucoma. Mirabegron is contraindicated in severe uncontrolled hypertension, so blood pressure is checked (Corcos et al., 2017). The nurse reports new confusion, falls, constipation or difficulty voiding. Section 28.6 summarizes these drugs in a table (Table 28.3).

Containment and dignity. Pads, briefs and external catheters keep a person dry while treatment works, and containment is sometimes the most realistic goal, for example with advanced dementia (Bettez et al., 2012). An indwelling catheter is never a substitute for continence care (CDC, 2009). The nurse answers call bells promptly, offers toileting help on a schedule, changes wet products quickly, protects the skin (Chapter 35) and uses respectful language. Continence care is skilled nursing work that preserves dignity, mobility and independence.

28.4 Kidney Stones

A kidney stone forms when minerals that are normally dissolved in urine come out of solution and build up into a hard mass. **Urolithiasis** is the general term for stones anywhere in the urinary tract. Trouble starts when a stone moves into the ureter and blocks the flow of urine. Kidney function and acute kidney injury are covered in Chapter 27.

How Stones Form and Who Gets Them

Stones form when urine carries more of a substance than it can keep dissolved, so crystals form and grow. Concentrated urine makes this more likely. Most stones range from the size of a grain of sand to a pea (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2017a). The main types are:

- **Calcium stones:** the most common type, mostly calcium oxalate and less often calcium phosphate.
- **Uric acid stones:** these develop in urine that is too acidic; diets heavy in meat, fish and shellfish raise the risk.
- **Struvite stones:** linked to urinary tract infection; they can appear suddenly and enlarge fast.
- **Cystine stones:** the result of cystinuria, an inherited disorder (NIDDK, 2017a).

Risk factors include male sex, a family history of stones, a low fluid intake, a past stone, obesity, gout, inflammatory bowel disease or past bowel surgery, hyperparathyroidism, repeated urinary tract infections and long-term use of some drugs, such as topiramate (NIDDK, 2017a). The Canadian Urological Association (CUA) describes stone disease as a systemic condition linked with obesity, metabolic syndrome and diabetes (Bhojani et al., 2022).

In a Canadian study of hospital and emergency department records (all provinces and territories except Quebec), kidney stone episodes needing acute care or a procedure rose from 277 per 100,000 people in 2013 to 290 per 100,000 in 2018, and 59.9% of episodes involved men (Ordon et al., 2024). Stones often come back: the CUA reports recurrence rates of 30% to 50% within 10 years of a first symptomatic stone (Bhojani et al., 2022).

Renal Colic and Care

Renal colic is the severe pain of a stone moving through or blocking the ureter. The pain is sharp, is felt in the back, side, lower abdomen or groin, and may come in waves. Nausea, vomiting, frequent or painful voiding and **hematuria**, blood in the urine that can turn it pink, red or brown, are common. Fever and chills point to infection (NIDDK, 2017b).

The CUA recommends ultrasound with a plain X-ray of the kidneys, ureters and bladder (KUB) as the first imaging for an acute ureteral stone, and careful use of computed tomography (CT), preferably at a low dose (Lee et al., 2021; Figure 28.2). The team also checks for infection (section 28.1).

Pain relief. The CUA guideline reports that nonsteroidal anti-inflammatory drugs (NSAIDs) relieved renal colic better than morphine in comparison studies. It recommends keeping opioid use to a minimum and teaching the patient what to expect (Lee et al., 2021). NSAIDs are not safe for everyone; the prescriber weighs kidney function and bleeding risk (Chapter 5). The nurse reassesses pain after each dose.

Passing the stone. Small stones, under about 5 mm, often pass on their own (Dushinski, 2021). **Medical expulsive therapy (MET)** is the use of a drug to help a ureteral stone pass. The CUA states that any benefit is for larger (5 to 10 mm) stones in the lower ureter, and that the pros and cons are weighed with the patient. If an obstructing stone has not passed after 4 to 6 weeks, surgery should likely be considered (Lee et al., 2021). The CUA recommends that any stone the patient collects, for example by straining the urine as instructed, be sent for analysis, because knowing its composition guides prevention (Bhojani et al., 2022).

Figure 28.2 Non-contrast CT showing a stone in the upper right ureter (the bright white spot) causing mild blockage. CT is used carefully, preferably at a low dose. (credit: "KidneyStone" by James Heilman, MD/Wikimedia Commons, CC BY-SA 3.0)

An obstructed, infected kidney is an emergency. When a stone blocks the ureter and the urine above it is infected, the infected urine is trapped under pressure, and sepsis can follow quickly (Chapter 4). The CUA states that obstructive pyelonephritis needs early, goal-directed treatment that includes timely **decompression**, drainage of the blocked kidney (Lee et al., 2021). Drainage is by a **ureteral stent**, a thin tube passed up the ureter from the bladder, or a **nephrostomy tube**, placed through the skin of the back into the kidney (Lee et al., 2021). Antibiotics are essential, but they cannot drain a blocked kidney. Early intervention may also be needed for uncontrolled pain, worsening kidney function or significant frailty (Lee et al., 2021). A nurse who finds fever, chills, a rising heart rate, falling blood pressure, new confusion or falling urine output in a patient with a known or suspected stone escalates at once (Chapter 6).

Procedures. In **shock wave lithotripsy (SWL)**, shock waves from outside the body break the stone into fragments that pass in the urine (Figure 28.3). In **ureteroscopy**, a thin scope is passed through the urethra and bladder into the ureter to break up or remove the stone. For ureteral stones, SWL gives stone-free rates similar to ureteroscopy, with more repeat treatments but fewer complications (Lee et al., 2021). Ureteroscopy made up 73.5% of first stone procedures in Canada (Ordon et al., 2024).

Routine stenting after uncomplicated ureteroscopy is likely unnecessary, but a stent is placed for a suspected ureteral injury or narrowing, a single kidney or reduced kidney function (Lee et al., 2021). Stents make urinary symptoms markedly worse; an alpha-blocker, an anticholinergic drug or both may ease them (Lee et al., 2021). The nurse makes sure the patient knows the stent is temporary and when it will be removed.

Preventing Recurrence

The CUA makes fluid the first line of prevention: every person who has had a stone should aim for a urine output of 2.5 L a day, mostly from water. Each extra 200 mL of fluid a day was linked with a 13% lower stone risk (Bhojani et al., 2022). Diet advice

Figure 28.3 Kidney stone fragments after shock wave lithotripsy, beside a millimetre scale. Patients may be asked to strain their urine so that fragments can be analyzed. (credit: "Kidney stones" by Arconsoli/Wikimedia Commons, CC BY-SA 4.0)

depends on the stone type (Bhojani et al., 2022):

- **Calcium:** do not cut calcium; the goal is 1,000 to 1,200 mg a day, with any supplements taken with meals.
- **Sodium:** with recurrent calcium stones, limit sodium to 1,500 mg a day and never more than 2,300 mg.
- **Animal protein:** people who have had repeated calcium or uric acid stones eat moderate amounts.
- **Oxalate and vitamin C:** limit high-oxalate foods and avoid vitamin C supplements above 1,000 mg a day.
- **Cystine stones:** the urine target rises to 3 L a day.

People at high risk of recurrence, such as those with repeated or non-calcium stones or a single kidney, are offered a full metabolic evaluation, and some need a preventive drug. Those on preventive treatment have repeat testing within 6 months and then yearly (Bhojani et al., 2022).

PATIENT EDUCATION

Preventing Another Kidney Stone

- **Drink through the day.** Aim to pass about 2.5 L of urine every day, which means drinking more than that. Water is the best choice. Keep a water bottle with you, and drink more in hot weather and when you exercise.
- **Keep calcium in your diet.** Do not cut out milk products or other calcium-rich foods unless your health care provider tells you to. Take any calcium supplement with a meal.
- **Go easy on salt.** Read labels on processed and restaurant foods, which are often high in sodium.
- **Eat moderate amounts of meat, fish and poultry.** Large servings raise the risk of calcium and uric acid stones.
- **Ask before taking vitamin C.** High-dose supplements can raise oxalate in the urine.
- **Save the stone.** If you are asked to strain your urine, bring any stone you catch to your appointment so it can be tested.
- **Get help right away** for fever or chills with flank pain, pain that medicine does not control, vomiting that stops you from keeping fluids down, or passing very little urine. Call 9-1-1 if you feel faint or confused.

28.5 Benign Prostatic Hyperplasia and Prostate Surgery

The prostate sits just below the bladder and wraps around the urethra. When it enlarges, it can squeeze the urethra and make the bladder harder to empty. This section covers benign enlargement of the prostate, its drugs and care after prostate surgery, including continuous bladder irrigation. Urinary retention is covered in section 28.3.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is a non-cancerous enlargement of the prostate and one of the most common age-related conditions in men (Elterman et al., 2022). BPH does not raise the risk of prostate cancer (Canadian Cancer Society [CCS], n.d.-f), but the two can occur together, and both are assessed when symptoms begin (Figure 28.4).

BPH causes **lower urinary tract symptoms (LUTS)**. Voiding symptoms include a weak or interrupted stream, hesitancy, straining and a feeling of incomplete emptying. Storage symptoms, such as urgency, frequency and **nocturia** (waking at night to void), are often the most bothersome (Elterman et al., 2022). The CUA guideline recommends a formal symptom inventory, such as the **International Prostate Symptom Score (IPSS)**, a short questionnaire the patient completes, at the first visit and to follow the response to treatment (Elterman et al., 2022).

BPH can lead to complications. The CUA lists them as reasons to consider surgery: repeated or ongoing urinary retention, repeated urinary tract infections, bladder stones, repeated hematuria and kidney damage caused by the obstruction (Elterman et al., 2022). Acute urinary retention, the sudden inability to void with a painful, distended bladder, is urgent and is managed as section 28.3 describes. The nurse asks about drugs that can trigger it, such as those with anticholinergic effects.

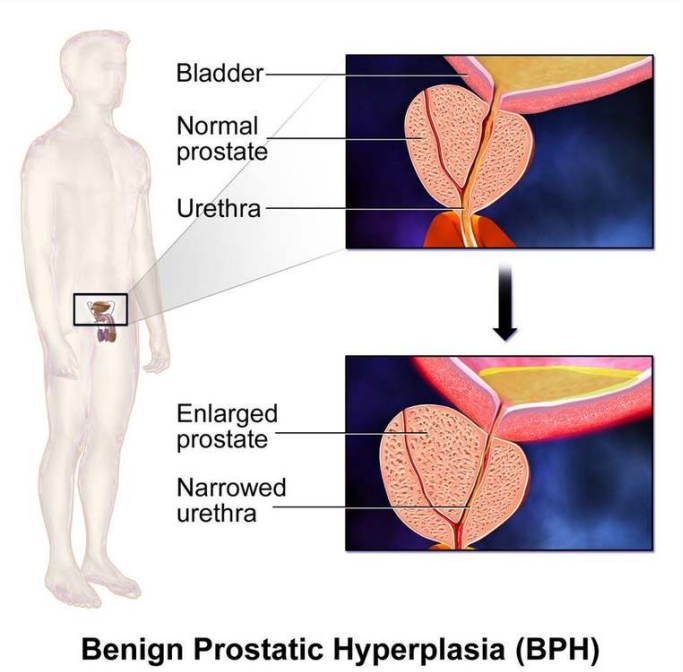

Figure 28.4 Comparison of a normal prostate and urethra (top) with benign prostatic hyperplasia (bottom), in which nodular enlargement of the prostate compresses the prostatic urethra and obstructs bladder outflow. (credit: "Benign Prostatic Hyperplasia (BPH)" by BruceBlaus/Wikimedia Commons, CC BY-SA 4.0)

Drugs for BPH. Two drug classes are the mainstay (Table 28.3).

- **Alpha-blockers** (for example, tamsulosin and silodosin) relax the smooth muscle of the prostate and bladder neck. The most common adverse effect is dizziness, and ejaculatory changes are reported most often with tamsulosin and silodosin (Elterman et al., 2022). The Canadian product monograph for tamsulosin warns that blood pressure can drop. Patients should sit or lie down at the first sign of dizziness or weakness, and they should not drive or do hazardous tasks for 12 hours after the first dose (Teva Canada, 2021). Tamsulosin is linked to **intraoperative floppy iris syndrome**, a problem with the iris during cataract or glaucoma surgery. The patient's eye surgeon needs to know about the drug, and starting tamsulosin when such surgery is already planned is not recommended (Teva Canada, 2021). Controlled-release tablets are swallowed whole. Older adults who become dizzy are at risk of falls (Chapter 8).
- **5-alpha reductase inhibitors (5-ARIs)** (for example, finasteride and dutasteride) shrink the prostate by about 25% to 30% (Elterman et al., 2022). They work slowly; the finasteride monograph says a trial of at least 6 months is generally needed. Finasteride lowers the prostate-specific antigen (PSA) level (section 28.6) by about half within 6 months, so anyone reading a PSA result must know the patient takes it (Sanis Health, 2020). People who are or may become pregnant should not touch finasteride tablets that are crushed or broken; the tablet coating stops contact with the drug when whole tablets are handled normally (Sanis Health, 2020). Sexual side effects can occur. The monograph also asks patients to report mood changes and any breast lumps, pain or nipple discharge (Sanis Health, 2020).

Table 28.3 Drugs for urinary and prostate conditions, without doses (Auro Pharma, 2026; Elterman et al., 2022; Kokorovic et al., 2022; Lee et al., 2021; Sanis Health, 2020; Teva Canada, 2021; Verity Pharmaceuticals, 2021)

Class	Canadian examples	Used for	Nursing points
Alpha-blockers	tamsulosin, silodosin	BPH and LUTS; sometimes to help pass a ureteral stone or ease stent symptoms	Dizziness and low blood pressure, especially after the first dose: rise slowly, no driving for 12 hours after the first dose; tell the eye surgeon before cataract or glaucoma surgery; swallow controlled-release tablets whole; report a prolonged painful erection; fall risk in older adults.

Class	Canadian examples	Used for	Nursing points
5-alpha reductase inhibitors	finasteride, dutasteride	BPH with an enlarged prostate	Takes about 6 months to judge the effect; lowers PSA by about half, so tell whoever orders a PSA test; people who are or may become pregnant should not touch crushed or broken finasteride tablets; report mood changes and breast lumps or discharge.
Antimuscarinics	oxybutynin, solifenacin	Urge incontinence and storage symptoms (section 28.3)	Anticholinergic effects, a particular concern in older adults (section 28.3); use with caution when there is obstruction or a high post-void residual.
Beta-3 agonists	mirabegron	Urge incontinence and storage symptoms (section 28.3)	Can raise blood pressure: measure it before starting and periodically; use with caution when the bladder outlet is obstructed.
NSAIDs	ketorolac, ibuprofen	Renal colic	Check kidney function, bleeding risk and other conditions before giving; reassess pain; aim to keep opioid use low.
Androgen deprivation therapy	leuprolide, degarelix	Advanced or higher-risk prostate cancer	Hot flashes, bone loss, weight gain, diabetes risk, lipid changes, muscle loss, fatigue, mood and memory changes, loss of libido; teach calcium, vitamin D and exercise; support bone density testing and metabolic monitoring.
Intravesical BCG (live bacteria)	VERITY-BCG	Non-muscle-invasive bladder cancer after TURBT	Biohazard handling; delay after traumatic catheterization, visible hematuria or infection; retain 2 hours, void sitting, bleach the toilet for 6 hours; report fever above 39 °C lasting more than 12 hours.

Using both classes together lowers the risk of urinary retention and of needing surgery in men with a larger prostate (Elterman et al., 2022). When storage symptoms dominate, an antimuscarinic drug or a beta-3 agonist may help. The CUA advises caution when there is significant obstruction or a high post-void residual, because these drugs can worsen retention (Elterman et al., 2022; section 28.3).

Surgery and Continuous Bladder Irrigation

In a **transurethral resection of the prostate (TURP)**, the surgeon passes a scope through the urethra and uses an electrical wire loop to cut away the inner part of the gland while the outer shell stays in place (The Ottawa Hospital [TOH], 2010). The CUA calls standard (monopolar) TURP the reference surgical treatment for moderate to severe symptoms. Alternatives include bipolar TURP, holmium laser enucleation, laser vaporization, a prostatic urethral lift, water vapour therapy and simple prostatectomy by open, laparoscopic or robotic surgery (Elterman et al., 2022). A urethral lift, for example, may suit a man who wants to preserve ejaculation (Elterman et al., 2022).

After TURP, the patient usually returns with a large **three-way catheter**. One channel inflates the balloon, one drains urine, and one carries irrigation fluid into the bladder. **Continuous bladder irrigation (CBI)** runs sterile 0.9% sodium chloride into the bladder and out through the drainage channel without stopping. It keeps blood from clotting in the bladder and keeps the catheter open (Agency for Clinical Innovation [ACI], 2026). No Canadian bladder irrigation guideline was found, so the steps below follow one published toolkit from New South Wales, Australia, as an example protocol; the nurse always follows the local protocol and orders. The fluid is kept at room temperature, because cold fluid can cause bladder spasms and leaking around the catheter (ACI, 2026).

Nursing care during CBI centres on four tasks.

- **Adjust the flow to the bleeding.** The nurse raises the irrigation rate when the drainage becomes redder or shows more clots, then watches the drainage and the patient's comfort (ACI, 2026). Each unit's protocol names a target drainage colour and how to titrate, and the nurse follows the protocol and the order.
- **Calculate true urine output.** The drainage bag holds urine plus irrigation fluid. **True urine output** is the total volume drained minus the volume of irrigation instilled (ACI, 2026). If 3,000 mL of irrigation ran in and 3,350 mL drained out, the patient made 350 mL of urine. The nurse records irrigation in, total out, true output, drainage colour and clots on the fluid balance record.
- **Watch for clot retention. Clot retention** occurs when clots block the catheter. The signs are slowed or absent drainage, lower abdominal pain that worsens as the bladder fills, a distended bladder above the pubic bone, urine leaking around the catheter and

sometimes sweating, a rapid pulse and low blood pressure (ACI, 2026). Because irrigation keeps flowing in, a blocked bladder fills fast.

- **Act in order.** When drainage is less than the irrigation going in, or pain rises, the nurse turns off the irrigation inflow and checks the catheter and tubing for kinks, loops and clots. Next, the nurse palpates the bladder, considers a bladder scan and recalculates the output. If a clot is the cause, the protocol may allow closed or manual irrigation to remove it. Manual irrigation is done only when ordered, by a clinician who is authorized and competent to do it. If these steps fail, the nurse notifies the urology team (ACI, 2026). Nurses do not reinsert or replace a catheter after urologic surgery without the urologist's authorization (ACI, 2026).

Bladder spasms cause a strong urge to void and cramping pain above the pubic bone (TOH, 2010). Because spasms and a blocked catheter feel alike, the nurse rules out blockage first, then gives any ordered antispasmodic. If the drainage stays red or the clots increase even after the irrigation rate is raised, the nurse notifies the urology team (ACI, 2026). Bright red drainage together with a rising heart rate and falling blood pressure suggests hemorrhage, and the nurse escalates at once (Chapter 6). The catheter is secured to the thigh to limit movement (ACI, 2026). CBI stops only on a medical order, and the urology team reviews it at least daily (ACI, 2026). New confusion or agitation after TURP is reported at once (see the Going Deeper box).

Before discharge, the nurse teaches the patient to drink 1 to 2 L of fluid a day unless his fluids are restricted, and to rest and drink more if blood appears in the urine. He should avoid heavy lifting (more than 7 kg) and strenuous exercise for 2 weeks, avoid straining at stool by eating high-fibre foods, and avoid long car rides until his follow-up visit (TOH, 2010). Sexual activity can usually resume after 3 to 4 weeks, as discussed with the urologist. Semen may now flow backward into the bladder, called **retrograde ejaculation**. This is harmless, though urine may look cloudy afterward and fertility may be affected (TOH, 2010). He calls the urologist for a fever above 38.5 °C, chills, trouble passing urine, or flank or low back pain (TOH, 2010). Large clots that make it hard to void, or being unable to void even with a full bladder, need a call to the surgeon or, if the surgeon cannot be reached, a visit to the nearest emergency department (Toronto East Health Network [TEHN], 2019).

GOING DEEPER

Transurethral Resection Syndrome

Required for RN students; optional for PN students.

Monopolar TURP needs an irrigating fluid without electrolytes, such as glycine, because electrolyte solutions disperse the cutting current. As prostate tissue is cut, open veins absorb this fluid (Gupta et al., 2010). Large volumes cause **transurethral resection syndrome (TUR syndrome)**: dilutional hyponatremia with fluid overload (section 3.4). Absorbing 1 L of fluid within an hour can lower serum sodium by about 5 to 8 mmol/L. Risk rises with resections longer than 60 minutes and with large glands (Gupta et al., 2010).

Early signs include dizziness, headache, nausea, shortness of breath, high blood pressure, a slow heart rate and dysrhythmias. Restlessness, confusion and blurred vision follow. Without treatment, the patient can become hypotensive and go into cardiac arrest (Gupta et al., 2010). Signs can begin during surgery or after it, for example 30 to 45 minutes after the operation ends (Gupta et al., 2010). A nurse who notices new confusion or agitation after TURP checks orientation and vital signs and reports at once, including when the change began, any analgesia given, the irrigation volume and the true urine output (ACI, 2026). The team checks the sodium urgently and corrects it carefully (section 3.4).

Bipolar TURP uses saline instead, and a Cochrane review found that it probably slightly reduces TUR syndrome, by about 20 cases per 1,000 patients (moderate-certainty evidence; Alexander et al., 2019).

CLINICAL JUDGMENT

No Drainage and Rising Pain

Names and details are fictional; this is a composite story.

Wilfred Osei-Bonsu, 79, is on day 1 after a TURP, with CBI running through a three-way catheter. At 06:00, he rings the bell, grimacing and saying he needs to void "right now."

- **Recognize cues:** The drainage bag has gained only 40 mL in the past hour while irrigation ran at the ordered rate. The tubing is dark red with small clots. Urine is leaking around the catheter onto the pad. His lower abdomen is firm and tender above the pubic bone. His heart rate is 98, up from 80 overnight.
- **Analyze cues:** Fluid is going in but not coming out. The firm bladder and leaking point to a blocked catheter, not just a spasm.

- **Prioritize hypotheses:** Clot retention is the most likely cause and the most urgent, because the bladder is filling with irrigation fluid. A bladder spasm, a kinked tube or bleeding are also possible.
- **Generate solutions:** Stop the inflow. Check the tubing. Confirm the bladder volume. Follow the unit's catheter irrigation protocol. Notify urology if the blockage does not clear.
- **Take action:** The nurse clamps the irrigation inflow and finds no kinks, but sees a clot in the drainage port. A bladder scan shows a large volume. Under the protocol and the standing order for manual irrigation, the nurse withdraws several clots with sterile technique. Drainage flows again. The nurse pages the urology resident with an SBAR report, restarts the irrigation at a higher rate as the order allows and records the volumes.
- **Evaluate outcomes:** Within 30 minutes, the drainage is lighter, Mr. Osei-Bonsu's pain has dropped from 8 to 2 out of 10, and leaking has stopped. His heart rate is 82. The nurse rechecks hourly and documents the true urine output.

PRACTICE STORY

Bright Red and Clotted

Names and details are fictional; this is a composite story.

Nurse: Camille Marchand, RN. Years in practice: 6. Setting: surgical unit, Ontario.

Bernard came back from his TURP at suppertime, 81 years old, with continuous bladder irrigation running. At handover, the drainage was cherry red but flowing. By 21:00, Priya, the RPN on our team, came to find me. "Bernard's bag has hardly changed, and he's rocking in the bed."

I went in. The drainage tubing was bright red and clotted, and the bag had gained maybe 30 mL in an hour while the irrigation ran. He was sweaty and his lips had lost their colour, and he was gripping the bed rail. His pad was soaked; urine was leaking around the catheter. Heart rate 112, up from 84 at 19:00. Blood pressure 138/80.

I clamped the inflow first. A bladder full of saline and clots was not going to get better with more saline. I checked the tubing from his body to the bag: no kinks, but a dark clot was sitting in the drainage port. The bladder scanner showed a large volume. Our protocol lets RNs hand-irrigate after a urology order, and there was one. I pulled back several clots and the drainage started again, still bright red.

Then I paged the urology resident. "Bernard Lavoie, day 0 after TURP. Clot retention, partly cleared by hand irrigation. Drainage still bright red, heart rate 112, up from 84. I've stopped the inflow. I'd like you to see him now." She came within 20 minutes, washed out more clots and adjusted the irrigation rate. By midnight the drainage was light pink and his heart rate was 88.

What stays with me is that Priya noticed first. She saw a bag that wasn't filling and a man who couldn't settle, and she didn't wait.

Reflect: Priya's employer allows only RNs to hand-irrigate after urologic surgery. Using authority, competence and context, what could Priya do safely on her own, and when should she bring in the RN? What would change if her employer's policy allowed RPNs to perform this skill?

28.6 Prostate and Bladder Cancer

Prostate and bladder cancer are common in Canada, and both affect urinary function and quality of life. General cancer treatment is covered in Chapter 9 and sexual health after treatment in Chapter 29.

Prostate Cancer

Apart from non-melanoma skin cancers, prostate cancer is the cancer diagnosed most often in men in Canada. In 2026, an estimated 29,300 men will be diagnosed with it (23% of new cancers in men) and 5,300 will die of it, which ranks it second among causes of cancer death in men. Roughly 1 in 9 men will be diagnosed with prostate cancer, and roughly 1 in 34 will die of it (Brenner et al., 2026; CCS, n.d.-c). Prostate cancers vary: some grow slowly, while others are fast-growing, and telling them apart drives decisions about testing and treatment.

Risk factors. Risk rises with age; most cases are found in men in their 60s. A father, brother or son with prostate cancer raises the risk, more so with several affected relatives or a relative diagnosed before 65. Inherited gene changes, most often in *BRCA2* or *HOXB13*, explain a small share of cases, and excess body weight also raises risk (CCS, n.d.-f). Prostate cancer is diagnosed more often among Black men (including those of African or Caribbean ancestry), who also tend to have faster-growing tumours and a

higher chance of dying from the disease (CCS, n.d.-f). This finding describes groups, not the cause in any one person. The nurse avoids assumptions and makes sure Black patients receive clear, unhurried information about testing and treatment (Chapter 2).

Screening with PSA. PSA is a protein made by the prostate and measured in a blood test. Canadian guidance on PSA screening differs (Table 28.4). The Canadian Task Force on Preventive Health Care (2014) recommends against PSA screening at any age, while the CUA (2022) suggests offering it, after shared decision-making, to men expected to live more than 10 years (Bell et al., 2014; Mason et al., 2022). The nurse presents both positions accurately, helps the patient name what matters to him and refers him to his primary care provider to decide.

Table 28.4 PSA screening: what two Canadian bodies recommend (Bell et al., 2014; Mason et al., 2022)

Body	Recommendation (in this book's words)	Date	What the nurse discusses
Canadian Task Force on Preventive Health Care	Do not screen for prostate cancer with PSA. Against for men under 55 (strong recommendation, low-quality evidence), 55 to 69 (weak recommendation, moderate-quality evidence) and 70 and older (strong recommendation, low-quality evidence). Applies to men never diagnosed with prostate cancer, including those with urinary symptoms or BPH.	November 2014 (CMAJ)	A weak recommendation means the right choice depends more on a man's own values; explain possible benefits and harms; urinary symptoms alone are not a reason to screen under this guideline.
Canadian Urological Association	Offer PSA screening, through shared decision-making, to men with a life expectancy over 10 years. Start at 50 for most men and at 45 for men at higher risk, such as those with a family history. Repeat every 4 years if PSA is below 1 mcg/L (1 ng/mL) and every 2 years if 1 to 3 mcg/L. Stop at 70 (consider stopping at 60 if PSA is below 1 mcg/L). Recommends MRI before biopsy for men who would choose curative treatment.	April 2022 update (Canadian Urological Association Journal)	Ask about family history and life expectancy; explain that a raised PSA leads to more tests, often MRI and possibly biopsy; support the patient's own decision with his primary care provider.

Active surveillance. Active surveillance is planned monitoring of a low-risk cancer, with the intent to cure if it changes. A CUA-endorsed guideline names it the preferred strategy for low-risk localized prostate cancer (Gleason score 6 or lower, now often reported as Grade Group 1). Monitoring includes PSA testing every 3 to 6 months, a digital rectal exam yearly, a confirmatory biopsy within 6 to 12 months and further biopsies at least every 3 to 5 years. Treatment is offered if the cancer is reclassified as higher risk. Active surveillance differs from watchful waiting, which avoids curative treatment in people with a limited life expectancy (Morash et al., 2015). The nurse explains the schedule and listens for the anxiety of living with an untreated cancer.

Radical prostatectomy. A **radical prostatectomy** removes the whole prostate and some nearby tissue, including the seminal vesicles, and a urinary catheter stays in for a time after surgery (CCS, n.d.-h; section 28.2). Urinary leakage is common after the catheter comes out and improves over time for most men, whatever the management. Pelvic floor muscle training is widely taught, but a Cochrane review found the evidence for its benefit after prostatectomy conflicting (Anderson et al., 2015). The nurse teaches the exercises as ordered, sets realistic expectations, suggests containment products and protects the skin (Chapter 35). Erectile changes are covered in Chapter 29.

Radiation and androgen deprivation therapy. Radiation therapy can cause bladder effects (frequent or burning urination, leakage, blood in the urine) and bowel effects (diarrhea, rectal pain or bleeding), some months or years later (CCS, n.d.-d; Chapter 9). **Androgen deprivation therapy (ADT)** lowers androgens such as testosterone, which help prostate cancer cells grow. Drugs such as leuprolide are given as an injection or an implant under the skin,, and degarelix is another option (CCS, n.d.-b; Table 28.3). The CUA guideline on ADT adverse effects describes these effects and responses (Kokorovic et al., 2022):

- **Hot flashes:** help patients identify and avoid triggers.
- **Bone loss:** adequate calcium (1,200 mg a day from food and supplements) and vitamin D from the start, bone density testing when long-term ADT begins and drug treatment when fracture risk is high.
- **Metabolic effects:** weight and fat gain, higher risk of diabetes, higher lipids and cardiac risk. Blood pressure, glucose and lipids are checked every 6 to 12 months, with support to stop smoking, eat well and exercise.
- **Muscle loss and fatigue:** supervised resistance and aerobic exercise.
- **Mood, thinking and sexual effects:** watch for depression and cognitive decline; loss of libido affects up to 90% of men.

People with a prostate who are not men. Transgender women keep the prostate after gender-affirming surgery. Estrogen and anti-androgen therapy changes PSA levels, which may be lower than in cisgender men with prostate cancer. Transgender women appear to develop prostate cancer less often than cisgender men, and no established screening guidelines exist for them (Ismail et al., 2025). The nurse uses the person's name, pronouns and preferred anatomical terms and helps them discuss testing with their provider (Chapter 2; Chapter 29).

Bladder Cancer

Smoking is the main risk factor for bladder cancer; risk rises the more and longer a person smokes and falls after quitting. Risk also rises with age, especially after 65, and men are affected more often than women. Other risks include workplace chemicals (painting, rubber, metal, textile and dye manufacturing, transportation), arsenic in drinking water, past cyclophosphamide chemotherapy or pelvic radiation, and long-term bladder irritation, including from long-term catheters (CCS, n.d.-e).

Blood in the urine (Figure 28.5) is the most frequent sign of bladder cancer; it may be visible or found only on urinalysis, and early bladder cancer may cause no symptoms at all (CCS, n.d.-g). The CUA recommends imaging, especially with visible hematuria, with contrast CT as the first choice (Bhindi et al., 2021). Cystoscopy, a look inside the bladder with a scope, finds the tumour.

Figure 28.5 Visible blood in the urine (gross hematuria), with a dipstick that is positive for blood. Visible hematuria in an adult is always reported and investigated.

Resection and intravesical therapy. Transurethral resection of bladder tumour (TURBT) removes the tumour through a scope, with a sample of the muscle beneath it to show how deep the cancer goes. Patients with a presumed low-risk tumour are offered a single dose of chemotherapy into the bladder within 24 hours. For higher-risk non-muscle-invasive cancer, the standard is **intravesical BCG**, live, weakened bacillus Calmette-Guérin bacteria instilled into the bladder through a catheter, weekly for 6 weeks and then as maintenance for 1 to 3 years. Bladder cancer often recurs, so surveillance cystoscopy starts 3 months after TURBT (Bhindi et al., 2021).

Because BCG is a live organism, the Canadian monograph sets out precautions (Verity Pharmaceuticals, 2021):

- **Before:** treatment starts 2 to 3 weeks after resection, once the lining has healed. It is postponed after a traumatic catheterization, during visible hematuria, during a urinary tract infection and for fever until it is assessed. The patient takes no fluids for 4 hours before the treatment and for 2 hours after it.
- **Handling:** it is prepared aseptically in a biological safety cabinet, with personal protective equipment, and supplies are discarded as biohazardous waste.
- **After:** the patient holds the drug for 2 hours, then voids sitting down. For 6 hours, bleach is added to the toilet after each void and left 15 minutes before flushing. The patient avoids intercourse for a week after each instillation or uses a condom.
- **Effects:** frequency, urgency, painful voiding and hematuria usually settle within 2 days; fever and flu-like symptoms are also common. A fever above 39 °C lasting more than 12 hours needs urgent assessment, because systemic BCG infection can be fatal.

Cystectomy and ileal conduit. For high-risk cancer that does not respond to BCG, removal of the bladder (radical cystectomy) is the standard for patients fit for surgery (Bhindi et al., 2021). In an **ileal conduit**, a short piece of small intestine becomes a channel: the ureters drain into one end, and the other end forms a stoma, a **urostomy**, that drains urine into a pouch. Before surgery, the surgeon or a nurse specialized in wound, ostomy and continence (NSWOC) marks a site the patient can see, away from skin creases (Nurses Specialized in Wound, Ostomy and Continence Canada [NSWOCC], 2022). Ostomy principles are covered in section 25.6. Urostomy points include (NSWOCC, 2022):

- **Stoma:** moist and pinkish-red; swollen at first, shrinking over 6 to 8 weeks, so the barrier opening is re-measured.
- **Stents and mucus:** stents drain the ureters for anywhere from about 5 days to 2 weeks, sometimes longer; mucus threads in the urine are normal, because the conduit is intestine.
- **Pouching:** empty at one-third to one-half full, and use a night drainage bag; clean the skin with warm water.
- **Report:** urine flow that slows or stops, heavy bleeding, a marked change in stoma size or colour, blood or clots in the urine, gritty white deposits or wart-like skin changes near the stoma, and signs of infection.

CANADIAN CONTEXT

Prostate and Bladder Cancer in Canada

Bladder cancer is projected to affect 13,200 people in Canada in 2026: 9,900 men and 3,300 women. About 2,500 people will die from it, including 1,750 men and 720 women (CCS, n.d.-a). Together with prostate cancer, that is a large group of people living with urinary changes after treatment, often for many years.

These figures are reported by sex assigned at birth (CCS, n.d.-a). Transgender women and non-binary people with a prostate are therefore hard to see in the data, and research on their risk is limited (CCS, n.d.-f).

Several bladder cancer risks are preventable at the population level. Smoking is the main one. Workplace exposures in painting, rubber, metal, textile and dye manufacturing and transportation also matter, as does arsenic in drinking water (CCS, n.d.-e). Asking about work history, offering support to quit smoking and asking about drinking water sources are practical nursing actions.

Black men are diagnosed with prostate cancer more often than other men and tend to have faster-growing tumours and higher death rates from it (CCS, n.d.-f). Clear information about the screening options in Table 28.4, and fair access to testing and follow-up, are the nurse's focus (Chapter 2).

SCOPE IN PRACTICE

Catheters, Bladder Scans and Who Does What

- **Authority:** in Ontario, putting an instrument "beyond the opening of the urethra" is one of the controlled acts authorized to nursing, and inserting or irrigating a urinary catheter falls under it. RNs and RPNs need an order or directive unless they have authority to initiate; CNO allows initiation of this act only for limited purposes, such as assisting a patient with health management activities, and not in public hospitals (College of Nurses of Ontario [CNO], 2025a, 2025c). RNs and RPNs have authority to use portable bladder ultrasound for routine nursing assessments (CNO, 2025b). Catheter removal and scan-based catheterization protocols usually work through a medical directive (section 28.2; Chapter 1, section 1.3).
- **Competence:** CBI, manual irrigation of a blocked three-way catheter and BCG handling need specific knowledge and skill; a nurse not yet taught a skill seeks education and supervision first.
- **Context:** employer policy decides who manages CBI, hand-irrigates after urologic surgery or gives intravesical drugs; limiting these to RNs or urology nurses is an employer decision, not a CNO rule. An RPN consults the RN as a patient's needs change, and every nurse who sees clot retention, heavy bleeding or new confusion acts at once and escalates.
- **Across Canada:** the province or territory matters; practical nurses (PNs), called licensed practical nurses (LPNs) in some provinces, follow their own regulator and employer. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (CNO, 2026).

Chapter 28 Summary

28.1 Urinary Tract Infection

- Cystitis causes dysuria, urgency, frequency and suprapubic pain; fever, rigors and flank or costovertebral angle tenderness suggest pyelonephritis, and signs of organ dysfunction suggest urosepsis, which needs immediate escalation.
- A midstream clean-catch specimen is collected after cleaning, and a catheter specimen comes from the sampling port, never the bag.
- Negative nitrite and leukocyte esterase results help rule out UTI, but a positive dipstick proves little; dipsticks are not used to diagnose UTI in long-term care or for adults over 65.

- Asymptomatic bacteriuria is common in older adults and is not screened for or treated, except in pregnancy and before urologic procedures that break the mucosa; a confused older adult without urinary or systemic signs needs a search for other causes.
- Nitrofurantoin, fosfomycin and, where resistance allows, trimethoprim-sulfamethoxazole are guideline choices for cystitis; pyelonephritis always needs a culture, and treatment is reassessed within about 3 days.
- Cranberry products probably reduce UTIs in women with recurrent UTIs but are not supported for older adults in institutions.

28.2 Urinary Catheters and CAUTI Prevention

- The length of time a catheter stays in is the most important risk factor for CAUTI, and many catheters have no appropriate indication.
- Appropriate indications include acute retention or obstruction, output monitoring in critical illness, selected surgery, open sacral or perineal wounds with incontinence, prolonged immobilization and comfort at the end of life; incontinence and convenience are not indications.
- Insertion is aseptic with the smallest catheter that drains well; the system stays closed, the bag stays below the bladder and off the floor, and catheters are not changed at fixed intervals.
- Daily review, nurse-driven removal protocols and alternatives such as intermittent and external catheters reduce catheter use.
- CAUTI is suspected with fever, suprapubic tenderness or flank pain; cloudy or smelly urine alone is not a reason to culture.

28.3 Urinary Retention and Incontinence

- Retention may be acute or chronic; causes include prostate enlargement, anticholinergic drugs and opioids, anesthesia, constipation and neurologic disease.
- A bladder scanner measures the post-void residual; the nurse follows the unit protocol's thresholds and prefers intermittent catheterization to reinserting an indwelling catheter.
- Incontinence affects 30% to 60% of people over 65 but is not a normal part of aging; the main types are stress, urgency, mixed, overflow and functional.
- Assessment includes a bladder diary, urinalysis, a search for temporary causes and, when needed, a PVR.
- Pelvic floor muscle training, bladder training, lifestyle changes and prompted voiding come first; antimuscarinics carry cognitive risk in older adults, and an indwelling catheter is never a substitute for continence care.

28.4 Kidney Stones

- Stones form when urine carries more of a substance than it can keep dissolved; calcium stones are most common, followed by uric acid, struvite (infection) and cystine stones.
- Renal colic causes sharp, wave-like pain in the back, side or groin, often with nausea and hematuria; the CUA recommends ultrasound with KUB X-ray first and low-dose CT when needed.
- The CUA guideline found that NSAIDs relieved renal colic better than morphine and recommends keeping opioid use low; any benefit of medical expulsive therapy is for 5 to 10 mm stones in the lower ureter.
- An obstructed, infected kidney is an emergency that needs antibiotics and urgent decompression by stent or nephrostomy; the nurse escalates at once.
- Prevention starts with a urine output of 2.5 L a day, normal dietary calcium, less sodium, moderate animal protein and diet advice matched to the stone type.

28.5 Benign Prostatic Hyperplasia and Prostate Surgery

- BPH causes voiding and storage symptoms; the CUA recommends a symptom score such as the IPSS, and complications include retention, infections, stones, hematuria and kidney damage.
- Alpha-blockers can cause dizziness and low blood pressure and are linked to floppy iris syndrome in eye surgery; 5-alpha reductase inhibitors take months to work, halve the PSA and should not be handled crushed by people who are or may become pregnant.

- During continuous bladder irrigation, the nurse adjusts the flow to the bleeding, calculates true urine output and watches for clot retention: no drainage, rising pain, a full bladder and leaking.
- For a blocked catheter, the nurse stops the inflow, checks the tubing, assesses the bladder, follows the protocol and calls urology if it does not clear.
- TUR syndrome is dilutional hyponatremia from absorbed irrigating fluid during monopolar TURP; new confusion, nausea, slow pulse and high blood pressure after TURP need urgent escalation.

28.6 Prostate and Bladder Cancer

- Prostate cancer is the most common cancer in men in Canada; an estimated 29,300 men will be diagnosed in 2026, and it is diagnosed more often in Black men.
- The Canadian Task Force (2014) recommends against PSA screening, while the CUA (2022) suggests offering it through shared decision-making; the nurse presents both accurately.
- Active surveillance is the preferred option for low-risk cancer; after prostatectomy, leakage is common and usually improves; ADT causes hot flashes, bone and muscle loss, metabolic, mood and sexual effects that need monitoring and exercise.
- Smoking is the main risk factor for bladder cancer, and visible hematuria needs investigation; intravesical BCG is a live agent with strict handling, voiding and fever precautions.
- After cystectomy with an ileal conduit, mucus in the urine is normal; a marked change in stoma colour, stopped urine flow or signs of infection are reported at once, and an NSWOC supports teaching.

Key Terms (60)

5-alpha reductase inhibitor (5-ARI): a drug that shrinks the prostate over months and lowers the PSA level by about half.

active surveillance: planned monitoring of a low-risk prostate cancer with PSA tests, examinations and biopsies, with treatment offered if the cancer changes.

alpha-blocker: a drug that relaxes smooth muscle in the prostate and bladder neck, improving urine flow; can cause dizziness and low blood pressure.

androgen deprivation therapy (ADT): treatment that lowers testosterone to slow the growth of prostate cancer.

asymptomatic bacteriuria (ASB): Bacteria in the urine at a significant count in a person with no signs or symptoms of urinary tract infection; usually not screened for or treated.

benign prostatic hyperplasia (BPH): non-cancerous enlargement of the prostate that can narrow the urethra.

bladder diary: A record of fluid intake, voids, urgency and leaks kept over several days to assess bladder problems.

bladder scanner: A portable ultrasound device that estimates the volume of urine in the bladder.

bladder training: A schedule of voiding at set times, with intervals lengthened gradually, combined with urge-suppression techniques.

catheter-associated urinary tract infection (CAUTI): A urinary tract infection in a person who has, or recently had, a urinary catheter.

clot retention: blockage of a urinary catheter by blood clots, so the bladder fills and cannot drain.

continuous bladder irrigation (CBI): constant flow of sterile 0.9% sodium chloride into and out of the bladder through a three-way catheter to prevent clots.

costovertebral angle: The angle on the back between the lowest rib and the spine; tenderness here suggests kidney involvement.

cystitis: Infection limited to the bladder, usually causing dysuria, urgency, frequency and suprapubic pain.

decompression: drainage of a kidney blocked by a stone, by ureteral stent or nephrostomy tube; urgent when the blocked kidney is infected.

dysuria: Pain or burning on urination.

external catheter: A device that collects urine from outside the body, such as a sheath over the penis or a suction device against the vulva.

functional incontinence: Leakage because a person cannot reach or use the toilet in time, for example because of limited mobility or dementia.

hematuria: blood in the urine, which may make it pink, red or brown or be seen only on testing.

ileal conduit: a channel made from a short piece of small intestine that carries urine from the ureters to a stoma on the abdomen.

indwelling urinary catheter: A tube passed into the bladder through the urethra or abdominal wall, held by a balloon and draining continuously into a closed bag.

intermittent catheterization: Passing a catheter into the bladder to drain it and then removing it; done with sterile technique in hospital and clean technique at home.

International Prostate Symptom Score (IPSS): a short questionnaire used to rate the severity of lower urinary tract symptoms and follow the response to treatment.

intraoperative floppy iris syndrome: a problem with the iris during cataract or glaucoma surgery linked to alpha-blockers such as tamsulosin.

intravesical BCG: live, weakened bacillus Calmette-Guérin bacteria instilled into the bladder to treat non-muscle-invasive bladder cancer.

leukocyte esterase: An enzyme from white blood cells; a positive dipstick result suggests pyuria.

lower urinary tract symptoms (LUTS): voiding symptoms (weak stream, hesitancy, straining, incomplete emptying) and storage symptoms (urgency, frequency, nocturia).

medical expulsive therapy (MET): use of a drug to help a ureteral stone pass; any benefit is for larger (5 to 10 mm) stones in the lower ureter.

midstream clean-catch specimen: A urine sample collected from the middle of the stream after the genital area is cleaned, to reduce contamination by skin bacteria.

nephrostomy tube: a tube placed through the skin of the back into the kidney to drain urine.

nitrites: Chemicals formed when certain bacteria convert nitrate in urine; a negative result does not rule out bacteriuria.

nocturia: waking at night to pass urine.

nurse-driven catheter removal protocol: A protocol, often a medical directive, that lets nurses remove a urinary catheter when no listed indication remains.

overflow incontinence: Leakage from a bladder that overfills because it cannot empty.

pelvic floor muscle training (PFMT): Repeated, correctly performed contractions of the pelvic floor muscles to improve continence.

post-void residual (PVR): The volume of urine left in the bladder right after voiding.

prompted voiding: A toileting approach for frail or cognitively impaired people in which staff check regularly, ask about the need to void, help to the toilet and give praise.

prostate-specific antigen (PSA): a protein made by the prostate and measured in a blood test, used in prostate cancer screening and follow-up.

pyelonephritis: Infection that has reached the kidney, usually with fever, rigors and flank pain or costovertebral angle tenderness.

pyuria: White blood cells in the urine; it occurs with both infection and asymptomatic bacteriuria.

radical prostatectomy: surgical removal of the whole prostate and some nearby tissue, including the seminal vesicles.

renal colic: severe, often wave-like pain in the back, side, lower abdomen or groin caused by a stone moving through or blocking the ureter.

retrograde ejaculation: flow of semen backward into the bladder rather than out through the urethra, common after TURP.

shock wave lithotripsy (SWL): use of shock waves from outside the body to break a stone into fragments that pass in the urine.

stress incontinence: Leakage of urine with coughing, sneezing, laughing, lifting or other exertion.

three-way catheter: an indwelling urinary catheter with separate channels for the balloon, drainage and irrigation inflow.

transurethral resection of bladder tumour (TURBT): removal of a bladder tumour through a scope passed into the bladder, with a sample of the muscle beneath.

transurethral resection of the prostate (TURP): removal of the inner prostate tissue with an electrical wire loop passed through the urethra.

transurethral resection syndrome (TUR syndrome): dilutional hyponatremia and fluid overload caused by absorption of irrigating fluid during transurethral surgery.

true urine output: during bladder irrigation, the total volume drained minus the volume of irrigation instilled.

ureteral stent: a thin, flexible tube placed in the ureter, from the kidney to the bladder, to keep urine draining.

ureteroscopy: passing a thin scope through the urethra and bladder into the ureter to break up or remove a stone.

urge incontinence: Leakage of urine with or right after a sudden, strong urge to void that is hard to delay; also called urgency incontinence.

urinary incontinence: Any involuntary leakage of urine.

urinary retention: Inability to empty the bladder completely or at all; it may be acute or chronic.

urinary tract infection (UTI): An infection anywhere in the urinary tract, from the urethra to the kidneys.

urine culture: A laboratory test that identifies bacteria in urine, counts them and tests their susceptibility to antibiotics.

urolithiasis: stones anywhere in the urinary tract.

urosepsis: Sepsis that starts from an infection of the urinary tract.

urostomy: a stoma that drains urine into a pouch on the abdomen.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Dorothy Kowalchuk (Questions 1–4): Dorothy Kowalchuk, 86, lives in a long-term care home in Nova Scotia; she has moderate dementia, walks with a walker and is usually continent with reminders, and today the licensed practical nurse (LPN) finds her sleepier and more confused than usual since yesterday, with dark, strong-smelling urine, a urine dipstick (done by a care aide) positive for leukocyte esterase and nitrites, no bowel movement for 4 days, poor fluid intake, no complaints of pain on voiding, a temperature of 37.2 °C, blood pressure 118/70 mm Hg, heart rate 84 beats/min and respiratory rate 18 breaths/min.

1. [CORE] Which interpretation of Mrs. Kowalchuk's positive dipstick is most accurate?

a. It confirms a bladder infection, which is the most likely explanation for her new confusion, sleepiness and dark urine.

b. It suggests pyelonephritis, because both the nitrite and leukocyte esterase results were positive today.

c. It cannot separate infection from bacteriuria, which is common in residents, so other causes need to be assessed.

d. It is a false result caused by her concentrated urine, so it can be ignored and the test repeated tomorrow.

Answer: c — As many as half of long-term care residents have bacteriuria without infection, and dipsticks are not used to diagnose UTI in this setting, so a positive result does not explain her change in health (section 28.1, Asymptomatic Bacteriuria and Lifespan box). Option a assumes a UTI that has not been shown. Option b is wrong because pyelonephritis is recognized by fever, rigors and flank pain, not by dipstick results. Option d is wrong because concentration does not make both pads falsely positive, and repeating a dipstick would not help.

2. [CORE] Which assessment should the LPN do next to find the cause of Mrs. Kowalchuk's change?

a. Assess her abdomen and bowel pattern, fluid intake, recent medication changes and her attention and thinking.

b. Collect a midstream clean-catch urine specimen so that a culture can be sent to the laboratory today.

c. Insert an in-and-out catheter to obtain a clean specimen, because she cannot follow collection steps.

d. Check her temperature every 15 minutes for the next 2 hours so that a fever is detected as soon as it begins to rise.

Answer: a — The nurse looks for other causes of a change in an older adult, such as constipation, dehydration, medications and delirium, before assuming a UTI (section 28.1, Lifespan box; section 8.2). She has not had a bowel movement in 4 days and has been drinking little. Options b and c are wrong because she does not meet minimum criteria for a culture, and catheterizing to collect urine adds risk. Option d is excessive for a resident with stable vital signs; regular reassessment is enough.

3. [CORE] Mrs. Kowalchuk's daughter visits and says, "Mom always gets confused with a bladder infection. Please send her urine and get her started on antibiotics." Which response by the LPN is best?

a. "I understand. I'll collect a urine sample now and ask the nurse practitioner for an antibiotic today."

b. "Antibiotics are never used for older adults in long-term care, so we will not be testing her urine."

c. "The dipstick was positive, so the nurse practitioner will decide about antibiotics once the culture results come back from the lab."

d. "You know her well. Many residents have bacteria in the urine without infection, so we're checking other causes first."

Answer: d — Choosing Wisely Canada advises staff to understand family concerns and explain the other possible causes and the reason for any test before collecting a culture (section 28.1, Lifespan box). Option a agrees to a test and treatment that are not indicated. Option b is false; antibiotics are used when an infection meets criteria. Option c treats the dipstick as meaningful and implies antibiotics are likely, which is misleading.

4. [CORE] The LPN reports to the nurse practitioner (NP). Which statement best fits the situation?

a. "Mrs. Kowalchuk has a positive dipstick and dark urine; can I get an order for an antibiotic for a UTI?"

b. "Mrs. Kowalchuk is more confused, has had no bowel movement in 4 days and is drinking poorly; vital signs are stable and she has no urinary symptoms. I'd like you to assess her."

c. "Mrs. Kowalchuk is more confused today, so I'll recheck her at the end of my shift and call you if she gets worse."

d. "Mrs. Kowalchuk's dipstick is positive, so I'd like an order to send a urine culture before you decide on treatment."

Answer: b — A situation, background, assessment, recommendation (SBAR) report gives the change, the relevant findings (including the absence of urinary symptoms and fever) and a clear request (section 28.1; section 6.2). Option a asks for treatment based on a dipstick, which is not used to diagnose UTI. Option c delays reporting a change in mental status. Option d asks for a culture that minimum criteria do not support.

5. [CORE] The nurse teaches a woman to collect a midstream clean-catch urine specimen. Which statement shows she understands?

a. "I'll clean with the wipes, start peeing into the toilet, then move the cup into the stream to catch the middle part."

b. "I'll fill the cup with the very first urine of the day, because that part has the most bacteria in it."

c. "I'll clean from back to front with a single wipe, then catch all of my urine in the container so that none of it is missed."

d. "I'll leave the cup in the bathroom until the afternoon, when I can bring it to the lab with my other papers."

Answer: a — The first part of the stream flushes skin bacteria away, so the midstream portion is collected after cleaning with downward strokes (section 28.1, Specimens and Urinalysis). Option b collects the first urine, which is more likely to be contaminated. Option c wipes in the wrong direction and collects the whole void. Option d is wrong because the specimen must reach the laboratory within 2 hours or be refrigerated.

6. [CORE] A urine culture is ordered for a patient with an indwelling catheter who has a new fever. How should the nurse collect the specimen?

a. Pour urine from the drainage bag into a sterile container, because the bag holds the most recently produced urine.

b. Disconnect the catheter from the tubing and let urine drip from the catheter end into a sterile cup.

c. Disinfect the sampling port, clamp the tubing briefly below it and withdraw urine with a sterile syringe.

d. Remove the catheter and ask the patient to provide a midstream specimen within the next 2 hours.

Answer: c — Catheter specimens are taken aseptically from the sampling port, keeping the system closed (section 28.1, Specimens and Urinalysis; section 4.2). Option a is wrong because urine for culture is never taken from the bag. Option b opens the closed system, which raises infection risk. Option d delays the culture and removes a catheter that may still be needed, without an order.

7. [CORE] A patient admitted with cystitis develops new findings. Which finding most strongly suggests the infection has reached the kidney?

a. Burning on urination and needing to void every hour

b. Cloudy urine with a strong odour noted in the drainage bag and urinal this morning

c. Pink-tinged urine and mild discomfort above the pubic bone

d. A temperature of 38.9 °C with chills and tenderness at the costovertebral angle

Answer: d — Fever, rigors and flank or costovertebral angle tenderness show that infection has moved beyond the bladder, as in pyelonephritis (section 28.1, Cystitis, Pyelonephritis and Urosepsis). Options a and c are bladder symptoms of cystitis. Option b is not a reliable sign of infection at all.

8. [CORE] A 52-year-old woman with type 2 diabetes has a urine culture sent with her routine blood work. It grows more than 10^8 CFU/L of one organism. She has no urinary symptoms and no fever. What does the nurse expect?

a. A short course of an antibiotic, because diabetes raises her risk of developing a kidney infection later

b. No antibiotic, because guidelines advise against treating bacteriuria without symptoms in diabetes

c. A repeat culture every month until the bacteria clear, to prevent pyelonephritis from developing

d. Admission for IV antibiotics, because of the high colony count and her diabetes

Answer: b — This is asymptomatic bacteriuria, and the IDSA guideline recommends against screening for or treating it in people with diabetes (section 28.1, Asymptomatic Bacteriuria). Option a treats bacteriuria that does not need treatment and risks adverse effects and resistance. Option c is screening, which is not recommended. Option d is wrong because a colony count without symptoms is not an infection.

9. [CORE] A 34-year-old woman is starting nitrofurantoin for cystitis. Which statement shows she needs more teaching?

a. "I'll take every dose as prescribed for the number of days on the label."

b. "I'll call the clinic if I get a fever, pain in my side or back, or start throwing up."

c. "I'll drink fluids through the day unless I've been told to limit them."

d. "I'll keep any pills I have left over for the next time I get these symptoms."

Answer: d — Saving leftover antibiotics leads to self-treatment without assessment and fuels resistance, so she needs more teaching (section 28.1, Treatment and Teaching; section 4.5). Options a, b and c are correct: take the antibiotic as prescribed, seek care if signs of kidney infection appear, and drink fluids unless restricted.

10. [CORE] Which situations are appropriate indications for an indwelling urinary catheter? Select all that apply.

a. A patient with acute urinary retention from bladder outlet obstruction

b. A critically ill patient in septic shock who needs hourly urine output

c. A patient with dementia who is incontinent at night

d. A patient receiving comfort care at the end of life who prefers a catheter

e. A patient who can void but needs a urine sample for culture

f. An incontinent patient with an open stage 4 sacral pressure injury

g. A patient with delirium who keeps getting out of bed to use the toilet

Answer: a, b, d, f — Acute retention or obstruction, accurate output measurement in critical illness, comfort at the end of life and helping an open sacral or perineal wound heal when the patient is incontinent are appropriate indications (section 28.2, Indwelling Catheters). Incontinence (c) is managed with continence care, not a catheter. Collecting urine from a patient who can void (e) is an inappropriate use. Delirium (g) is not an indication, and a catheter can worsen delirium and immobility.

11. [CORE] The nurse sees a care aide helping a catheterized patient walk in the hall. Which action needs correction?

a. The care aide carries the drainage bag at waist height as they walk together.

b. The care aide keeps the tubing free of kinks and loops during the walk.

c. The care aide has emptied the bag into the patient's own labelled measuring container.

d. The care aide reminds the patient not to pull on the catheter or tubing.

Answer: a — The bag must stay lower than the bladder throughout, including during walks, so urine does not flow back (section 28.2, Indwelling Catheters). Options b, c and d are correct practices: unobstructed flow, a separate container for each patient and preventing traction.

12. [CORE] A patient has had an indwelling catheter for 4 days after a hip fracture. Which finding should the nurse report as a possible catheter-associated urinary tract infection?

a. Urine in the bag that is cloudy and darker than yesterday, with no other changes

b. A new temperature of 38.6 °C with suprapubic tenderness and no other source found

c. Sediment in the tubing that the nurse notices while emptying the bag this morning

d. A urine culture sent on admission, before the catheter, that grew a small amount of mixed organisms

Answer: b — CAUTI is suspected when a catheterized patient has signs such as fever, suprapubic tenderness or costovertebral angle pain (section 28.2, Recognizing CAUTI). Cloudy or dark urine (a) or sediment (c) alone is not a reason to culture. Option d is an old result, taken before the catheter, that does not indicate a current infection.

13. [CORE] An older man's indwelling catheter was removed at 0600. At 1300 he has not voided, says he feels "full," and his lower abdomen is firm above the pubic bone. What should the nurse do first?

a. Encourage him to drink two large glasses of water to help him void.

b. Reinsert an indwelling catheter so that the bladder does not overfill again.

c. Scan his bladder as the unit protocol allows and report the result.

d. Document the findings and reassess him at the end of the shift.

Answer: c — The findings suggest retention after catheter removal; the nurse measures the bladder volume as the protocol allows and acts on the result, often with intermittent catheterization rather than an indwelling catheter (section 28.3, Urinary Retention). Option a adds volume to a bladder that may not be able to empty. Option b skips assessment and reinserts a catheter, which the post-removal algorithm aims to avoid. Option d delays care and risks bladder injury.

14. [CORE] An 80-year-old woman with severe hip arthritis says, "I know when I need to go, but by the time I get my walker and reach the bathroom, I've already leaked." Which plan best addresses this type of incontinence?

a. Teach her to do pelvic floor contractions several times a day for 12 weeks.

b. Offer help to the toilet on a regular schedule and keep a commode and call bell close by.

c. Ask the prescriber to start an antimuscarinic medication to calm her overactive bladder muscle.

d. Measure her post-void residual after each void for the next 24 hours.

Answer: b — She has functional incontinence: she senses the need to void but cannot reach the toilet in time because of limited mobility (section 28.3, Urinary Incontinence; Table 28.2). Scheduled toileting help, a nearby commode and a call bell target the cause. Option a treats stress incontinence. Option c treats urgency incontinence and adds anticholinergic risk. Option d is used when emptying is in question, which her history does not suggest.

15. [CORE] An 84-year-old man started oxybutynin 1 week ago for urgency incontinence. Which finding should the nurse report to the prescriber?

a. He is voiding every 3 hours during the day.

b. He reports one leak in the past 2 days.

c. He has a slightly dry mouth after meals.

d. He has new confusion and has not had a bowel movement in 4 days.

Answer: d — Antimuscarinics such as oxybutynin can cause confusion and constipation in older adults and add to anticholinergic burden, so new confusion with constipation needs prompt reporting (section 28.3, Urinary Incontinence). Options a and b suggest the treatment is helping. Option c is a common, mild adverse effect that can be managed with sips of water and mouth care.

16. [CORE] An RPN on a medical unit finds that a patient with a urinary catheter has a temperature of 39.1 °C, heart rate 122 beats/min, blood pressure 88/52 mm Hg and new confusion. What should the RPN do first?

a. Call for help at once through the rapid response process and inform the RN.

b. Collect a urine specimen from the sampling port and send it for culture.

c. Remove the catheter, because it is the likely source of the infection.

d. Give acetaminophen as ordered for the fever and recheck all of the vital signs in 1 hour.

Answer: a — These findings suggest sepsis, possibly from the urinary tract. Every nurse who notices deterioration acts and escalates at once, and the RPN consults the RN as the patient's needs change (section 28.1, Cystitis, Pyelonephritis and Urosepsis; Chapter 6). Options b and c may be part of later care, but they do not come before escalation. Option d delays treatment of a possibly septic patient.

17. [CORE] An RPN is asked to perform intermittent catheterization for a patient with retention. The order is in place, but the RPN has not performed the procedure since school. Using CNO's scope framework, what should the RPN do?

a. Perform it, because an order exists and RPNs are authorized for the controlled act.

b. Decline and tell the charge nurse that intermittent catheterization is outside the scope of practice of RPNs.

c. Ask an RN to perform it every time it is needed for this patient from now on.

d. Tell the charge nurse and get support or supervision to perform it safely, following employer policy.

Answer: d — CNO's Scope of Practice standard asks nurses to have authority, competence and context; here the RPN has authority (an order and a controlled act authorized to RPNs) but needs to confirm competence, so the RPN seeks support as employer policy allows (CNO, 2025c; Chapter 1, section 1.3; section 28.6, Scope in Practice box). Option a ignores competence. Option b is wrong because the act is within RPN scope with an order. Option c hands off the task without building the needed competence. Employer policy and province or territory also matter.

18. [RN] A 30-year-old woman has dysuria and frequency. Her urinalysis shows positive leukocyte esterase and negative nitrite, and the culture grows *Enterococcus faecalis* at 10^8 CFU/L. Which explanation for the negative nitrite is most accurate?

a. The bacteria were not in the bladder long enough to multiply into a significant count.

b. *Enterococcus* does not convert nitrate to nitrite, so the nitrite test stays negative.

c. A negative nitrite result means the culture was probably contaminated during collection.

d. Leukocyte esterase blocks the nitrite reaction when both are present in the same sample.

Answer: b — The nitrite test depends on bacteria that convert nitrate to nitrite, and *Enterococcus* does not, so a negative nitrite does not exclude infection (section 28.1, Going Deeper box). Option a is wrong because the count of 10^8 CFU/L is significant. Option c misreads the meaning of a negative nitrite. Option d is not how the reagent pads work.

19. [RN] **A medical unit uses a nurse-driven catheter removal directive. Which patient's catheter should the nurse remove under the directive?**

a. A man receiving continuous bladder irrigation after transurethral resection of the prostate

b. A woman admitted with pneumonia who had a catheter placed in the emergency department "to monitor output," and who is now stable and walking

c. A man with a long-term catheter that was in place before admission for chronic retention

d. A woman with an open stage 4 sacral pressure injury and ongoing incontinence

Answer: b — A catheter placed for output monitoring in a patient who is now stable and walking has no remaining indication, so the directive supports removal (section 28.2, Indwelling Catheters; Clinical Safety box). Continuous bladder irrigation (a), a long-term catheter present before admission (c) and an open sacral wound with incontinence (d) are listed indications to keep the catheter.

20. [RN] **Six hours after knee surgery under spinal anesthesia, a patient voids 150 mL and has no discomfort. A bladder scan right afterward shows 560 mL. The unit protocol defines retention as a PVR over 500 mL in a patient without symptoms or over 300 mL in one who has symptoms. What should the nurse do?**

a. Repeat the scan in 6 hours, because the patient has no discomfort.

b. Insert an indwelling catheter and keep it until the patient is walking.

c. Perform intermittent catheterization as the protocol directs and reassess voiding.

d. Encourage the patient to drink more fluid to stimulate another void within an hour.

Answer: c — A PVR above 500 mL meets the protocol's definition of retention even without symptoms, and intermittent catheterization is preferred to an indwelling catheter (section 28.3, Urinary Retention). Option a waits while the bladder overfills; many patients feel no urge after spinal anesthesia. Option b uses an indwelling catheter when intermittent drainage is preferred. Option d adds volume to a bladder that is not emptying.

Case: Gerald Fontaine (Questions 21–26): Gerald Fontaine, 76, returned to the surgical unit at 14:00 after a monopolar transurethral resection of the prostate (TURP) for benign prostatic hyperplasia. He has a three-way catheter with continuous bladder irrigation (CBI) of 0.9% sodium chloride. His preoperative serum sodium was 139 mmol/L. At 17:00 he tells the nurse, "It feels like I have to pee, and it's getting worse." The drainage is dark red with several clots, and only 50 mL has drained in the past hour although the irrigation is running at the ordered rate. His lower abdomen is firm above the pubic bone, and urine is leaking around the catheter onto the bed pad. Heart rate 104, blood pressure 148/86 mm Hg, respiratory rate 20, temperature 36.8 °C, SpO2 96% on room air.

21. [CORE] **Which findings should the nurse recognize as cues that the catheter may be blocked? Select all that apply.**

a. Dark red drainage containing several clots

b. Only 50 mL drained in an hour while the irrigation runs at the ordered rate

c. A firm lower abdomen above the pubic bone

d. Urine leaking around the catheter onto the bed pad

e. A temperature of 36.8 °C

f. An SpO2 of 96% on room air

g. A strong urge to void that is getting worse

Answer: a, b, c, d, g — Clots in the drainage, drainage far below the irrigation running in, a firm, distended bladder, leaking around the catheter and a growing urge to void are all signs of clot retention (section 28.5, Surgery and Continuous Bladder Irrigation). A normal temperature (e) does not point to blockage; it makes infection less likely at this stage. An SpO2 of 96% (f) is normal and unrelated to catheter patency.

22. [CORE] **Which explanation best fits Mr. Fontaine's findings?**

a. Bladder spasms from cold irrigation fluid, with the catheter still draining freely

b. Clot retention, with irrigation fluid collecting in a bladder that cannot drain

c. Expected bleeding after the resection that needs no change in his care

d. A urinary tract infection caused by the three-way catheter placed in surgery

Answer: b — Fluid is going in but not coming out, the bladder is firm and urine is bypassing the catheter, which together point to clot retention (section 28.5). Spasms (a) cause urgency and leaking, but a freely draining catheter would not let the bladder fill and harden; blockage is ruled out first. Some bleeding is expected after TURP (c), but clots that stop drainage need action. Infection (d) is unlikely within 3 hours of surgery and would not explain the lack of drainage.

23. [CORE] What should the nurse do first?

a. Increase the irrigation rate so the extra fluid can flush the clots through the catheter

b. Deflate the catheter balloon and pull the catheter back slightly to free the clot

c. Stop the irrigation inflow and check the catheter and tubing for kinks, loops and clots

d. Give the ordered as-needed antispasmodic and reassess the drainage in 1 hour

Answer: c — When drainage is less than the irrigation going in, the nurse turns off the inflow so the bladder stops filling, then checks the tubing before taking further steps under the protocol (section 28.5). Raising the rate (a) pushes more fluid into a blocked bladder. The nurse does not deflate, reposition or replace a catheter after urologic surgery without the urologist's authorization (b). An antispasmodic (d) does not clear a blockage, and waiting an hour lets the bladder overfill.

24. [CORE] The urology resident clears the clots, and the irrigation is restarted. Over the next 4 hours, 4,200 mL of irrigation is instilled and 4,650 mL drains. The drainage is light pink, and Mr. Fontaine rates his pain 2 out of 10. What is his true urine output for these 4 hours?

a. 4,200 mL

b. 8,850 mL

c. 4,650 mL

d. 450 mL

Answer: d — True urine output is the total drained minus the irrigation instilled: 4,650 − 4,200 = 450 mL, about 112 mL an hour, which is adequate (section 28.5). 4,200 mL (a) is the irrigation volume. 8,850 mL (b) wrongly adds the two volumes. 4,650 mL (c) is the total drainage, which includes the irrigation fluid.

25. [RN] At 21:00, Mr. Fontaine is restless and asks why he is "at the train station." He has vomited once. Heart rate 52, blood pressure 176/96 mm Hg. His serum sodium is now 124 mmol/L. Which hypothesis should the nurse treat as the priority?

a. Transurethral resection syndrome from irrigation fluid absorbed during surgery

b. Postoperative delirium caused by unfamiliar surroundings, disrupted sleep and pain

c. Hypovolemia from bleeding into the bladder after the resection

d. Nausea and vomiting as delayed side effects of the spinal anesthesia

Answer: a — New confusion, vomiting, a slow heart rate, high blood pressure and a sodium that has fallen from 139 to 124 mmol/L after monopolar TURP fit TUR syndrome, a dilutional hyponatremia with fluid overload (Going Deeper box, section 28.5). Delirium (b) is possible in an older adult, but it does not explain the falling sodium, and an acute cause must be found first (Chapter 8). Hypovolemia from bleeding (c) would cause a fast heart rate and low blood pressure, not the opposite. Anesthesia (d) does not explain the confusion, slow pulse or low sodium.

26. [CORE] Which action should the nurse take first?

a. Give the ordered as-needed antiemetic, then recheck his orientation and vital signs at the next scheduled assessment

b. Notify the surgeon urgently using SBAR, reporting the sodium, vital signs, change in orientation and fluid totals

c. Increase the maintenance infusion of 0.9% sodium chloride to bring his serum sodium back up

d. Encourage oral fluids to settle his stomach and help clear any remaining clots from the bladder

Answer: b — TUR syndrome can progress to hypotension and cardiac arrest, so the nurse escalates at once with the time of onset, vital signs, sodium, irrigation in and true urine output (section 28.5; Chapter 6). An antiemetic and a later recheck of orientation and vital signs (a) delay treatment. Changing the infusion (c) is not within the nurse's authority without an order, and sodium must be corrected carefully under the prescriber's direction (section 3.4). Extra oral fluid (d) adds free water and could lower the sodium further.

27. [CORE] A patient in the emergency department has a 4-mm stone in the lower ureter and severe colicky pain. Which statement about pain relief reflects the Canadian Urological Association guideline?

a. Opioids are the first choice, because NSAIDs are too weak to relieve the pain of a moving stone

b. Pain relief should be held until a CT scan has confirmed the exact size and position of the stone

c. Once medical expulsive therapy has started, the stone will pass quickly and analgesia can stop

d. NSAIDs relieved renal colic better than morphine in comparisons, and opioid use should be kept low

Answer: d — The CUA guideline reports that NSAIDs outperformed morphine and recommends minimizing opioids for renal colic, with patient teaching (section 28.4, Renal Colic and Care). Opioids are not the preferred first choice (a). Pain relief is never held for imaging (b). Medical expulsive therapy is not a pain treatment, and its benefit is limited to larger stones (c).

28. [CORE] A patient who has had two calcium oxalate stones asks how to prevent another. Which advice matches the Canadian Urological Association guideline?

a. Cut out milk, cheese and other calcium-rich foods to lower the calcium in the urine

b. Take vitamin C supplements of at least 1,000 mg each day to keep the urine acidic

c. Drink enough, mostly water, to pass about 2.5 L of urine every day

d. Drink about 1 L of fluid a day, because larger amounts dilute the blood sodium

Answer: c — The CUA recommends that stone formers aim for a urine output of 2.5 L a day, with water as the first-line choice (section 28.4, Preventing Recurrence). Dietary calcium is not restricted; the goal is 1,000 to 1,200 mg a day (a). Vitamin C supplements above 1,000 mg a day are not recommended because they can raise urine oxalate (b). One litre a day (d) is far below the target and leaves the urine concentrated.

29. [CORE] A patient is going home with a ureteral stent after ureteroscopy. Which statement shows that the teaching was effective?

a. "The stent will dissolve on its own, so I don't need any follow-up for it."

b. "Needing to pass urine often and urgently is common while the stent is in, and I know when it will come out."

c. "If I feel the urge to void often, it means the stent has moved out of place, and I should go to the emergency department."

d. "Because the stone is gone, I can stop drinking extra fluids as soon as I get home."

Answer: b — Stents commonly cause urinary symptoms such as frequency and urgency, and the patient needs to know the stent is temporary and when it will be removed (section 28.4). A stent does not dissolve and must be removed or changed as planned (a). Frequency and urgency are expected stent symptoms, not a sign of movement in themselves (c). Fluid remains the main way to prevent recurrence (d).

30. [CORE] A 68-year-old man is starting tamsulosin for benign prostatic hyperplasia. Which teaching point should the nurse include?

a. "Get up slowly, and don't drive or do anything hazardous for 12 hours after your first dose."

b. "Crush the tablet and mix it into applesauce if it is hard to swallow, so the drug can work faster."

c. "This drug shrinks the prostate, so it will take about 6 months before you notice any change in your stream."

d. "Your PSA level will fall by about half on this drug, so your doctor will need to double the result."

Answer: a — The tamsulosin monograph warns that blood pressure can drop, especially at the start, and advises no driving or hazardous tasks for 12 hours after the first dose (section 28.5, Drugs for BPH). Controlled-release tablets must be swallowed whole (b). Shrinking the prostate over about 6 months (c) and halving the PSA (d) describe 5-alpha reductase inhibitors such as finasteride, not alpha-blockers.

31. [CORE] A patient taking finasteride says his daughter-in-law, who is pregnant, sometimes sets out his pills. What should the nurse teach?

a. Finasteride affects only the prostate, so it poses no risk to anyone else in the home

b. She can handle the whole coated tablets but should not touch any that are crushed or broken

c. He should stop taking finasteride until the baby is born to protect his daughter-in-law

d. She must wear gloves to touch the pill bottle and should wash the bottle after each use

Answer: b — The finasteride monograph states that people who are or may become pregnant should not touch crushed or broken tablets, and that the coating stops contact with the drug when whole tablets are handled (section 28.5; Table 28.3). The drug can affect a developing fetus, so (a) is wrong. Stopping treatment (c) is unnecessary and is a decision for the prescriber. Gloves for the bottle (d) are not required.

32. [CORE] A patient is going home 2 days after TURP. Which statement shows a need for more teaching?

a. "I'll drink 1 to 2 litres a day unless my doctor tells me to limit fluids."

b. "If my urine looks cloudy after sex, it's because semen can now flow back into my bladder."

c. "I'll eat more fibre so I don't strain when I have a bowel movement."

d. "I'll be back at the gym lifting weights later this week, since I feel fine."

Answer: d — Heavy lifting (more than 7 kg) and strenuous exercise are avoided for about 2 weeks after TURP because they can cause bleeding (section 28.5). Drinking 1 to 2 L a day (a), understanding retrograde ejaculation (b) and preventing constipation (c) are correct.

33. [CORE] An RPN on a surgical unit in Ontario is caring for a patient on continuous bladder irrigation whose catheter has stopped draining. The unit protocol allows manual irrigation after urologic surgery only by RNs. What should the RPN do?

a. Stop the irrigation inflow, check the tubing and bladder volume, and get the RN and the urology team involved at once

b. Hand-irrigate the catheter, because RPNs in Ontario are authorized to put an instrument beyond the opening of the urethra

c. Wait for the next RN assessment, because a patient on CBI is outside the RPN's scope of practice

d. Remove the three-way catheter and insert a new one to restore drainage, then report the change

Answer: a — The RPN acts at once within their own role: stopping the inflow, checking for kinks and assessing the bladder, then bringing in the RN and urology as the patient's needs change (Scope in Practice box, section 28.6; section 28.5). Legal authority (b) is not enough when the employer limits the skill to RNs; context matters. Waiting (c) is unsafe; every nurse who notices deterioration acts and escalates, and CNO has no rule placing CBI outside RPN practice. Nurses do not replace a catheter after urologic surgery without the urologist's authorization (d).

34. [CORE] A 57-year-old man with no symptoms asks the nurse whether he should have a PSA test. Which response is most accurate?

a. "Every major Canadian group now recommends a yearly PSA test for all men from age 50, so you are already due for one."

b. "PSA testing is recommended only for men who are having trouble passing urine, so you would not need one until symptoms start."

c. "Canadian groups differ, so let's talk through the benefits and harms and what matters to you before you see your provider."

d. "PSA testing is no longer done in Canada, because an MRI scan of the prostate has now replaced the blood test."

Answer: c — The Canadian Task Force (2014) recommends against PSA screening, while the CUA (2022) suggests offering it through shared decision-making to men with a life expectancy over 10 years; the nurse presents both and supports the man's own decision (section 28.6; Table 28.4). No Canadian body recommends yearly testing for everyone from age 50 (a). The Task Force recommendation applies to men with urinary symptoms too, and urinary symptoms are not a screening indication (b). PSA is still used; the CUA recommends MRI before biopsy, not instead of PSA (d).

35. [CORE] A man with low-risk prostate cancer has chosen active surveillance. Which statement shows he understands it?

a. "I'll have regular PSA tests and biopsies, and treatment is offered if the cancer changes."

b. "Active surveillance means my cancer has been cured without any treatment."

c. "Since nothing is being done, I won't need any more tests unless I get symptoms."

d. "This is the same as watchful waiting, which is used when cure is no longer the goal."

Answer: a — Active surveillance is planned monitoring with PSA tests, rectal exams and biopsies, with the intent to cure if the cancer is reclassified to higher risk (section 28.6, Prostate Cancer). The cancer is still present (b). Monitoring is scheduled, not symptom-driven (c). Watchful waiting (d) is different: it avoids treatment with curative intent in people with a limited life expectancy.

36. [CORE] The nurse is teaching a patient who has just had intravesical BCG instilled for bladder cancer. Which instructions are correct? Select all that apply.

a. Keep the drug in the bladder for 2 hours, as instructed.

b. Sit down to void when emptying the bladder after treatment.

c. For 6 hours after treatment, add bleach to the toilet after each void and wait 15 minutes before flushing.

d. Drink at least 1 L of water just before the instillation to protect the bladder.

e. Report a fever above 39 °C that lasts more than 12 hours.

f. Avoid intercourse for 1 week after each treatment, or use a condom during the whole course and for 1 week beyond it.

g. A fever after BCG is expected, so there is no need to call about any fever.

Answer: a, b, c, e, f — The VERITY-BCG monograph directs a 2-hour retention, voiding sitting down, bleach in the toilet for 6 hours, reporting a high or prolonged fever and protecting sexual partners (section 28.6, Bladder Cancer). Fluids are avoided for 4 hours before the instillation and for 2 hours after it (d). Mild flu-like symptoms are common, but a high or prolonged fever may signal systemic BCG infection, which can be fatal (g).

37. [CORE] On day 3 after cystectomy with an ileal conduit, which finding should the nurse report at once?

a. Mucus threads in the urine collecting in the pouch

b. A swollen, moist, pinkish-red stoma that bleeds slightly when cleaned

c. A dark purple-black stoma with no urine draining for the past 2 hours

d. Two small stents coming out of the stoma and draining urine

Answer: c — A marked change in stoma colour and urine flow that slows or stops must be reported at once (section 28.6, Bladder Cancer). Mucus threads are normal because the conduit is made from intestine (a). A swollen, moist, pinkish-red stoma with slight bleeding on cleaning is expected early after surgery (b). Stents draining urine are expected for days to weeks after surgery (d).

38. [CORE] Three hours after TURP, a patient's drainage is bright red with large clots even though the nurse has increased the irrigation rate. His heart rate has risen from 82 to 118, his blood pressure has fallen from 132/80 to 98/60 mm Hg, his lips and nail beds look pale, and his skin is clammy. What should the nurse do?

a. Increase the irrigation rate again and recheck the drainage colour and vital signs in 1 hour

b. Stop the irrigation completely so that the clots can seal the bleeding vessels in the prostate

c. Encourage oral fluids and reassure him that heavy bleeding is expected on the day of surgery

d. Escalate at once through the rapid response process, because these signs suggest active bleeding

Answer: d — Bright red drainage with clots that does not lighten with more irrigation, together with a rising heart rate, falling blood pressure, pallor and clammy skin, suggests hemorrhage and early shock; the nurse escalates immediately (section 28.5; Chapter 6). Waiting an hour (a) delays treatment. Stopping irrigation (b) lets clots block the catheter. Some bleeding is expected, but these vital sign changes are not (c).

39. [RN] A patient with a known 6-mm stone in the upper ureter now has a temperature of 39.2 °C, rigors, a heart rate of 124, a blood pressure of 88/52 mm Hg and a serum creatinine higher than on admission. Which plan should the nurse anticipate?

a. Start tamsulosin as medical expulsive therapy and observe for 4 to 6 weeks to see whether the stone passes

b. Book shock wave lithotripsy for later today to break the stone into fragments small enough to pass

c. Begin sepsis care with antibiotics and prepare for urgent drainage of the kidney by ureteral stent or nephrostomy tube

d. Give IV fluids and analgesia overnight and repeat the CT scan in the morning before deciding on any procedure

Answer: c — This is an obstructed, infected kidney with sepsis. The CUA states that obstructive pyelonephritis needs early goal-directed therapy with timely decompression by stent or nephrostomy, alongside sepsis care (section 28.4; Chapter 4). Medical expulsive therapy and observation (a) are for stable patients without infection. Treating the stone itself (b) is not the first step; the CUA calls for timely decompression of the blocked, infected kidney. Waiting until morning (d) risks worsening sepsis and kidney injury.

40. [RN] A 71-year-old man is starting long-term androgen deprivation therapy for prostate cancer. Which plan reflects the Canadian Urological Association guideline on managing its adverse effects?

a. Bone density testing at the start, calcium and vitamin D, supervised exercise, and regular metabolic checks

b. Breast irradiation or tamoxifen started before the first injection to prevent breast enlargement in every patient

c. Rest and reduced activity to manage the fatigue that ADT causes, with exercise resumed after treatment ends

d. Bone density testing only after he has a fracture, because bone loss from ADT is uncommon in men

Answer: a — The CUA guideline recommends bone density screening for men starting long-term ADT, adequate calcium and vitamin D from the start, supervised exercise and metabolic monitoring every 6 to 12 months (section 28.6, Prostate Cancer; Table 28.3). Routine prevention of breast enlargement is not recommended (b). Exercise is the recommended response to fatigue, not rest (c). Bone loss is an expected effect of ADT, and screening is not delayed until a fracture (d).

29 Reproductive and Breast Health in Adult Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Hold respectful, inclusive sexual health conversations and take a focused sexual health history in medical-surgical care.
2. Care for adults with breast cancer before and after breast surgery, including drain care, lymphedema risk and body image.
3. Provide nursing care for adults with common gynecologic conditions and after hysterectomy, and explain breast and cervical screening as Canadian programs state it.
4. Support informed discussion of menopause symptoms and treatment options, including menopausal hormone therapy.
5. Recognize, test for and support treatment of sexually transmitted and blood-borne infections, including partner notification and public health reporting.
6. Recognize the danger of PDE5 inhibitors with nitrates and provide affirming care for transgender and nonbinary patients, using the CJMM.
7. Distinguish RN and RPN roles in sexual and reproductive health care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5, 6	Clinician; Scholar	Foundations of Practice
1, 4, 5, 6	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Questions about sex, breasts and reproductive organs touch almost every adult a medical-surgical nurse cares for, even when the reason for admission lies elsewhere. A new drug can dampen desire or cause erectile problems. Surgery and cancer treatment can change how the body looks and works. A pill a patient forgot to mention can turn a routine nitrate order into a danger. Many patients will not raise these topics unless the nurse does. This chapter gives the nurse the knowledge and the words to open these conversations and to give safe care when reproductive and breast health are part of the picture.

Section 29.1 shows how to talk about sexual health, take a focused sexual health history and respond when a patient might be pregnant. Section 29.2 covers breast cancer, from screening to breast surgery, drain care and lymphedema. Section 29.3 covers common gynecologic conditions, hysterectomy, gynecologic cancers in brief and the breast and cervical screening programs. The second half of the chapter turns to menopause and midlife health (29.4), sexually transmitted and blood-borne infections (29.5), and erectile dysfunction and gender-affirming care (29.6).

The chapter builds on earlier ones. Scope of practice for registered nurses (RNs) and registered practical nurses (RPNs) is taught in section 1.3 and the Clinical Judgment Measurement Model (CJMM) in section 1.4; consent, privacy and documentation are in Chapter 1. Care of Two-Spirit, lesbian, gay, bisexual, transgender, queer, intersex and additional sexually and gender diverse (2SLGBTQI+) people, cultural safety and trauma- and violence-informed care are in Chapter 2. Perioperative care and surgical drains are in Chapter 7, pain in Chapter 5, cancer treatment in Chapter 9, HIV and adult immunization in Chapter 21, and urinary incontinence and prostate cancer in Chapter 28. Pregnancy, labour and birth are outside this book.

When a source reports data for "women," this chapter keeps that word. When care depends on anatomy, the chapter names the organ, because not everyone with a cervix or breasts is a woman.

29.1 Sexual Health in Medical-Surgical Care

Talking About Sexual Health

Illness and its treatment often reach into sexual life. Breast surgery can change body image, hysterectomy can bring vaginal dryness or painful intercourse, and removal of both ovaries brings on menopause at once (Canadian Cancer Society [CCS], n.d.-f, n.d.-g). Fatigue, pain, stomas, drains and many medications affect desire and function too. Patients rarely bring these worries up on their own, so the nurse makes room for them.

The Public Health Agency of Canada (PHAC) notes that sexual health visits can feel intrusive and prefers a brief, routine assessment, because extensive ones may make some people uncomfortable (PHAC, 2026b). In practice, the nurse:

- chooses a private place and a moment when the patient is comfortable, and asks permission before starting;
- says why the questions matter, such as "Some of the medicines you are taking can affect sex, so I ask everyone about it";
- tells the patient that they may skip any question, and explains how their information is kept confidential and the limits of that confidentiality, such as reporting duties (Chapter 1; section 29.5);
- uses plain words, asks which terms the patient uses for their body and which pronouns they use, and then uses those terms (PHAC, 2026b);
- leaves the door open: a person who is not ready today may want to talk at another visit.

PHAC's guide suggests telling people that testing for sexually transmitted and blood-borne infections (STBBIs) is offered to everyone, and it notes that many people who may be at risk do not see themselves that way (PHAC, 2026b). The same principle applies to sexual health conversations. The nurse does not assume that age, disability, illness, relationship status or a hospital bed means a person is not sexually active or does not care about sex. Older adults, people with disabilities and people living in long-term care have sexual health needs, and they are often the people no one asks.

Many patients carry a history of sexual violence or other trauma. A trauma- and violence-informed approach (section 2.2) means explaining each step, offering choices, keeping the body covered and stopping when the person asks. PHAC includes intimate partner and sexual violence among the topics of a sexual health assessment (PHAC, 2026b); if a patient discloses violence, the nurse responds with belief and support and follows the employer's process for safety planning and referral.

Documentation follows the College of Nurses of Ontario (CNO) Documentation standard (Chapter 1). The nurse records what care needs, such as a medication the patient takes for erectile dysfunction or a pregnancy test result, and not every detail of a patient's sexual life.

Taking a Sexual Health History

A **sexual health history** is a focused set of questions about a person's sexual activity, partners, protection, past infections and reproductive health. PHAC's guide groups the content into a few areas (PHAC, 2026b):

- **Sexual activity and partners:** the types of sex (oral, vaginal, anal) and the number and kinds of partners, without assumptions about the partners' gender.
- **Protection:** condoms and other barriers, vaccines, regular testing, human immunodeficiency virus (HIV) pre-exposure and post-exposure prophylaxis (PrEP and PEP; section 21.4), and any barriers to protection, including whether the person can freely negotiate safer sex.
- **Past STBBIs:** earlier testing, results and treatment, for the person and their partners.
- **Symptoms:** discharge, sores, pain or bleeding.
- **Reproductive health:** for people with a uterus, the first day of the last menstrual period, contraception and the date of the last cervical screening test.

Questions work best when they ask about bodies and behaviours, not identity. "Do you have sex with men, women or both?" misses people whose partners are nonbinary and says nothing about which infections or screening tests are relevant. "What parts of your body do you use for sex?" or "Could any of your partners become pregnant?" gives the nurse what care requires. An **organ**

inventory is a respectful record of the reproductive and sex organs a person has at present, such as a cervix, uterus, ovaries, breasts, prostate or testes. Screening follows organs: in Ontario, cervical screening is for people who have a cervix, whatever their gender (Ontario Health, n.d.-b). Section 29.6 applies the organ inventory to gender-affirming care.

In a medical-surgical setting, the nurse usually needs only part of the history. A patient starting a drug that can harm a fetus needs questions about pregnancy and contraception. A patient with chest pain needs to be asked about erectile dysfunction pills before a nitrate is given (section 29.6). A patient going home after pelvic surgery needs to know when sexual activity can safely resume.

When a Patient Might Be Pregnant

Pregnancy changes what is safe. Before surgery, imaging that uses radiation and some drugs, the nurse asks about the possibility of pregnancy and arranges a pregnancy test when the employer's policy calls for one (section 7.2). Asking about the date of the last menstrual period, which PHAC also includes in a sexual health assessment, is part of this (PHAC, 2026b). Some common drugs must be avoided in pregnancy; for example, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are avoided and are stopped in people trying to become pregnant (section 19.2). The nurse makes sure people who could become pregnant know this.

Pregnancy is also one of the few situations in which bacteria in the urine without symptoms are looked for and treated. In 2018, the Canadian Task Force on Preventive Health Care recommended screening pregnant women once in the first trimester with a urine culture for **asymptomatic bacteriuria** (a weak recommendation based on very low-quality evidence; Moore et al., 2018). The Infectious Diseases Society of America also recommends screening and treatment in pregnancy, whereas most other adults are not screened (Nicolle et al., 2019; section 28.1). Gestational diabetes, glucose intolerance first recognized in pregnancy, is defined in section 22.1.

Blood pressure in pregnancy follows its own rules. The Society of Obstetricians and Gynaecologists of Canada (SOGC) guideline on hypertensive disorders of pregnancy sets definitions and thresholds specific to pregnancy (Magee et al., 2022), so the adult targets in Chapter 19 do not apply. A pregnant patient with severe hypertension, or with new symptoms such as headache or changes in vision, may be developing a serious complication, so the nurse escalates at once for urgent obstetric assessment. Care of pregnancy, labour and birth belongs to obstetric teams and is outside this book.

29.2 Breast Cancer Care

Breast Cancer in Canada

Not counting non-melanoma skin cancers, breast cancer is the most common cancer among women in Canada. The Canadian Cancer Society estimates that in 2026, 32,400 women in Canada will receive a breast cancer diagnosis (26% of new cancer cases in women) and 5,400 will die of the disease (13% of cancer deaths in women) (Brenner et al., 2026; CCS, 2026a). Over their lifetime, an estimated 1 in 8 women in Canada are expected to be diagnosed with breast cancer, and 1 in 35 to die of it (CCS, 2026a).

The Canadian Cancer Society lists these risk factors (CCS, n.d.-c):

- older age, with the highest numbers of cases in women aged 50 to 69;
- breast cancer in a first-degree relative, which roughly doubles the risk;
- inherited changes in the BRCA1 or BRCA2 gene, which are rare but raise lifetime risk sharply;
- dense breast tissue;
- alcohol, with risk rising as intake rises;
- physical inactivity, and excess body weight after menopause;
- menopausal hormone therapy used for a long time, particularly estrogen combined with a progestin for 5 years or longer (section 29.4);
- starting periods at 11 or younger or reaching menopause after 55;
- having a first full-term pregnancy after age 35, never giving birth, or not breastfeeding;
- radiation to the chest, especially before age 30.

Everyone has some breast tissue, so breast cancer can occur in anyone (CCS, n.d.-c). In 2026, an estimated 300 men in Canada will receive a breast cancer diagnosis and 60 will die of it (CCS, 2026a). Men with an inherited BRCA change, especially BRCA2, and men with Klinefelter syndrome have a higher risk (CCS, n.d.-c). Whatever the person's sex or gender, the nurse encourages anyone with a breast change to have it assessed.

Little research describes breast cancer risk in transgender and nonbinary people (CCS, n.d.-c). Screening programs set eligibility by body and history rather than by gender. The Ontario Breast Screening Program, for example, includes trans and nonbinary people, and transfeminine people become eligible after at least 5 consecutive years of feminizing hormones (Ontario Health, n.d.-a). Section 29.6 returns to screening by organ.

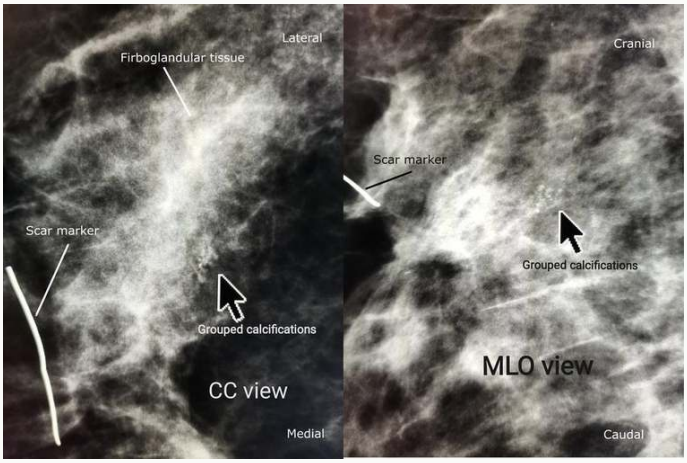

Figure 29.1 Craniocaudal (CC) and mediolateral oblique (MLO) mammogram views showing grouped microcalcifications (arrows) that warrant diagnostic follow-up. (credit: "Mammogram images of clustered calcifications at CC view and MLO view" by Cerevisae/Wikimedia Commons, CC BY-SA 4.0)

Screening and Diagnosis

A **screening mammogram** is an X-ray of the breasts in a person with no symptoms, taken to find cancer early. Recommendations about when to start and how often to screen have changed in recent years, and they differ between provinces (Figure 29.1).

The Canadian Task Force on Preventive Health Care released draft breast screening recommendations in May 2024 (Canadian Task Force on Preventive Health Care [CTFPHC], 2024). The draft treated screening from 40 to 74 as a personal choice informed by benefits and harms. For ages 40 to 49, it suggested not screening everyone but offering mammography every 2 to 3 years to those who choose it; for 50 to 74, it suggested mammography every 2 to 3 years; for 75 and older, it suggested no screening. All three were conditional recommendations with very low certainty. The draft was not finalized before the Task Force's mandate ended on March 31, 2026, and PHAC now supports a new National Advisory Committee on Preventive Health Services (CTFPHC, n.d.).

Provinces run their own programs (Table 29.1). In October 2024, the Ontario Breast Screening Program (OBSP) expanded to people aged 40 to 49. It now screens women, Two-Spirit, trans and nonbinary people aged 40 to 74, most of them every 2 years, and people can book their own mammogram. The program suggests that people in their 40s first discuss screening with a family doctor, nurse practitioner (NP) or Health811 navigator. The High Risk OBSP offers yearly mammography and breast magnetic resonance imaging (MRI) to people aged 30 to 69 with, for example, a known BRCA1, BRCA2, TP53 or PALB2 gene change or chest radiation before age 30 (Ontario Health, n.d.-a). After 74, screening continues only with a referral.

Table 29.1 Breast and cervical screening in Canada (CTFPHC, 2013, 2024; Ontario Health, n.d.-a, n.d.-b; Government of Ontario, 2026)

Screening	Who and how often (as stated, with date)	Test	What the nurse discusses
Breast: Ontario Breast Screening Program (expanded October 2024)	Women, Two-Spirit, trans and nonbinary people aged 40 to 74 without symptoms; most every 2 years; people aged 40 to 49 encouraged to talk with a provider first and may book their own appointment; over 74 by referral	Mammogram	Benefits and harms; how to book; breast changes need assessment at any time
Breast: High Risk OBSP	Ages 30 to 69 with, for example, a known BRCA1, BRCA2, TP53 or PALB2 gene change or chest radiation before age 30; every year	Mammogram and breast MRI (ultrasound if MRI is not appropriate)	Referral through a primary care provider; genetic counselling
Breast: Canadian Task Force draft (May 2024; not finalized)	Ages 40 to 49: offered every 2 to 3 years to those who choose it; 50 to 74: every 2 to 3 years; 75 and older: not suggested	Mammogram	Screening as an informed personal choice

Screening	Who and how often (as stated, with date)	Test	What the nurse discusses
Cervical: Ontario Cervical Screening Program (HPV test since March 2025)	People with a cervix aged 25 or older who have ever had sexual contact; most every 5 years; every 3 years for people who are immunocompromised; most can stop between 65 and 69	HPV test on a sample taken with a small brush	Starting at 25; screening after HPV vaccination; what a positive result means
Cervical: Canadian Task Force (2013)	Ages 25 to 69 every 3 years; not routinely before 25; may stop at 70 or older after adequate screening (3 negative Pap tests in 10 years)	Pap test	Recommendation published before HPV testing; provincial programs now differ

Dense breast tissue raises the risk of breast cancer (CCS, n.d.-c). The 2024 draft did not suggest added ultrasound or MRI for dense breasts alone, because no evidence showed better outcomes (CTFPHC, 2024). The nurse explains the program that applies to the patient, encourages a shared decision with the primary care provider and does not give a personal opinion.

Screening is for people without symptoms. A lump, a thick or hard area, or a change in the skin or nipple needs assessment, whatever the date of the last mammogram. Diagnosis usually starts with a diagnostic mammogram and ultrasound, which shows whether a lump is solid or a fluid-filled cyst. A **biopsy**, such as a core needle biopsy, is needed to confirm breast cancer; no other test gives a definite diagnosis (CCS, n.d.-a). The pathologist also reports whether the cancer cells carry hormone receptors and extra HER2 protein, which guides treatment (see the Going Deeper box). Waiting for biopsy results is a time of high anxiety; the nurse gives clear information about when and how results will come and who to call.

GOING DEEPER

Hormone Receptor and HER2 Status

Required for RN students; optional for PN students.

Breast cancer cells are tested for three proteins. **Hormone receptor status** tells whether the cells carry **estrogen receptors (ER)**, progesterone receptors (PR) or both. Receptor-positive cancers use these hormones to grow, so knowing the status helps the team predict whether hormone-blocking treatment will work. These cancers tend to be less aggressive and to have a better short-term outlook, but they can come back many years after treatment (CCS, 2023).

Human epidermal growth factor receptor 2 (HER2) is a protein on the cell surface. A HER2-positive cancer makes more of it than normal, grows and spreads faster and is more likely to recur. It is also more likely to respond to drugs that target HER2 (CCS, 2023; CCS, n.d.-a). A cancer that lacks hormone receptors tends to be more aggressive (CCS, 2023).

These results shape the plan. People with receptor-positive cancer are usually offered **endocrine therapy**, which blocks the production or action of hormones, such as tamoxifen or an aromatase inhibitor. People with HER2-positive cancer are offered treatment that includes HER2-targeted drugs. Chapter 9 covers these treatments. The nurse supports adherence, because daily tablets with side effects such as hot flashes and sexual changes (section 9.3) can be hard to sustain.

Figure 29.2 Healed surgical scar across the breast mound and lateral chest wall following mastectomy and breast reconstruction. (credit: "Breast reconstruction (1)" by Linda Bartlett/National Cancer Institute, Public domain)

Breast Surgery and Nursing Care

Most people with breast cancer have surgery to the breast and to the lymph nodes under the arm (Table 29.2). **Breast-conserving surgery** takes out the tumour along with a rim of healthy tissue around it and is usually followed by radiation. A **mastectomy** removes all the breast tissue; a skin-sparing mastectomy keeps the skin when reconstruction is done at the same operation (CCS, n.d.-f). A **sentinel lymph node biopsy** removes the first node or nodes that drain the tumour to check them for cancer, while an **axillary lymph node dissection** removes the underarm nodes, usually when cancer has reached them. Lymphedema is more common after dissection than after sentinel node biopsy (CCS, n.d.-f; Figure 29.2).

Table 29.2 Breast cancer surgery and nursing care (CCS, n.d.-f; Hôpital Montfort, n.d.; Interior Health, n.d.)

Procedure	What is removed	Main nursing points	Teaching
Breast-conserving surgery (lumpectomy)	The tumour and a rim of normal tissue	Pain; bleeding or fluid collection at the site; usually followed by radiation	Wound care; signs of infection; radiation appointments
Total (simple) mastectomy	All breast tissue and the tissue over the chest muscle	Closed suction drain; pain; chest numbness; body image	Drain care and output log; arm exercises; bra or breast form
Sentinel lymph node biopsy	The first lymph node or nodes that drain the tumour	Underarm pain and numbness; arm and shoulder movement	Arm exercises; lymphedema warning signs
Axillary lymph node dissection	Underarm lymph nodes	Drain under the arm; shoulder stiffness; highest lymphedema risk of these procedures	Lymphedema risk reduction; early report of swelling or infection

Procedure	What is removed	Main nursing points	Teaching
Mastectomy with reconstruction	Breast tissue, with the breast reshaped at the same operation (skin-sparing mastectomy keeps the skin)	Care of the reconstructed area as the surgeon orders	Surgeon's limits on activity; signs to report

General postoperative care follows section 7.6, and pain care follows Chapter 5. Some people develop **post-mastectomy pain syndrome**, nerve pain in the chest, armpit or arm that lasts after healing (CCS, n.d.-f). Numbness along the inner upper arm is common after mastectomy or node dissection (Interior Health, n.d.).

A **closed suction drain** is a soft tube from the wound to a compressible bulb that draws out blood and lymph. Many patients go home with it, and it is removed when drainage has fallen (CCS, n.d.-f). To empty it, the nurse or patient washes their hands, opens the plug, pours the fluid into a measuring container, taking care not to touch the inner surface of the plug, squeezes the bulb flat and closes the plug while it is still squeezed to restore suction (Interior Health, n.d.). Each amount and its colour go on an output log that the patient brings to follow-up. The fluid is often bloody at first and, over time, turns from red to pink and then to light yellow or clear, while the amount should fall (Alberta Health Services, 2022).

Bleeding is the early danger. A drain filling quickly with bright red fluid, a tense and growing swelling of the chest wall, a rising heart rate or a falling blood pressure suggests a collection of blood (hematoma) or active bleeding. Any nurse who sees these acts at once and escalates (sections 6.1 and 7.6). A **seroma**, a collection of fluid under the skin flap, can build up in the wound, including after the drain comes out; it is reported to the surgical team, because some collections need to be drained (CCS, n.d.-f). Redness, warmth, fever or foul drainage suggests infection.

Gentle arm and shoulder exercises begin soon after surgery to prevent stiffness. One Ontario hospital program has patients exercise slowly, within their pain limit, two to three times a day, and keep the arm below shoulder height for overhead movements while a drain is in place; fuller stretches are added at 3 to 6 weeks (Hôpital Montfort, n.d.). The nurse reinforces the program the surgeon or physiotherapist gives.

Breast surgery can change body image and self-esteem (CCS, n.d.-f), and loss of a breast can affect identity, sexuality and relationships. The nurse invites the patient to look at the incision when ready, answers questions about reconstruction and offers peer support, such as Canadian Cancer Society programs. An **external breast form** (breast prosthesis) is a shape made of foam, silicone or another material and worn inside a bra; some people choose one when they do not want reconstruction or while they wait for it (Waterloo Regional Health Network, 2026). A soft, supportive bra without underwires may be more comfortable (Interior Health, n.d.).

PATIENT EDUCATION

Going Home After Breast Surgery

- **Your drain:** Wash your hands. Open the plug, pour the fluid into the measuring cup and write down the amount and colour. Squeeze the bulb flat and close the plug while it is squeezed. Wash your hands again.
- **Your output log:** Bring it to your follow-up visit; the surgeon uses it to decide when the drain comes out.
- **Washing:** Sponge bathe while you have a drain, unless your surgeon says otherwise.
- **Arm exercises:** Do your exercises 2 or 3 times a day, slowly and within your comfort. Keep your arm below shoulder height for overhead exercises while the drain is in.
- **Lifting:** Avoid heavy lifting and any pushing or pulling that needs effort until your surgeon says you can.
- **Call your surgeon's office (or, if you cannot reach them, go to the emergency department) if you have:** pain that keeps getting worse despite medicine; more redness or swelling at the incision; more drainage or foul-smelling drainage; a temperature of 38.5 °C or higher (Interior Health, n.d.).
- **Swelling of your arm, hand or chest:** report it early.
- **Feelings:** It is normal to have strong feelings about your body. Ask about support groups and peer visitors.

Lymphedema

Lymphedema is swelling that develops when lymph cannot drain normally and builds up in the tissues. After breast cancer treatment it affects the arm, hand or chest on the treated side. The risk rises with the number of lymph nodes removed and with radiation to the nodes, spread of cancer to the nodes, infection and excess body weight (CCS, n.d.-b).

Early signs are subtle: a feeling of fullness or heaviness, aching or burning, skin that feels tight or warm, rings or sleeves that feel tight, and swelling of the hand or fingers. Other signs include hardening or thickening of the skin and difficulty moving a nearby joint (CCS, n.d.-b). The nurse teaches patients to report these changes early, so that assessment and treatment can begin.

Advice about protecting the arm is changing. The Canadian Cancer Society advises avoiding blood pressure readings and needle sticks (blood draws, intravenous lines, injections) in the affected arm, and alternating arms when nodes were removed on both sides (CCS, n.d.-b). The research behind this advice is limited. In a prospective study of patients screened for lymphedema at one centre from 2005 to 2014, blood draws, injections and air travel were not associated with increases in arm volume, while axillary dissection, regional node radiation, a body mass index of 25 or more and cellulitis were; the authors concluded that blood draws, injections and blood pressure readings in the arm on the treated side, and air travel, may not raise the risk (Ferguson et al., 2016). In practice, the nurse follows the employer's policy and the patient's wishes, uses the other arm when possible and never delays urgent care to avoid the at-risk arm.

What the sources agree on is protecting the skin, because infection raises the risk. Patients keep the skin clean and moisturized, protect it from cuts, burns and bites, treat small wounds promptly and report redness, warmth or fever at once. Staying active and keeping a healthy weight also help (CCS, n.d.-b). The nurse refers anyone with signs of lymphedema to the team; treatment such as manual lymph drainage and compression is provided by physiotherapists or massage therapists with special training, and compression garments are used only when a physician or physiotherapist recommends them (CCS, n.d.-b).

29.3 Gynecologic Conditions and Surgery

Common Gynecologic Conditions

Abnormal uterine bleeding (AUB) is uterine bleeding that differs from the person's usual menstrual pattern in amount, duration, frequency or regularity, or that occurs between periods. Heavy bleeding over months can lead to **iron deficiency anemia** (Chen et al., 2025; section 20.2). The nurse asks about the number of pads or tampons used, clots and flooding, and looks for fatigue, shortness of breath on exertion and pallor, which on medium and dark skin is checked where pigment does not hide colour, such as the conjunctiva, mouth, nail beds and palms (section 20.2) (Figure 29.3).

Uterine fibroids are non-cancerous growths of the muscle of the uterus. The SOGC describes them as very common; most cause no symptoms and need no treatment. When fibroids cause AUB, iron deficiency anemia, or pelvic pain or pressure, the SOGC advises a low threshold for investigation. Many treatments exist, and the choice depends on the fibroids, the symptoms and the person's plans for pregnancy (Chen et al., 2025). Untreated symptomatic fibroids reduce quality of life, so the nurse takes heavy bleeding and pressure symptoms seriously.

In **endometriosis**, tissue similar to the uterine lining grows outside the uterus and causes chronic inflammation. Common sites are the ovaries, the fallopian tubes, the ligaments behind the uterus and the bowel. The SOGC estimates that it affects about 10% of women, plus transgender, nonbinary and gender-diverse people in numbers that are not known, and that diagnosis in Canada is delayed by at least 5 years (Society of Obstetricians and Gynaecologists of Canada [SOGC], n.d.-a). Pain is the main symptom: painful periods (dysmenorrhea), pain with intercourse (dyspareunia), painful bowel movements or urination and pelvic pain lasting more than 3 months. Fatigue, bloating and infertility also occur. Under the 2024 SOGC guideline, endometriosis can be diagnosed clinically, from the symptoms, a physical examination and ultrasound, so that treatment need not wait for surgery (Singh et al., 2024; SOGC, n.d.-a). Hormonal treatment, such as combined hormonal contraceptives or a progestin, is first-line, with non-steroidal anti-inflammatory drugs (NSAIDs) for pain, physiotherapy and counselling (SOGC, n.d.-a). Persistent pelvic pain is real pain; the nurse believes the patient and uses the approaches in Chapter 5.

Pelvic organ prolapse is the descent of the bladder, uterus, top of the vagina or rectum into or beyond the vaginal opening, as the muscles and connective tissue that support them weaken. People may describe a bulge or heaviness in the vagina, sometimes with urinary or bowel symptoms. Options include pelvic floor muscle training, a **pessary** (a removable device placed in the vagina to support the organs) and surgery. A patient with a pessary needs it removed and cleaned on the schedule their provider sets, and reports new bleeding, discharge or pain. In hospital, the nurse asks about a pessary on admission so that its care is included in the care plan (Figure 29.4).

Hysterectomy and Gynecologic Surgery

A **hysterectomy** is removal of the uterus. A total hysterectomy takes out both the uterus and the cervix; a radical hysterectomy, used for some cancers, also removes the upper vagina and nearby tissue. A **bilateral salpingo-oophorectomy (BSO)** removes both ovaries and fallopian tubes and is often done at the same time. For uterine cancer, most people have laparoscopic surgery through several small incisions, sometimes with robotic assistance; the open abdominal route is now used less often because serious complications such as infection are more likely and recovery takes longer, and the vaginal route removes the uterus through the vagina (CCS, n.d.-g).

After surgery, the nurse watches for the complications the Canadian Cancer Society lists: pain, infection, vaginal bleeding, blood clots, bowel obstruction and bladder problems (CCS, n.d.-g). In practice, this means:

- **Bleeding:** checking pads and the wound, and treating a rising heart rate, falling blood pressure or swelling abdomen as possible internal bleeding even when the pad is dry (sections 6.1 and 7.6);
- **Voiding:** confirming that the patient passes urine after the catheter is removed and using a bladder scan as the unit protocol directs (sections 7.6 and 28.3);
- **Bowel function and mobility:** early walking, return of bowel function and venous thromboembolism (VTE) prevention as ordered (sections 7.6 and 19.6);
- **The wound:** monitoring incisions for redness, drainage and separation (section 7.6);
- **Sensation:** asking about tingling or numbness of the thighs, which can follow surgery for uterine cancer (CCS, n.d.-g).

Removing both ovaries before natural menopause causes **surgical menopause**, an abrupt drop in hormones (CCS, n.d.-g); menopausal symptoms such as hot flashes are described in section 29.4. Other effects can include vaginal dryness, painful intercourse and, before menopause, the end of fertility (CCS, n.d.-g). Some people feel relief, others grief, and many feel both. The nurse asks how the patient feels about the surgery, answers questions about sex after surgery and refers to the surgical team for specific limits on lifting, driving and intercourse.

Gynecologic Cancers in Brief

For 2026, the Canadian Cancer Society estimates these numbers of new diagnoses and deaths among women in Canada: uterine cancer, 8,800 diagnoses and 1,750 deaths; ovarian cancer, 3,000 and 1,950; and cervical cancer, 1,700 and 450 (CCS, 2026b, 2026c, 2026d).

Cervical cancer is caused by persistent infection with high-risk types of **human papillomavirus (HPV)**. Ontario replaced the Pap test with an HPV test as its cervical screening test in March 2025 (Government of Ontario, 2026; Table 29.1). A positive result shows a high-risk HPV type, one that can occasionally lead to cancer; it does not mean that cancer is present, and depending on the situation, the next step may be a repeat test in 2 years or a colposcopy, a closer look at the cervix by a specialist (Government of Ontario, 2026). The Ontario program includes women, Two-Spirit people, and transmasculine and nonbinary people who have a cervix. Screening does not need to start before 25, even after sexual contact, and is not needed by a person who has never had sexual contact with another person. People who have had the HPV vaccine (section 21.6) still need screening (Ontario Health, n.d.-b). Table 29.1 compares the national and Ontario recommendations.

Ovarian cancer often causes no symptoms early. Later symptoms are vague and easy to blame on other problems: bloating, abdominal or pelvic pain or pressure, feeling full quickly, urinary urgency or frequency, back pain and fatigue (CCS, n.d.-d). The nurse encourages a person with symptoms that persist to have them assessed.

Uterine (endometrial) cancer most often shows itself through abnormal vaginal bleeding, including any bleeding or spotting after menopause. Other signs include unusual discharge that may be blood-stained or foul-smelling, pain with sex and pelvic pain or pressure (CCS, n.d.-e). Bleeding after menopause is never treated as normal; the nurse makes sure it is reported and assessed. Treatment for gynecologic cancers is covered in Chapter 9. After surgery that removes pelvic lymph nodes, lymphedema of the legs or pelvis can occur (CCS, n.d.-g).

LIFESPAN CONSIDERATIONS

Older Adults and Reproductive Health

- **Bleeding after menopause:** Abnormal vaginal bleeding, including any bleeding or spotting after menopause, is the sign of uterine cancer seen most often, so it is always reported for assessment (CCS, n.d.-e). Older adults may not mention it unless asked.
- **Prolapse and pessaries:** On admission, the nurse asks whether the patient uses a pessary and who removes and cleans it, and includes it in the care plan and the discharge plan.
- **Sexual health:** Many older adults remain sexually active, and STBBIs occur at every age. The nurse offers the same respectful questions and testing as for younger adults (PHAC, 2026b) and remembers that medications, surgery and dementia can affect intimacy and consent (Chapter 1).
- **When screening ends:** In Ontario, most people can stop cervical screening between 65 and 69 (Ontario Health, n.d.-b), and the OBSP stops mailing invitations and results letters after age 74; screening continues by referral (Ontario Health, n.d.-a). Stopping screening does not mean ignoring symptoms.
- **Breast cancer:** Risk rises with age (CCS, n.d.-c). After surgery, older adults may need extra help with drain care at home, arm exercises and transport to follow-up.

29.4 Menopause and Midlife Health

Menopause is a normal life stage, not a disease. Still, its symptoms can disrupt sleep, work and relationships, and they often surface during care for something else. The sources in this section mostly describe women. The same physiology applies to transgender men and nonbinary people who have ovaries, so the nurse uses each person's own words for their body (section 29.1).

Menopause and Its Symptoms

Menopause is the permanent end of menstruation caused by the loss of ovarian follicles. It is confirmed in hindsight, after 12 months in a row with no period and no other cause. In Canada, menopause occurs at an average age of 51, and most people reach it between about 45 and 55 (Society of Obstetricians and Gynaecologists of Canada [SOGC], n.d.-b). **Perimenopause** is the transition before menopause, when periods change and symptoms often begin. It can start 4 to 8 years before the final period and includes the 12 months after it. Menopause before age 45 is called early menopause, and loss of ovarian function before 40 is called premature ovarian insufficiency (SOGC, n.d.-b).

Surgical menopause follows removal of both ovaries (bilateral oophorectomy; section 29.3). Chemotherapy or pelvic radiation can also bring on menopause. Induced menopause is often more sudden and its symptoms more severe than natural menopause (SOGC, n.d.-b). When a person loses ovarian function before age 45, the SOGC recommends considering hormone replacement until the average age of natural menopause (Yuksel et al., 2021).

Vasomotor symptoms, mainly hot flashes and night sweats, top the list of menopause symptoms. As many as 80% of women have them, about 20% to 25% have symptoms severe enough to disrupt daily life, and they last an average of 7.4 years (SOGC, n.d.-b). A hot flash is a sudden feeling of heat in the face, neck and chest. On lighter skin it may show as redness; on darker skin, flushing can be hard to see, so the nurse relies on the person's report and on sweating. Sleep problems affect 40% to 60% of people in the transition. Perimenopause is also a time of greater vulnerability to new or worsening mood disorders, including depression (SOGC, n.d.-b).

Genitourinary syndrome of menopause (GSM) describes a group of symptoms in the vulva, vagina and lower urinary tract caused by falling estrogen. It includes vaginal dryness, itching, pain with intercourse and light bleeding, as well as urinary frequency, urgency and stress incontinence (SOGC, n.d.-b). Many people do not mention it unless asked (section 29.1). Continence care is covered in section 28.3.

Treatment Options

The nurse supports an informed choice rather than recommending a treatment.

Menopausal hormone therapy (MHT) is estrogen, given alone or with a progestogen, to relieve menopause symptoms. The SOGC states that no treatment relieves vasomotor symptoms better than MHT, and that it is safe to start in women who have no contraindications and are younger than 60 or within 10 years of their final period. The choice and the length of treatment are individualized, based on symptoms, health conditions, family history, goals and preferences, and are reviewed over time (Yuksel et al., 2021). People who still have a uterus need a progestogen, or another option the prescriber chooses, to protect the uterine lining; after a hysterectomy, estrogen can be used on its own (Yuksel et al., 2021).

The North American Menopause Society, now called The Menopause Society, reaches the same conclusion. For people under 60 or within 10 years of menopause who have no contraindications, the benefits outweigh the risks for treating bothersome hot flashes and preventing bone loss. For people who start MHT after 60 or more than 10 years after menopause, the balance is less favourable because the absolute risks of stroke, coronary heart disease, dementia and VTE are higher. Transdermal routes and lower doses may lower the risk of VTE and stroke (The 2022 Hormone Therapy Position Statement of The North American Menopause Society Advisory Panel [NAMS Advisory Panel], 2022). Short-term use of estrogen with a progestogen does not appreciably raise breast cancer risk, and estrogen alone may carry a lower risk; longer use may carry a rare added risk (NAMS Advisory Panel, 2022).

The Canadian product monograph for a transdermal estradiol gel lists who should not take estrogen. Contraindications include known, suspected or past breast cancer; other estrogen-dependent cancers; untreated endometrial hyperplasia; undiagnosed abnormal genital bleeding; current or past venous or arterial thromboembolism (including stroke, myocardial infarction or angina); known clotting disorders; active liver disease; pregnancy or breastfeeding; classical migraine; and porphyria. Estrogen should not be used to prevent heart disease, and the prescriber chooses the lowest dose that works, for the shortest time that meets the treatment goal (Organon Canada, 2026).

Vaginal estrogen is a low-dose estrogen placed in the vagina to treat GSM. The Menopause Society recommends low-dose vaginal estrogen or other local therapies for bothersome GSM that over-the-counter moisturizers and lubricants do not relieve; it suits people of any age and can continue for as long as needed (NAMS Advisory Panel, 2022).

For people who cannot or prefer not to take hormones, the SOGC names non-hormonal prescription options: certain antidepressants, gabapentinoids, clonidine and oxybutynin, each with its own adverse effects. Cognitive behavioural therapy also shows benefit. The evidence does not support any single natural health product, and compounded "bioidentical" hormones have not been tested as rigorously as Health Canada–approved products. The SOGC also recommends offering people the option of working with a cultural leader on traditional therapies (Yuksel et al., 2021).

The nurse:

- asks about symptoms, sleep, mood and sexual comfort in plain language;
- recognizes cues that matter for treatment choices, such as a past clot, breast cancer or unexplained bleeding, and passes them to the prescriber;
- explains why a progestogen is added when a uterus is present;
- teaches that any bleeding after menopause must be reported and investigated (section 29.3).

Midlife Health

Estrogen loss speeds bone loss, so bone health and osteoporosis screening matter (Chapter 33). Cardiovascular risk factors such as blood pressure, lipids and glucose deserve attention (Chapters 17, 19 and 22), and MHT is not a way to prevent heart disease (Organon Canada, 2026). Bladder symptoms and pelvic floor health are addressed in section 28.3. Sexual health remains part of whole-person care in midlife and older age. The nurse invites questions about desire, comfort and relationships without assuming that interest in sex ends with menopause.

29.5 Sexually Transmitted and Blood-Borne Infections

A **sexually transmitted and blood-borne infection** (STBBI) is an infection that spreads through sexual contact, blood or both. Medical-surgical nurses meet STBBIs in many ways: a positive test during admission, a pelvic infection after a missed diagnosis, a rash that turns out to be syphilis, or a patient's question asked in private. This section covers common bacterial, viral and parasitic

sexually transmitted infections. HIV, pre-exposure prophylaxis (PrEP) and post-exposure prophylaxis (PEP) are in Chapter 21; hepatitis B and C are in Chapter 26.

STBBIs in Canada

Chlamydia is the sexually transmitted infection reported most often in Canada (Public Health Agency of Canada [PHAC], 2025b), and gonorrhea is the second most common (PHAC, 2026a). Syphilis rates rose steeply from 2014. In 2023, 12,135 cases of infectious syphilis were reported, a rate of 30.5 per 100,000 population. That rate was 16% lower than in 2022, the first national decrease since 2014, but still 77% higher than in 2018 (PHAC, 2025c). Congenital syphilis has also re-emerged (Canadian Context: Syphilis in Canada).

These numbers are not spread evenly. PHAC states that health inequities and the social and structural determinants of health help explain differences between populations (PHAC, 2025c), and its technical report on syphilis names stigma, discrimination, poverty and exposure to violence as conditions that can limit access to health care and treatment (PHAC, 2020). For patients from rural, remote and northern communities, the nurse also considers how distance from services may affect testing and follow-up. Rates in 2023 were highest in the Northwest Territories, Nunavut, Saskatchewan, Yukon and Manitoba (PHAC, 2025c). Regional rates describe the conditions people live in, not the people themselves. Cultural safety, distinctions-based care for First Nations, Inuit and Métis patients, and trauma-informed care are covered in Chapter 2.

Common Infections

Chlamydia is caused by the bacterium *Chlamydia trachomatis*, and **gonorrhea** by *Neisseria gonorrhoeae*. Both infect the cervix, urethra, rectum or throat. Both often cause no symptoms. As many as 70% of sexually active females and more than half of males with chlamydia have none (Thunder Bay District Health Unit [TBDHU], 2026), and gonorrhea is frequently present without symptoms, which is why screening is essential for finding cases (PHAC, 2026a). When chlamydia does cause symptoms, they may include discharge from the cervix or urethra and burning or frequency on urination (TBDHU, 2026). Untreated chlamydia can spread and cause **pelvic inflammatory disease** (PID), an infection of the uterus, fallopian tubes and nearby pelvic structures, which can lead to ectopic pregnancy, infertility and chronic pelvic pain. Chlamydia can also cause epididymo-orchitis and reactive arthritis (PHAC, 2025b).

N. gonorrhoeae can quickly develop resistance to several classes of antibiotics (PHAC, 2026a). This is why the national guide recommends ceftriaxone alone, given intramuscularly, for uncomplicated gonorrhea; why culture is collected in some situations, because it shows which drugs still work; and why everyone treated needs a test of cure (PHAC, 2026a). Doxycycline or azithromycin is recommended for chlamydia in adults who are not pregnant (PHAC, 2025b). Provincial and territorial guidance may differ because resistance patterns vary.

Syphilis is caused by the bacterium *Treponema pallidum*. It moves through stages, and it can be missed at each one:

- **Primary:** a painless open sore (chancre) at the site of contact, with swollen nearby lymph nodes. Because it does not hurt and heals on its own within weeks, it is easy to ignore (Figure 29.5).
- **Secondary:** a rash that usually does not itch, which can be subtle on darker skin and may appear on the trunk, palms and soles, with fever, malaise, swollen lymph nodes and mucous patches; headache, meningitis and eye inflammation can occur.
- **Latent:** no symptoms; a positive blood test is the only sign.
- **Tertiary:** years later, damage to the heart and blood vessels, the nervous system or other tissues (Hastings Prince Edward Public Health, 2023; Sexually Active Client? Think Syphilis!, n.d.; PHAC, 2025d).

Syphilis is diagnosed with blood tests. Infectious syphilis is treated with benzathine penicillin G given intramuscularly, and neurosyphilis needs specialist care and intravenous antibiotics (PHAC, 2025d). **Congenital syphilis** is syphilis passed from a pregnant person to the fetus.

Genital herpes is a lifelong infection with herpes simplex virus (HSV). HSV-2 has been the usual cause, but genital HSV-1 infections have risen considerably. Recurrences can be noticed or unnoticed, and the virus is often shed without symptoms, so it can spread from a person with no sores. A recent infection also raises the risk of acquiring and passing on HIV. Oral acyclovir,

famciclovir or valacyclovir treats outbreaks, and daily suppressive therapy is recommended for frequent or severe recurrences and can lower transmission to a partner (PHAC, 2021).

HPV (section 29.3) has many types. Types 6 and 11 cause most **anogenital warts**, which are spread by skin-to-skin contact and are usually diagnosed by looking at them. Most warts eventually go away on their own but often come back, and treatment removes warts without clearing the virus (PHAC, 2025a). Oncogenic HPV types and cervical screening are discussed in section 29.3, and the HPV vaccine in Chapter 21.

Trichomoniasis is caused by the parasite *Trichomonas vaginalis*. It can cause a purulent vaginal discharge, itching, pain on urination and pain with intercourse. It raises the risk of acquiring HIV and of preterm birth. Metronidazole is the first-line treatment, and partners are treated together with the patient to prevent reinfection (Cenkowski et al., 2022).

Figure 29.5 A primary syphilitic chancre on the tongue, showing the characteristic firm, round, painless ulcerated lesion at the site of inoculation. (credit: "Circular primary syphilitic chancre on the tongue" by CDC/Robert E. Sumpter, Public Health Image Library #12623, Public domain)

The main points for each infection are compared side by side (Table 29.3).

Table 29.3 Common sexually transmitted infections at a glance (PHAC, 2021, 2025a, 2025b, 2025d, 2026a; Cenkowski et al., 2022; TBDHU, 2026)

Infection	Common findings	Testing	Treatment (named only)	Nursing and public health points
Chlamydia	Often none; discharge, burning or frequency on urination	NAAT on first-void urine or vaginal, cervical, rectal or throat swab	Doxycycline or azithromycin	Reportable; partners from the past 60 days tested and treated; retest 3 months after treatment
Gonorrhea	Frequently none; serious complications if untreated	NAAT; culture when needed to check which antibiotics work	Ceftriaxone, intramuscular	Reportable; partners from the past 60 days; test of cure at every positive site
Infectious syphilis	Painless sore; later rash, swollen lymph nodes; may have no signs	Blood tests (serology)	Benzathine penicillin G, intramuscular	Reportable; contacts traced by stage; repeat blood tests to confirm response
Genital herpes	Genital sores during outbreaks; often shed without symptoms	NAAT or viral culture from a sore	Acyclovir, famciclovir or valacyclovir	Lifelong; suppressive therapy option; patients encouraged to tell partners
Anogenital warts (HPV)	Growths on genital or anal skin	Diagnosed by looking; biopsy if unusual	Removal or topical therapies	Treatment does not clear HPV; review vaccination and cervical screening
Trichomoniasis	Discharge, itching, pain on urination or with intercourse	NAAT (most sensitive in women)	Metronidazole	Treat partners at the same time to prevent reinfection

Testing, Treatment and Public Health

A **nucleic acid amplification test** (NAAT) detects the genetic material of an organism and is the most sensitive test for chlamydia and gonorrhea. Specimens can be first-void urine (the first part of the stream) or vaginal, cervical or urethral swabs; throat and rectal swabs are taken based on the sexual history and on what the local laboratory offers (PHAC, 2025b, 2026a). The nurse explains each specimen, offers self-collection where policy allows, and labels specimens with the site. A positive test is a reason to offer testing for other STBBIs, including HIV and syphilis (Chapter 21).

Partner notification is the process of telling sexual partners that they may have been exposed so that they can be tested and treated. For chlamydia and gonorrhea, the national guides call for testing and treating all partners from the 60 days before symptoms began or, without symptoms, before the test was taken (PHAC, 2025b, 2026a). Syphilis tracing goes back further, depending on the stage (PHAC, 2025d). Partner notification is not a public health requirement for herpes or warts, but patients are encouraged to tell partners (PHAC, 2021, 2025a). Public health staff can help notify partners without naming the patient.

In Ontario, chlamydia, gonorrhea and syphilis are diseases of public health significance under the *Health Protection and Promotion Act* and its regulations. As Ontario law sets out, physicians and other health care providers, laboratories and hospital administrators report suspected or confirmed cases to the local medical officer of health as soon as possible or by the next working day, and Ontario's privacy law allows this disclosure (Middlesex-London Health Unit, 2026). Chlamydia and syphilis are reportable in every province and territory (PHAC, 2025b, 2025d), though each sets its own rules. The nurse follows employer policy on who files the report and protects the patient's privacy within the team (Chapter 1).

Follow-up completes treatment:

- **Gonorrhea:** a test of cure at every positive site. Culture can be taken at least 3 days after treatment; NAAT should wait 3 to 4 weeks or longer, because leftover genetic material can give a false positive (PHAC, 2026a).
- **Chlamydia:** a test of cure at 3 weeks in some situations, such as pregnancy or doubtful adherence, and repeat screening for everyone 3 months after treatment (PHAC, 2025b).
- **Syphilis:** repeat blood tests at set intervals to confirm the response (PHAC, 2025d).

Nursing care follows the clinical judgment model (Chapter 1, section 1.4). The nurse **recognizes cues** that may point to an STBBI in a patient admitted for something else: unexplained discharge, genital or mouth sores, a new rash, pelvic or testicular pain, or a positive result in the chart. The nurse **analyzes** these cues alongside the sexual health history (section 29.1) and **takes action** by reporting them, offering testing as ordered or as a medical directive allows, and using calm, non-judgmental language. Fever, worsening pelvic pain or signs of sepsis in a patient with possible PID are escalated at once (Chapters 4 and 6).

Teaching covers:

- taking every dose of oral treatment and returning for follow-up tests;
- avoiding sex until treatment is complete and partners have been treated, as the prescriber or public health advises;
- regular testing; for example, the national guide recommends syphilis screening every 3 to 6 months for people with multiple partners (PHAC, 2025d);
- condoms, other prevention and vaccines (Chapter 21);
- returning if symptoms persist or come back.

Age is never a reason to skip a sexual health conversation or an offer of testing. Older adults may have new partners later in life, and in an older patient, discharge or burning on urination can be mistaken for a urinary tract infection or for menopause changes (sections 28.1 and 29.4).

CANADIAN CONTEXT

Syphilis in Canada

After years of increases, Canada reported 12,135 cases of infectious syphilis in 2023, or 30.5 per 100,000 population. The rate fell 16% from 2022, the first national drop since 2014, but remained 77% above the 2018 level. PHAC cautions that one year of data is not a trend (PHAC, 2025c).

- **Who is affected:** 64% of 2023 cases were in males, and cisgender gay, bisexual and other men who have sex with men accounted for 27% of all cases. The rate in females was 204% higher than in 2018 (PHAC, 2025c).
- **Congenital syphilis:** 53 confirmed early cases were reported in 2023, a rate of 14.5 per 100,000 live births. That was 56% lower than in 2022 but 220% higher than in 2018. Of the provincial rates published, Manitoba's was the highest, and Ontario had the most confirmed cases (PHAC, 2025c).
- **Prevention:** The national guide recommends syphilis screening for everyone early in pregnancy, and again later for those at ongoing risk (PHAC, 2025d).

- **Treatment supply:** Health Canada reports a shortage of Bicillin L-A, the benzathine penicillin G product that Pfizer markets in Canada, caused by a manufacturing disruption and expected to last until February 2027. Health Canada has allowed a Portuguese-authorized benzathine penicillin product to be imported in the meantime (Health Canada, 2026).

29.6 Erectile Dysfunction and Gender-Affirming Care

Erectile Dysfunction

Erectile dysfunction (ED) is the inability to get or keep an erection firm enough for satisfying sex. It is common in Canada and becomes more common and more severe with age (Domes et al., 2021). An erection depends on healthy blood vessels, nerves, hormones and emotional well-being, so ED often signals a problem elsewhere (Figure 29.6).

The Canadian Urological Association (CUA) notes that ED and cardiovascular disease share many risk factors, and that in some people ED may be an early signal of later heart and blood vessel events. Risk factors include older age, diabetes, high cholesterol, hypertension, obesity, metabolic syndrome, inactivity and smoking. The CUA suggests considering blood glucose, glycated hemoglobin (HbA1c) and lipid tests to look for undiagnosed diabetes and high cholesterol (Domes et al., 2021). Medications, stress, performance anxiety and mental illness can also contribute, and including the partner in care improves outcomes. Exercise, quitting smoking and cutting down on alcohol and cannabis are first steps (Domes et al., 2021). The nurse who hears about ED does not dismiss it as a private matter; it is a reason to check blood pressure, glucose and cardiovascular risk (Chapters 17, 19 and 22).

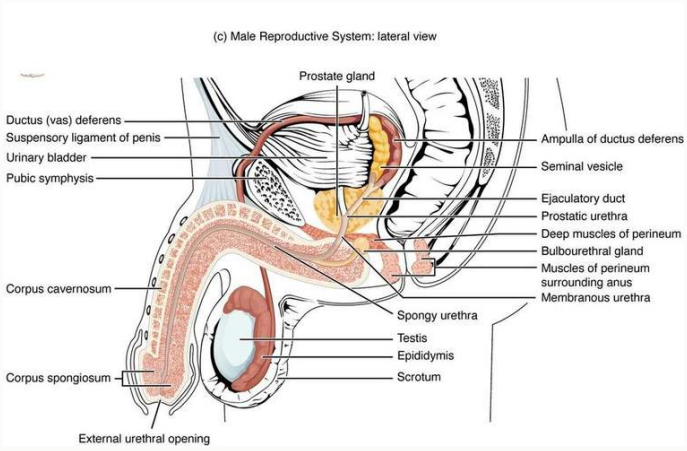

Figure 29.6 Sagittal view of the male reproductive and lower urinary structures, including the erectile tissue of the corpus cavernosum and corpus spongiosum (cropped to panel [c]). (credit: modification of "Figure 27.2, Male Reproductive System" by J. Gordon Betts et al./OpenStax, Anatomy and Physiology 2e, CC BY-NC-SA 4.0)

The CUA strongly recommends a **phosphodiesterase type 5 (PDE5) inhibitor** as the first drug for ED. These drugs block the PDE5 enzyme, which allows more blood flow into the penis during sexual arousal. Sildenafil, tadalafil and vardenafil are the PDE5 inhibitors the guideline names. Common adverse effects are headache, flushing, indigestion and nasal congestion; vision changes can occur with sildenafil and vardenafil, and muscle aches with tadalafil. A lower dose may be needed for people over 65, people with liver or kidney impairment and people taking drugs that strongly block the liver enzyme CYP3A4 (Domes et al., 2021). Other options include vacuum devices, alprostadil inserted into the urethra or injected into the penis, and a penile implant (Domes et al., 2021).

The most dangerous interaction is with **nitrates**, such as nitroglycerin and isosorbide. Both drug groups act on the same nitric oxide pathway that relaxes blood vessels, and together they can cause a sudden, severe and potentially life-threatening drop in blood pressure (Sun Pharma Canada, 2024). The CUA lists regular or occasional nitrate use as an absolute contraindication to PDE5 inhibitors (Domes et al., 2021). The Canadian product monographs describe the time windows differently for each drug:

- **Sildenafil:** the monograph states that it is not known when nitrates, if needed, can be safely given after a dose (BGP Pharma, 2023).
- **Tadalafil:** if a nitrate is judged medically necessary because a situation is life-threatening, at least 48 hours should pass after the last dose, and the nitrate is then given only with close medical supervision and hemodynamic monitoring (Sun Pharma Canada, 2024).
- **Vardenafil:** the same conditions apply, with at least 24 hours after the last dose (Angita Pharma, 2022).

Because of this, every nurse asks about PDE5 inhibitors before giving a nitrate, every time (Chapter 17). Patients may not list them as "medications"; some buy them online, and some feel embarrassed to mention them.

Nursing care for ED centres on asking, listening and linking. The nurse includes erections in the sexual health history and medication review, uses plain words, and lets the patient know that ED is common and treatable. Cues such as new ED with chest discomfort on exertion, high blood pressure or high glucose are passed to the prescriber. Surgery or illness that affects nerves or blood flow, such as prostate surgery (Chapter 28) or diabetes (Chapter 22), can lead to ED, and the nurse helps the patient prepare questions for the surgeon or prescriber. Teaching for a person prescribed a PDE5 inhibitor includes taking it only as prescribed, telling every care provider about it, never combining it with a nitrate, and getting help at once for chest pain or the warning signs below. For older adults, who may take several heart and blood pressure drugs, the medication review is especially important.

Priapism is a prolonged erection that is not linked to sexual desire. The monographs tell patients to seek immediate medical help for an erection that lasts more than 4 hours, because without prompt treatment it can damage penile tissue and cause permanent loss of erections (BGP Pharma, 2023; Sun Pharma Canada, 2024). The nurse treats it as an emergency and reports it at once. Patients also stop the drug and get prompt care for sudden loss of vision or hearing (BGP Pharma, 2023).

Gender-Affirming Care in Medical-Surgical Settings

Gender-affirming care is care that respects and supports a person's gender identity. In a medical-surgical setting, it starts with basics. The basics of 2SLGBTQI+ inclusive care are in Chapter 2.

- **Names and pronouns:** Using the name a person uses in daily life and the correct pronouns is fundamental to good care (Bourns, 2019). The nurse asks once, privately, records the answer where the health record allows, and uses it consistently. When the legal name on a health card differs, the nurse uses it only where identification requires it.
- **Organ inventory:** Care and screening follow the organs a person has, not their gender identity (section 29.1). A transgender man may need cervical screening; a transgender woman still has a prostate (section 28.6). Ontario's breast and cervical screening programs include transgender and nonbinary people who meet their criteria (sections 29.2 and 29.3; Table 29.1).
- **Hormones around surgery:** Gender-affirming hormones include estradiol, anti-androgens such as spironolactone or cyproterone, and testosterone (Bourns, 2023). Clinicians once stopped estrogen before surgery out of concern for VTE. A review of the evidence found no data showing that holding hormones before gender-affirming surgery lowers that risk, and it recommends individual assessment for older patients and those with other risk factors (Zucker et al., 2021). Hormone therapy is generally expected before genital surgery or removal of the gonads unless it is contraindicated (Bourns, 2019). Of all routes, only transdermal estradiol has direct evidence of a lower clot risk, and the Sherbourne guidelines prefer it for people over 40 or with clot risk factors (Bourns, 2019). The nurse does not stop or hold hormones without an order, asks the surgical team or prescriber for a plan, and gives VTE prophylaxis as ordered (Chapters 7 and 19).
- **After gender-affirming surgery:** Patients may have surgery far from home and then return to a local hospital or clinic. A US gender-affirming care guideline states that, after vaginoplasty, following the dilation schedule is critical to healing and to keeping the vagina open, and that dilation continues regularly for at least a year (Meltzer, 2016). Bleeding, a hematoma, separation of the wound, trouble voiding and signs of infection are reported to the surgical team. After removal of the testes, anti-androgens are often no longer needed, but that decision belongs to the prescriber (Bourns, 2023).
- **Privacy and safety:** A person's gender history is shared only with those who need it for care. Room assignment follows hospital policy and the patient's identity, and questions are asked only when they matter for care, never out of curiosity.

Two-Spirit is a term chosen in 1990 by Indigenous people to describe the wide range of Indigenous understandings of gender and sexual diversity; its meaning varies from person to person and from community to community (Bourns, 2019). Many Two-Spirit identities exist across North America, and some carry spiritual or ceremonial meaning (Coleman et al., 2022). The nurse asks how a Two-Spirit patient wants to be identified and supported, including involving family, Elders or traditional practices, rather than assuming a meaning.

CLINICAL SAFETY

PDE5 Inhibitors and Nitrates

A PDE5 inhibitor taken with a nitrate can cause a sudden, severe and sometimes life-threatening drop in blood pressure (Domes et al., 2021).

- **Ask every time:** Before giving nitroglycerin in any form (spray, tablet, patch, ointment or infusion) or isosorbide, ask directly: "Have you taken any medicine for erections, such as sildenafil, tadalafil or vardenafil, in the past few days?" Ask privately, without judgment, and explain why it matters.
- **If the answer is yes, or unknown:** hold the nitrate, record the drug and the time of the last dose, and tell the prescriber at once. The time windows differ by drug and apply only to life-threatening situations under close monitoring (BGP Pharma, 2023; Sun Pharma Canada, 2024; Angita Pharma, 2022).
- **Document clearly:** add the PDE5 inhibitor to the medication history and flag it for the team.
- **Teach:** a patient who has been prescribed a nitrate should not use a PDE5 inhibitor, and anyone who gets chest pain after taking one calls 9-1-1 and tells the paramedics and the hospital what they took and when.

CLINICAL JUDGMENT

Chest Pain After an Erectile Dysfunction Pill

Names and details are fictional; this is a composite story.

Teodoro Alvarez, 58, is on day 2 after a laparoscopic cholecystectomy on a surgical unit. At 06:00 he reports a tight pressure in his chest. He has hypertension and type 2 diabetes. His heart rate is 102, blood pressure 128/78 mm Hg, respiratory rate 22 and SpO_2 94% on room air, and his skin is damp. A standing order allows sublingual nitroglycerin for chest pain.

- **Recognize cues:** New chest pressure, diaphoresis, a fast heart rate and cardiac risk factors. The nurse asks about erection medicines before reaching for the nitroglycerin. Mr. Alvarez says quietly that he takes tadalafil daily and took a tablet from his home supply yesterday at 20:00.
- **Analyze cues:** Fewer than 48 hours have passed since the last tadalafil dose, and daily tadalafil keeps a steady level of the drug in the blood (Sun Pharma Canada, 2024). His blood pressure is normal now, but nitroglycerin could drop it suddenly and dangerously. He had not listed tadalafil on admission because he did not think of it as a medicine.
- **Prioritize hypotheses:** Acute coronary syndrome is the leading concern; the drug interaction is the immediate safety risk.
- **Generate solutions:** Hold the nitroglycerin, escalate at once and prepare for cardiac assessment as ordered.
- **Take action:** The nurse calls the rapid response team using Situation, Background, Assessment, Recommendation (SBAR; Chapter 6), states the tadalafil timing clearly, stays with the patient, and obtains a 12-lead electrocardiogram (ECG) as the team directs. The physician orders other treatment and no nitrate.
- **Evaluate outcomes:** The pain eases, vital signs settle and the team documents the PDE5 inhibitor as a nitrate alert. The nurse updates the medication reconciliation and, before discharge, teaches Mr. Alvarez to tell every care provider, including paramedics, about his tadalafil.

SCOPE IN PRACTICE

Sexual Health Care and Who Does What

CNO's Scope of Practice standard asks whether a nurse has the **authority**, the **competence** and the right **context** for an activity (Chapter 1, section 1.3).

- **Testing:** RNs and RPNs collect STBBI specimens, such as urine and swabs, under an order or a medical directive and as employer policy allows. Both teach patients how to self-collect where that is offered.
- **Treatment:** STBBI treatment is given under a prescriber's order or a medical directive. Authorized RNs in Ontario can prescribe drugs from a set list, each for set purposes such as immunization, contraception, travel health and smoking cessation; treating STBBIs is not one of those purposes (College of Nurses of Ontario [CNO], n.d.), and RN prescribing does not apply in public hospitals. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027.
- **Competence:** Taking a sexual health history, counselling on partner notification and giving intramuscular injections need knowledge and practice. A nurse who has not developed these skills seeks education and support before taking them on.
- **Context:** The RPN consults the RN when a patient's needs become more complex, such as signs of PID with fever or pain, a positive test during pregnancy, or a disclosure of sexual violence. Every nurse escalates deterioration at once.
- **Confidentiality and reporting:** Both RNs and RPNs protect sexual health information and follow employer policy on reporting diseases of public health significance.

Employer policy and the province or territory shape these roles.

PRACTICE STORY

The Question I Almost Didn't Ask

Names and details are fictional; this is a composite story.

Nurse: Leila Khoury, RPN. Years in practice: 4. Setting: medical unit, Ontario.

Mr. Lachance was 66, admitted with pneumonia and heart failure. On my admission checklist there was a line about sexual health. I usually skipped it for older men on the medical unit. It felt awkward, and I told myself it was not why he was here.

That evening his wife had gone home, and he was chatting about his garden. I remembered a workshop where the instructor said that skipping the question is a decision too. So I said, "I ask everyone this. Some illnesses and medicines affect sexual health. Is there anything about that you want to mention, or any medicines for it that you take?"

He laughed, then went quiet. "My doctor doesn't know, but I get pills online. For erections." He had taken one the night before he came in. He did not know the name, but he described the blue tablet and the package.

I knew there was a new order for a nitroglycerin patch, due to be applied that night, written because of chest discomfort he had reported in the emergency department. I checked: the patch had not been applied yet. I asked him if I could share what he told me with the team, explained why, and he agreed.

I told Daniel, the RN on our team, right away, and together we called the physician. The patch was held, his blood pressure was monitored, and the pharmacist added the drug to his record as an alert. The next morning the physician talked with him about safer options and about bringing the package in so the drug could be identified.

What stays with me is how close I came to not asking. He would not have volunteered it, and no one else had asked.

Reflect: Which parts of this situation were within the RPN's own scope, and when did she need to involve the RN and the physician? How would you phrase a sexual health question so that it feels routine rather than intrusive?

Chapter 29 Summary

29.1 Sexual Health in Medical-Surgical Care

- Illness, surgery and medications often affect sexual health, and patients rarely raise it; the nurse asks every patient, in private, with permission and an explanation of why.
- PHAC prefers brief, routine assessments that use the patient's own terms for their body, explain confidentiality and its limits, and follow a trauma- and violence-informed approach.
- A sexual health history covers activity and partners, protection, past STBBIs, symptoms and reproductive health; questions about bodies and practices, and an organ inventory, are more useful than questions about identity.
- The nurse asks about possible pregnancy before surgery, radiation-based imaging and some drugs and follows the employer's testing policy; Canadian and US guidelines recommend screening for asymptomatic bacteriuria in pregnancy.
- Hypertension in pregnancy has its own definitions in the SOGC guideline; severe hypertension or new headache or visual change in pregnancy needs urgent obstetric assessment.

29.2 Breast Cancer Care

- Breast cancer is the most common cancer among women in Canada (excluding non-melanoma skin cancers): an estimated 32,400 women and 300 men will be diagnosed in 2026, and about 1 in 8 women will be diagnosed over their lifetime.
- The 2024 Canadian Task Force draft was not finalized before the Task Force's mandate ended in March 2026; since October 2024 the OBSP screens people aged 40 to 74, most every 2 years, with yearly mammography and MRI for high-risk people aged 30 to 69.
- Only a biopsy can confirm breast cancer; hormone receptor and HER2 status guide treatment.
- After breast surgery, the nurse manages the closed suction drain and output log, watches for bleeding, seroma and infection, reinforces arm exercises and supports body image.

- Lymphedema causes heaviness, aching and swelling; advice to avoid blood pressure and needles in the affected arm continues, though evidence for it is limited, while skin protection, infection prevention and early referral are well supported.

29.3 Gynecologic Conditions and Surgery

- Abnormal uterine bleeding, often from fibroids, can cause iron deficiency anemia; most fibroids cause no symptoms and need no treatment.
- Endometriosis affects about 10% of women, with a diagnostic delay of at least 5 years in Canada; the 2024 SOGC guideline supports clinical diagnosis so that treatment is not delayed.
- After hysterectomy, the nurse watches for bleeding (including internal bleeding with a dry pad), voiding problems, bowel function, VTE and infection; removing both ovaries causes surgical menopause.
- Ontario replaced the Pap test with HPV testing in March 2025: most eligible people with a cervix are screened every 5 years from age 25; a positive result is not a cancer diagnosis.
- Ovarian cancer has vague symptoms; any bleeding after menopause needs assessment, because abnormal bleeding is the sign of uterine cancer seen most often.

29.4 Menopause and Midlife Health

- Menopause is confirmed after 12 months in a row without a period; the average age in Canada is 51, and perimenopause can begin years earlier.
- Surgical or medically induced menopause is often sudden and more severe; the SOGC recommends considering hormone replacement until about age 51 when ovarian function is lost before 45.
- Hot flashes, night sweats, sleep problems, mood changes and genitourinary syndrome of menopause are common and treatable.
- The SOGC and The Menopause Society describe menopausal hormone therapy as the most effective treatment for hot flashes and as favourable for people under 60 or within 10 years of menopause who have no contraindications; a progestogen is added when a uterus is present.
- Contraindications include breast cancer, past clots, stroke or heart attack, undiagnosed bleeding and active liver disease; low-dose vaginal estrogen treats GSM at any age.
- The nurse supports an informed choice, reports contraindication cues and links midlife care to bone, heart and bladder health.

29.5 Sexually Transmitted and Blood-Borne Infections

- Chlamydia is the sexually transmitted infection reported most often in Canada; infectious syphilis fell in 2023 for the first time since 2014 but remains well above 2018 levels.
- Gonorrhea is frequently silent and can quickly develop antibiotic resistance; ceftriaxone is recommended, with a test of cure at every positive site.
- Syphilis can be missed at every stage; a painless sore or a subtle rash is a reason to test.
- NAAT on first-void urine or swabs is the most sensitive test for chlamydia and gonorrhea; partners from the past 60 days are tested and treated.
- In Ontario, chlamydia, gonorrhea and syphilis are reported to the medical officer of health; the nurse follows employer policy and protects privacy.
- A Health Canada–reported shortage of benzathine penicillin G is expected to last until February 2027.

29.6 Erectile Dysfunction and Gender-Affirming Care

- Erectile dysfunction shares risk factors with cardiovascular disease and may be an early warning sign.
- PDE5 inhibitors (sildenafil, tadalafil, vardenafil) with nitrates can cause severe hypotension; the nurse asks about them before every nitrate and holds the nitrate and escalates if the answer is yes or unknown.
- Canadian monographs give no safe interval for sildenafil and allow nitrates only in life-threatening situations, with close monitoring, after 48 hours for tadalafil and 24 hours for vardenafil.
- An erection lasting more than 4 hours is an emergency.

- Gender-affirming care uses the patient's name and pronouns, bases screening on organs present, and does not stop hormones around surgery without an order.
- Two-Spirit identities carry different meanings for different people and communities; the nurse asks rather than assumes.

Key Terms (48)

abnormal uterine bleeding: Uterine bleeding that differs from a person's usual menstrual pattern in amount, duration, frequency or regularity, or that occurs between periods.

anogenital warts: Skin growths in the genital or anal area caused mainly by HPV types 6 and 11.

asymptomatic bacteriuria: Bacteria in the urine without symptoms of urinary tract infection; screened for and treated in pregnancy but not in most other adults.

axillary lymph node dissection: Surgery that removes lymph nodes from the armpit, usually when breast cancer has spread to them.

bilateral salpingo-oophorectomy: Surgical removal of both ovaries and both fallopian tubes.

biopsy: Removal of a tissue sample for examination by a pathologist; the only test that confirms breast cancer.

breast-conserving surgery: Surgery that takes out a breast tumour with a rim of healthy tissue and keeps the rest of the breast; usually followed by radiation.

chlamydia: A sexually transmitted infection caused by Chlamydia trachomatis; the sexually transmitted infection reported most often in Canada.

closed suction drain: A soft tube from a wound to a compressible bulb that draws out blood and lymph by suction.

congenital syphilis: Syphilis passed from a pregnant person to the fetus.

endocrine therapy: Treatment that blocks the production or action of hormones that some cancers use to grow, such as tamoxifen or an aromatase inhibitor for breast cancer.

endometriosis: A chronic inflammatory condition in which tissue similar to the uterine lining grows outside the uterus, causing pain and sometimes infertility.

erectile dysfunction: The inability to get or keep an erection firm enough for satisfying sex.

external breast form: A breast prosthesis of foam, silicone or another material, worn inside a bra to restore shape after breast tissue is removed.

gender-affirming care: Care that respects and supports a person's gender identity.

genital herpes: A lifelong infection with herpes simplex virus that causes recurrent genital sores and can spread without symptoms.

genitourinary syndrome of menopause: A group of vulvar, vaginal and lower urinary tract symptoms, such as dryness, painful intercourse and urgency, caused by falling estrogen.

gonorrhea: A sexually transmitted infection caused by Neisseria gonorrhoeae, a bacterium that can quickly develop antibiotic resistance.

HER2: Human epidermal growth factor receptor 2, a cell-surface protein that some breast cancers make in excess; these cancers may respond to HER2-targeted drugs.

hormone receptor status: Whether cancer cells carry estrogen receptors, progesterone receptors or both, which predicts whether hormone-blocking treatment will work.

human papillomavirus: A common sexually transmitted virus; persistent infection with high-risk types causes cervical cancer.

hysterectomy: Surgical removal of the uterus; a total hysterectomy also removes the cervix.

lymphedema: Swelling caused by a build-up of lymph in the tissues when lymph cannot drain normally, often after lymph nodes are removed or treated with radiation.

mastectomy: Surgery that removes all of the breast tissue.

menopausal hormone therapy: Estrogen, alone or with a progestogen, used to relieve menopause symptoms.

menopause: The permanent end of menstruation caused by the loss of ovarian follicles, confirmed after 12 months in a row with no period and no other cause.

nucleic acid amplification test: A laboratory test that detects an organism's genetic material; the most sensitive test for chlamydia and gonorrhea.

organ inventory: A respectful record of the reproductive and sex organs a person has at present, used to guide screening and care without assumptions based on gender.

partner notification: The process of informing sexual partners of a possible exposure so they can be tested and treated.

PDE5 inhibitor: A drug that blocks phosphodiesterase type 5 to improve erections, such as sildenafil, tadalafil or vardenafil; contraindicated with nitrates.

pelvic inflammatory disease: Infection of the uterus, fallopian tubes and nearby pelvic structures, often a complication of chlamydia or gonorrhea.

pelvic organ prolapse: Descent of the bladder, uterus, top of the vagina or rectum into or beyond the vaginal opening because their supports have weakened.

perimenopause: The transition before menopause, when periods change and symptoms often begin; it can start 4 to 8 years before the final period and includes the 12 months after it.

pessary: A removable device placed in the vagina to support prolapsed pelvic organs.

post-mastectomy pain syndrome: Nerve pain in the chest, armpit or arm that persists after healing from breast surgery.

priapism: A prolonged erection not linked to sexual desire; an erection lasting more than 4 hours is an emergency.

screening mammogram: An X-ray of the breasts in a person with no symptoms, taken to find breast cancer early.

sentinel lymph node biopsy: Removal of the first lymph node or nodes that drain a tumour, to check whether cancer has spread to them.

seroma: A collection of fluid under the skin after surgery, such as under the skin flap after mastectomy.

sexual health history: A focused set of questions about a person's sexual activity, partners, protection, past sexually transmitted and blood-borne infections, symptoms and reproductive health.

sexually transmitted and blood-borne infection: An infection spread through sexual contact, blood or both.

surgical menopause: Menopause that begins abruptly when both ovaries are removed before natural menopause.

syphilis: A sexually transmitted infection caused by Treponema pallidum that progresses through primary, secondary, latent and tertiary stages.

trichomoniasis: A sexually transmitted infection caused by the parasite Trichomonas vaginalis.

Two-Spirit: A term chosen by Indigenous people in 1990 to describe the wide range of Indigenous understandings of gender and sexual diversity.

uterine fibroids: Non-cancerous growths of the muscle of the uterus.

vaginal estrogen: Low-dose estrogen placed in the vagina to treat genitourinary syndrome of menopause.

vasomotor symptoms: Hot flashes and night sweats, the most common symptoms of menopause.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mei Lin (Questions 1–4): Mei Lin Zhou, 58, is on day 1 after a left total mastectomy with sentinel lymph node biopsy on a surgical unit in Nova Scotia. A closed suction drain exits below the left chest incision and collected 60 mL of serosanguineous fluid overnight. At 0800 her blood pressure is 128/76 mm Hg, heart rate 82 beats/min, respiratory rate 16 breaths/min, temperature 37.1 °C and oxygen saturation 97% on room air, and she rates her pain 3 out of 10 with oral analgesics. She is expected to go home tomorrow with the drain in place. A licensed practical nurse (LPN) is caring for her.

1. [CORE] The LPN empties Ms. Zhou's drain at 0800. Which action is correct?

a. Measure and record the fluid, squeeze the bulb flat and close the plug while it is still squeezed.

b. Leave the bulb fully expanded after emptying it so that the fluid can flow into it freely by gravity.

c. Disconnect the bulb from the tubing and rinse it with tap water before closing the system again.

d. Empty the bulb only once each day, because opening the plug more often adds a risk of infection.

Answer: a — Suction depends on closing the plug while the bulb is compressed; the amount and colour are recorded on an output log (section 29.2, Breast Surgery and Nursing Care). Option b removes the suction the drain needs to work. Option c opens the closed system and invites contamination. Option d is wrong because the bulb is emptied as ordered and whenever it is about half full, not once a day; a full bulb loses suction (Alberta Health Services, 2022).

2. [CORE] At 1400, the LPN finds the bulb full of bright red fluid (90 mL in 2 hours) and the chest wall under the dressing tense and swollen. Ms. Zhou's heart rate is 108 beats/min and blood pressure 104/64 mm Hg. Which action should the LPN take first?

a. Empty the bulb, record the 90 mL on the output log and reassess the drainage again in one hour.

b. Apply an ice pack over the dressing and help Ms. Zhou turn onto her left side to apply pressure.

c. Stay with Ms. Zhou, recheck her vital signs and report the findings to the RN and surgeon at once.

d. Reinforce the dressing, remind her to keep the left arm low and document the change at the end of the shift.

Answer: c — Rapid bright red drainage, a tense swollen chest wall, a rising heart rate and a falling blood pressure suggest active bleeding or a hematoma, and any nurse who notices them acts and escalates at once (section 29.2; sections 6.1 and 7.6). Options a and d delay reporting a possible hemorrhage. Option b is not an ordered treatment and does not address the danger.

3. [CORE] Ms. Zhou says, "My friend said I can never have my blood pressure taken on my left arm again, for the rest of my life." Which response by the LPN is most accurate?

a. "Your friend is right: no blood pressures, blood tests or needles in that arm for life, or you will get lymphedema."

b. "Lymphedema does not happen after a sentinel node biopsy, so you can use that arm in any way you like."

c. "Many sources still advise using the other arm, though studies have not shown that it raises risk; protecting the skin from infection matters most."

d. "A compression sleeve worn every day from now on will prevent lymphedema, so I will ask for one before you go home."

Answer: c — The Canadian Cancer Society advises avoiding blood pressure readings and needles in the affected arm, but a prospective study found that blood draws and injections on the treated side were not linked to increases in arm volume and concluded that blood pressure readings may not be either, while cellulitis, axillary dissection, node radiation and higher body mass index were linked (section 29.2, Lymphedema). Option a overstates the evidence. Option b is wrong; lymphedema can follow sentinel node biopsy, though it is more common after dissection. Option d is wrong because compression garments are used only when a physician or physiotherapist recommends them.

4. [CORE] While the LPN changes the dressing, Ms. Zhou turns away and says, "My husband hasn't looked at me since the surgery. I don't know how I'll ever look at myself." Which response is best?

a. "Please don't worry. Most husbands get used to it quickly, and you can always have reconstruction later on."

b. "Try to focus on healing first. There will be plenty of time to think about your appearance after treatment."

c. "I will ask the surgeon to come and explain reconstruction to you and your husband before you go home."

d. "Many people feel this way after a mastectomy. Can you tell me more about what worries you most right now?"

Answer: d — Loss of a breast affects body image and relationships, and the nurse first acknowledges the feeling and invites the patient to say more (section 29.2, Breast Surgery and Nursing Care). Option a offers false reassurance and closes the conversation. Option b dismisses her concern. Option c jumps to a solution before the nurse knows what she needs; reconstruction may not be her concern at all.

5. [CORE] Ali Rahimi, 71, is recovering from abdominal surgery and has a new prescription for a drug that can affect sexual function. Which opening by the nurse best follows Canadian guidance for a sexual health conversation?

a. "I need to ask you some questions about your sex life now. Please answer every one, because they all matter for your care."

b. "Some of your new medicines can affect sex, so I ask everyone about it. Is it all right if I ask a few questions now?"

c. "At your age I don't suppose sex is much of a concern, but I'm required to ask, so please answer just yes or no."

d. "Your wife is here, so this is a good time for both of you to tell me whether sex has been a problem since surgery."

Answer: b — The nurse explains why the questions matter, makes them routine for everyone and asks permission, and the patient may decline any question (section 29.1, Talking About Sexual Health). Option a removes the patient's choice. Option c makes an ageist assumption. Option d breaches privacy by assuming the patient wants his partner present and assumes the partner's role.

6. [CORE] A nurse is completing an admission history for Jordan Tremblay, 34, a transgender man admitted for a bowel obstruction. Which question best supports an accurate organ inventory?

a. "Some of my questions depend on anatomy. Which of these organs do you have now: a cervix, uterus, ovaries or breasts?"

b. "Since you were born female, I will assume you still have all of your female organs unless you tell me otherwise."

c. "Have you finished your transition yet, or are you still planning to have more gender-affirming surgery at some point in the future?"

d. "Do you have sex with men, women or both, so that I know which tests you are likely to need?"

Answer: a — An organ inventory asks which organs the person has now, in a respectful, matter-of-fact way, because screening and care follow organs, not gender (section 29.1, Taking a Sexual Health History). Option b makes an assumption and uses language that may be distressing. Option c asks about transition in a way that is not needed for care. Option d asks about identity rather than body parts and practices, and does not tell the nurse which tests are relevant.

7. [CORE] Sophie Gagnon, 27, is scheduled for a computed tomography (CT) scan of the abdomen later today. Which action by the nurse is most appropriate?

a. Assume pregnancy is unlikely, because she was admitted for a medical problem and has not mentioned it to anyone on the unit.

b. Ask the radiology department to delay the CT for 2 weeks so that pregnancy can be safely ruled out.

c. Tell her to inform the CT technologist if she thinks she could be pregnant, and then continue with the plan as scheduled.

d. Ask about the possibility of pregnancy and her last menstrual period, and arrange a pregnancy test if policy requires it.

Answer: d — Before imaging that uses radiation, surgery and some drugs, the nurse asks about the possibility of pregnancy, including the last menstrual period, and follows the employer's testing policy (section 29.1, When a Patient Might Be Pregnant). Option a makes an unsafe assumption. Option b delays care without reason. Option c passes the nurse's responsibility to the patient.

8. [CORE] A patient who is 31 weeks pregnant is admitted to a medical unit with a kidney infection. At 1600 she reports a new severe headache and blurred vision, and her blood pressure is 166/112 mm Hg. Which action should the nurse take?

a. Give the acetaminophen ordered for headache and recheck her blood pressure in 4 hours.

b. Escalate at once for urgent obstetric assessment while staying with the patient.

c. Dim the room lights and encourage rest, since a kidney infection often causes a headache.

d. Treat her blood pressure using the adult targets the unit uses for patients with hypertension.

Answer: b — Hypertension in pregnancy has its own definitions and thresholds in the SOGC guideline, and a pregnant patient with severe hypertension or new symptoms such as headache or visual change needs urgent obstetric assessment (section 29.1, When a Patient Might Be Pregnant). Options a and c delay escalation of a possible emergency. Option d is wrong because the adult targets in Chapter 19 do not apply in pregnancy.

9. [CORE] Priya Sharma, 44, lives in Ontario, has no symptoms or family history of breast cancer and asks whether she can have a mammogram. Which response is accurate?

a. "Since October 2024, Ontario's program includes people in their 40s, most screened every 2 years; you can book it yourself."

b. "Ontario does not screen anyone in their 40s, so you will need to wait until you turn 50 before you can book a mammogram there."

c. "Everyone in Ontario over 40 must have a mammogram every year, and your family doctor will book it for you automatically."

d. "Because the national task force recommended against screening in your 40s, the Ontario program cannot offer it to you."

Answer: a — The OBSP expanded in October 2024 to people aged 40 to 49, most of whom are screened every 2 years, and people can book their own appointment; people in their 40s are encouraged to talk with a provider first (section 29.2, Screening and Diagnosis; Table 29.1). Option b is out of date. Option c is wrong about the interval and about screening being required. Option d misstates the task force draft, which suggested offering screening to people in their 40s who choose it and was not finalized.

10. [CORE] A nurse is teaching a patient who had an axillary lymph node dissection 3 months ago about early signs of lymphedema. Which findings should the patient report? Select all that apply.

a. A feeling of heaviness or fullness in the arm on the treated side

b. Rings or sleeves that feel tighter than usual on that side

c. Numbness along the inner upper arm that has been present since surgery

d. Swelling of the hand or fingers on the treated side

e. Aching or a burning feeling in the arm on the treated side

f. A healed incision that looks flat and pale

Answer: a, b, d, e — Early lymphedema causes fullness or heaviness, tight jewellery or clothing, swelling of the hand or fingers and aching or burning (section 29.2, Lymphedema). Option c describes numbness from nerve injury during surgery, which is common and not a sign of lymphedema. Option f is a normal healed incision.

11. [CORE] Two days after her drain was removed, a patient who had a mastectomy notices a soft, fluid-filled swelling under her incision. She has no fever, redness or increase in pain. Which is the nurse's best interpretation and action?

a. The swelling is lymphedema of the chest, so a compression garment should be fitted today.

b. The swelling is expected after any drain is removed and will always disappear without any follow-up.

c. The swelling is likely a seroma, so the nurse reports it to the surgical team, who may drain it.

d. The swelling is a sign of wound infection, so the nurse asks the surgeon for an antibiotic order.

Answer: c — A seroma is a collection of fluid under the skin flap that can build up after the drain is removed; the surgical team assesses it and may drain it (section 29.2, Breast Surgery and Nursing Care). Option a confuses seroma with lymphedema. Option b gives false reassurance. Option d does not fit; she has no signs of infection.

12. [CORE] Danielle Okafor, 39, has had heavy periods from uterine fibroids for a year. She reports changing a pad every hour on her heaviest days and becoming short of breath on stairs. Which nursing action is most important?

a. Reassure her that fibroids are very common and that most of them cause no symptoms and need no treatment.

b. Assess for iron deficiency anemia, including fatigue, pallor and her most recent hemoglobin result.

c. Teach her that fibroids are an early stage of uterine cancer and need to be removed promptly.

d. Advise her to limit fluids on heavy days to reduce the amount of bleeding during her period.

Answer: b — Fibroids that cause abnormal uterine bleeding can lead to iron deficiency anemia, and her shortness of breath on exertion suggests it (section 29.3, Common Gynecologic Conditions; section 20.2). Option a is true in general but ignores her symptoms. Option c is false; fibroids are not cancer. Option d is unsafe and would not reduce bleeding.

13. [CORE] Sarah Bjornson, 29, has had painful periods and pelvic pain for 6 years and asks, "Do I have to have surgery before anyone will treat me for endometriosis?" Which response reflects the 2024 SOGC guideline?

a. "Yes. Endometriosis can be confirmed only by surgery, and hormonal treatment cannot begin until it is."

b. "Yes, but only if a blood test for endometriosis is positive. That test comes first, before anything else."

c. "No. Treatment is mainly surgical, so the surgeon will decide whether the disease needs to be removed."

d. "No. It can be diagnosed from your history, an examination and ultrasound, and treatment can start then."

Answer: d — Under the SOGC guideline, endometriosis can be diagnosed clinically from symptoms, examination and ultrasound so that treatment is not delayed; surgery is not the main way to investigate it (section 29.3, Common Gynecologic Conditions). Option a describes an older approach that delays care. Option b is wrong; no blood test is described for diagnosis. Option c is wrong because hormonal treatment, not surgery, is first-line.

14. [CORE] Six hours after an indwelling catheter was removed following a laparoscopic hysterectomy, a patient has not voided and reports fullness above the pubic bone. What should the nurse do next?

a. Use a bladder scanner to measure the urine in her bladder and follow the unit protocol.

b. Reinsert an indwelling catheter right away and leave it in overnight to rest the bladder.

c. Encourage her to drink 1 L of water over the next hour to stimulate the urge to void.

d. Document the finding and reassess at the next routine check in 4 hours.

Answer: a — After catheter removal, the nurse confirms voiding and uses a bladder scan as the unit protocol directs (section 29.3, Hysterectomy and Gynecologic Surgery; sections 7.6 and 28.3). Option b skips assessment and adds catheter risk. Option c adds volume to a bladder that may already be overfull. Option d delays care for a patient with symptoms.

15. [CORE] Nadia Haddad, 42, is going home after a total hysterectomy with bilateral salpingo-oophorectomy for endometriosis. Which statement shows she understands her teaching?

a. "Since my uterus was removed, my periods will stop, but my hormone levels won't change until my natural menopause."

b. "Hot flashes are a sign of infection, so I should call the surgeon if I get them at home."

c. "Because both ovaries were removed, I may get hot flashes and vaginal dryness soon, and I can ask about treatment."

d. "I will need to keep having cervical screening every 5 years, just as I did before the surgery."

Answer: c — Removing both ovaries before natural menopause causes surgical menopause, with an abrupt drop in hormones that can bring hot flashes and vaginal dryness (section 29.3, Hysterectomy and Gynecologic Surgery; section 29.4). Option a would be true only if the ovaries remained. Option b mistakes a menopausal symptom for infection. Option d is wrong; a total hysterectomy removes the cervix, and cervical screening follows organs (section 29.1).

16. [CORE] An Ontario registered practical nurse (RPN) is caring for a patient 4 hours after a vaginal hysterectomy. The patient becomes pale and restless, her heart rate rises from 84 to 116 beats/min and her pad is soaked with bright red blood. Which action by the RPN is best?

a. Change the pad, document the amount of blood lost and recheck the patient's vital signs again in one hour's time.

b. Stay with the patient, call for help, report to the RN at once and activate the rapid response process as policy directs.

c. Ask the RN to take over the patient's care completely, because unexpected postoperative bleeding is outside the RPN's scope.

d. Raise the head of the bed and give the next dose of analgesic as ordered, because pain can raise the heart rate.

Answer: b — Every nurse who notices deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change and follows the rapid response process (section 29.3; sections 1.3 and 6.2). Option a delays escalation. Option c is wrong: the RPN does not step away from a deteriorating patient but acts and consults. Option d treats a possible hemorrhage as pain.

17. [CORE] A new RPN asks whether RPNs in Ontario take sexual health histories. Which response by the charge nurse is most accurate?

a. "No. Only RNs and nurse practitioners may ask patients about sexual health, because asking is a controlled act."

b. "Yes, but only when the patient's physician has written a specific order that allows the RPN to ask those questions."

c. "No. Sexual health questions are always left to the primary care provider after discharge."

d. "Yes, when you have the competence and employer policy supports it, and you consult the RN if needs become complex."

Answer: d — CNO describes scope through authority, competence and context; taking a sexual health history is not a controlled act, and the RPN consults the RN as the patient's needs become more complex. Employer policy and province or territory matter (section 29.1; section 1.3). Option a is wrong; history-taking is not a controlled act. Option b adds a requirement that does not exist. Option c misses the medical-surgical reasons for asking, such as medications and the possibility of pregnancy.

18. [RN] A pathology report for a patient with invasive breast cancer shows that the tumour is estrogen receptor-positive, progesterone receptor-positive and HER2-negative. Which treatment should the RN expect the oncology team to discuss as part of the long-term plan?

a. Endocrine therapy, such as tamoxifen or an aromatase inhibitor, to block the effects of the hormones

b. A HER2-targeted drug, given because the tumour cells are making more of the HER2 protein than normal cells do

c. No drug therapy at all, because receptor-positive tumours do not respond to systemic treatment

d. Menopausal hormone therapy to replace the estrogen that the tumour's receptors are binding

Answer: a — Hormone receptor-positive cancers use estrogen or progesterone to grow, so endocrine therapy that blocks hormone effects is usually offered (section 29.2, Going Deeper: Hormone Receptor and HER2 Status). Option b applies to HER2-positive cancers. Option c is wrong; receptor status predicts response to hormone-blocking therapy. Option d would feed a hormone-sensitive cancer.

19. [RN] Eight hours after an abdominal hysterectomy, a patient's heart rate has risen from 88 to 124 beats/min, her blood pressure has fallen from 132/80 to 88/54 mm Hg and her abdomen is more distended and tender. Her perineal pad has only a small amount of drainage. Which interpretation and action are correct?

a. The light pad rules out bleeding, so the RN gives the ordered analgesic and reassesses in an hour.

b. These findings suggest internal bleeding and early shock, so the RN escalates at once, gives oxygen and prepares for fluid resuscitation as ordered.

c. The findings suggest paralytic ileus, so the RN keeps the patient fasting and inserts a nasogastric tube.

d. The findings suggest pain from the incision, so the RN repositions the patient and rechecks vital signs in 30 minutes.

Answer: b — After hysterectomy, a rising heart rate, falling blood pressure and a distending abdomen suggest internal bleeding even when the pad is dry, and the RN treats this as possible hypovolemic shock and escalates at once (section 29.3, Hysterectomy and Gynecologic Surgery; sections 6.4 and 7.6). Option a wrongly relies on the pad. Options c and d explain away hemodynamic signs of bleeding and delay escalation.

20. [RN] A 36-year-old patient in Ontario received a positive result on her HPV screening test and asks the RN, "Does this mean I have cervical cancer?" Which response is most accurate?

a. "Yes. A positive HPV test means cancer cells were found, and you will need treatment right away."

b. "No. A positive result never needs any follow-up, because most HPV infections clear on their own."

c. "Not necessarily. It shows a type of HPV that can occasionally lead to cancer; a repeat test or colposcopy may come next."

d. "We can't say yet. You will need a Pap test every year from now on to see whether cancer develops."

Answer: c — In the Ontario program, a positive HPV result shows a high-risk type that can occasionally lead to cervical cancer; it does not mean cancer, and the next step may be a repeat test in 2 years or a colposcopy (section 29.3, Gynecologic Cancers in Brief; Table 29.1). Option a confuses HPV detection with cancer. Option b ignores the need for follow-up. Option d describes a test and interval that the Ontario program no longer uses.

Case: Normand Arsenault (Questions 21–26): Normand Arsenault, 64, arrives at the emergency department at 08:30 with chest pressure that began 40 minutes ago and spreads to his jaw. He has hypertension, type 2 diabetes and a 40-pack-year smoking history. His skin is pale and damp. Heart rate 98, blood pressure 138/84 mm Hg, respiratory rate 20, SpO_2 95% on room air, temperature 36.9 °C, capillary blood glucose 8.4 mmol/L. The triage protocol includes sublingual nitroglycerin for ischemic chest pain. While the nurse completes the medication history, Mr. Arsenault says he took sildenafil at about 22:00 last night.

21. [CORE] Which information should the nurse recognize as cues that need immediate attention? Select all that apply.

a. Chest pressure spreading to the jaw

b. Sildenafil taken about 10 hours ago

c. A triage protocol that includes nitroglycerin

d. Capillary blood glucose of 8.4 mmol/L

e. Pale, damp skin

f. Temperature of 36.9 °C

g. A 40-pack-year smoking history

Answer: a, b, c, e — Chest pressure spreading to the jaw with pale, damp skin suggests possible acute coronary syndrome (a, e). The recent sildenafil dose and the nitroglycerin protocol together create an immediate safety risk, because nitrates combined with a PDE5 inhibitor can cause a severe drop in blood pressure (b, c; section 29.6). A glucose of 8.4 mmol/L in a person with diabetes is not an urgent cue here (d). The temperature is normal (f). The smoking history is a background risk factor, not a cue that changes the immediate plan (g).

22. [CORE] Why does the sildenafil dose matter for Mr. Arsenault's care?

a. Sildenafil lowers the heart rate, so the nurse must check the pulse before any cardiac drug is given.

b. Sildenafil with a nitrate can cause a severe drop in blood pressure, and its monograph does not state when nitrates become safe.

c. Sildenafil commonly causes chest pain as a side effect, so the pain is probably harmless and needs no further tests.

d. Sildenafil raises blood glucose, which explains his capillary result and calls for an insulin correction dose.

Answer: b — The Canadian sildenafil monograph contraindicates all nitrates and states that it is unknown when a nitrate, if needed, can be safely given (b; section 29.6). Sildenafil does not slow the heart rate (a). Chest pain after a PDE5 inhibitor is never assumed to be harmless; it may be cardiac (c). Sildenafil does not explain the glucose result, and no correction dose is indicated (d).

23. [RN] Which hypothesis should the nurse treat as the priority?

a. Possible acute coronary syndrome, with a risk of severe hypotension if a nitrate is given

b. Anxiety about disclosing the sildenafil use, causing chest tightness and a rapid heart rate

c. Indigestion from the sildenafil, which commonly causes upper abdominal and chest discomfort

d. Hyperglycemia from poorly controlled diabetes, which needs correction before the chest pain is assessed

Answer: a — Chest pressure radiating to the jaw with diaphoresis in a person with several cardiac risk factors points to acute coronary syndrome until proven otherwise, and the recent PDE5 inhibitor makes nitrate use dangerous (a; sections 29.6 and Chapter 17). Anxiety and indigestion are possible, but assuming them first could miss a life-threatening problem (b, c). The glucose is only mildly raised and does not take priority (d).

24. [CORE] What should the nurse do first?

a. Give half of the usual nitroglycerin dose and recheck the blood pressure in 5 minutes before deciding on a second dose.

b. Give the nitroglycerin as the protocol directs because more than 6 hours have passed since the sildenafil dose.

c. Hold the nitroglycerin and tell the physician at once that sildenafil was taken at about 22:00 last night.

d. Ask Mr. Arsenault to wait until 24 hours have passed since his sildenafil dose before any chest pain treatment is given.

Answer: c — The nurse holds the nitrate and reports the drug and the timing at once so that the physician can choose another treatment (c; section 29.6). A smaller nitrate dose is still contraindicated (a). No 6-hour window exists, and the sildenafil monograph gives no safe interval (b). Delaying all chest pain treatment is unsafe; other treatments can be ordered (d).

25. [CORE] The physician orders no nitrates. Which plan should the nurse expect while Mr. Arsenault's chest pain is assessed?

a. Continuous cardiac monitoring, a 12-lead ECG and other treatments as ordered, with frequent vital signs

b. Discharge home with advice to stop sildenafil and to see his family doctor about his chest pain within a week

c. A nitroglycerin patch instead of the spray, because the slow release prevents a drop in blood pressure

d. An extra dose of sildenafil to widen the coronary arteries, since it acts on the same pathway as nitrates

Answer: a — Without nitrates, the team still assesses and treats possible acute coronary syndrome with monitoring, an ECG and other ordered drugs (a; section 29.6 and Chapter 17). Discharging a patient with possible ischemic chest pain is unsafe (b). A nitrate patch is still a nitrate and is contraindicated (c). Sildenafil is not a treatment for chest pain, and more would add to the risk (d).

26. [CORE] Mr. Arsenault's tests show no heart attack, and he will follow up with cardiology. Which statement shows that the teaching was effective?

a. "Next time I have chest pain I will use a nitroglycerin spray at home, as long as it has been 12 hours since my pill."

b. "If I get chest pain after taking my erection pill, I'll call 9-1-1 and tell the paramedics what I took and when."

c. "Erection pills only interact with nitroglycerin given by needle, so the spray and tablets are safe for me to use."

d. "I should stop telling health care staff about my erection pills because they are private and not real medications."

Answer: b — The patient calls 9-1-1 for chest pain and tells responders about the PDE5 inhibitor and the time it was taken so a nitrate is not given (b; section 29.6). No 12-hour safe window exists for sildenafil (a). The interaction applies to nitrates in every form (c). PDE5 inhibitors must always be reported as medications (d).

27. [CORE] A 50-year-old patient says she has not had a period for 8 months and asks whether she is "in menopause now." Which response is most accurate?

a. "You are in menopause, because 6 months without a period is enough to confirm it at your age."

b. "Menopause is confirmed only by a blood test of your hormone levels, so you will need to book one with your doctor this week."

c. "You are probably in perimenopause; menopause is confirmed after 12 months in a row with no period and no other cause."

d. "You cannot be in menopause yet, because menopause in Canada does not usually happen until the age of 55 or later."

Answer: c — Menopause is confirmed in hindsight after 12 months in a row with no period and no other cause; until then, she is in the perimenopausal transition (c; section 29.4). Six months is not enough (a). The SOGC definition is clinical and does not depend on a hormone test (b). The average age is 51, usually between 45 and 55 (d).

28. [CORE] A 63-year-old patient admitted for pneumonia mentions vaginal dryness, pain with intercourse and urinary urgency that have worsened over several years. Lubricants have not helped. What should the nurse do?

a. Explain that these are normal effects of aging that cannot be treated and will fade over time.

b. Advise her to start an over-the-counter herbal product for menopause, because natural products work as well as prescriptions.

c. Tell her that vaginal estrogen is unsafe after age 60 and that she should avoid all hormone products.

d. Recognize possible genitourinary syndrome of menopause and suggest she ask her prescriber about treatment options.

Answer: d — Dryness, painful intercourse and urinary urgency after menopause fit genitourinary syndrome of menopause, and The Menopause Society recommends low-dose vaginal estrogen or other local therapies when over-the-counter products fail; it can be used at any age (d; section 29.4). GSM is treatable, and local therapy can continue for as long as needed (a). The SOGC finds no single natural health product supported by evidence (b). The age limit for starting systemic hormone therapy does not apply to low-dose vaginal estrogen (c).

29. [CORE] A patient with a uterus is starting menopausal hormone therapy and asks why she must take a progestogen as well as estrogen. What should the nurse explain?

a. "The progestogen protects the lining of your uterus, which estrogen alone can cause to thicken."

b. "The progestogen makes the estrogen work faster, so your hot flashes will stop within a few days."

c. "The progestogen prevents blood clots, which removes the clotting risk that estrogen carries."

d. "The progestogen is only needed for the first month while your body gets used to the estrogen."

Answer: a — People with a uterus take estrogen with a progestogen (or another protective option) to protect the uterine lining; after a hysterectomy, estrogen can be used on its own (a; section 29.4). A progestogen does not speed symptom relief (b). Adding a progestogen does not remove clotting risk (c). It is taken for as long as estrogen is taken, continuously or in cycles (d).

30. [CORE] A man is being tested for chlamydia and gonorrhea. He reports only vaginal sex and has no symptoms. Which specimen does the nurse expect to collect for nucleic acid amplification testing?

a. A blood sample drawn from a vein, because both infections are diagnosed with serology tests

b. A first-void urine sample, collected from the first part of the urine stream

c. A midstream clean-catch urine sample, collected after cleansing the urethral opening

d. A swab of the throat, because the throat is the most common site of infection in men

Answer: b — For men, NAAT for chlamydia and gonorrhea is done on first-void urine; throat or rectal swabs are added based on the sexual history (b; section 29.5). Serology is used for syphilis, not chlamydia or gonorrhea (a). A midstream sample is used for urine culture, not for chlamydia and gonorrhea NAAT (c). Throat swabs are based on reported practices, not routine for everyone (d).

31. [CORE] A patient has a positive test for gonorrhea. Her symptoms began 3 weeks ago. Which partners should be tested and treated?

a. Only her current partner, because past partners are no longer at risk once the relationship has ended

b. Only partners who have symptoms, because people without symptoms do not spread gonorrhea

c. All partners from the past 12 months, because gonorrhea can stay silent for at least a year

d. All sexual partners from the 60 days before her symptoms began

Answer: d — The national gonorrhea guide calls for testing and treating all sexual partners from the 60 days before symptoms began, or before the test date without symptoms (d; section 29.5). Past partners within that window may be infected (a). Gonorrhea is frequently present without symptoms (b). The 12-month window does not match the guide (c).

32. [CORE] A patient on a medical unit mentions a painless sore on his penis that appeared 2 weeks ago and is now healing. Which response by the nurse is best?

a. "That kind of sore can be a sign of syphilis, even after it heals; I'll tell the team so that you can be tested."

b. "A painless sore that heals by itself is harmless, so there is no need to mention it to your physician."

c. "That sounds like genital herpes, which always causes painless sores, so you will need daily antiviral pills for life."

d. "You should wait to see whether a rash appears on your hands before anyone orders a test."

Answer: a — Primary syphilis often causes a painless sore that heals on its own while the infection continues, so testing is needed (a; section 29.5). Healing does not mean cure (b). Herpes does not always cause painless sores, does not always need lifelong daily treatment, and the diagnosis cannot be assumed without testing (c). Waiting for a secondary-stage rash delays treatment and allows spread (d).

33. [CORE] A patient newly diagnosed with genital herpes says, "I'll just avoid sex when I have sores, so my partner won't catch it." What should the nurse teach?

a. "That's correct; herpes spreads only when sores or blisters are visible."

b. "Your partner must be reported to public health by law, and public health staff will contact them and arrange testing."

c. "Herpes is cured after the first full course of antiviral pills, so after that you can no longer pass it on to any partner."

d. "Herpes can spread without sores, so ask your prescriber about ways to lower the risk, such as daily suppressive therapy."

Answer: d — HSV is often shed without symptoms, so transmission can occur without sores; daily suppressive therapy can reduce transmission (d; section 29.5). Visible sores are not the only risk (a). Partner notification for herpes is not a public health requirement; patients are encouraged to tell partners (b). Herpes is lifelong and not cured by treatment (c).

34. [CORE] A patient is prescribed metronidazole for trichomoniasis. Which instruction is most important to prevent the infection from coming back?

a. Use a vaginal douche daily for one week after finishing the medicine.

b. Repeat the course of metronidazole every month for the next 6 months.

c. Make sure your sexual partner or partners are treated at the same time.

d. Avoid all dairy products while taking the medicine and for 3 days afterward.

Answer: c — Treating partners together with the patient prevents reinfection (c; section 29.5). Douching is not a treatment (a). Monthly repeat courses are not recommended (b). Dairy avoidance is not part of trichomoniasis care (d).

35. [CORE] An RN on a medical unit in an Ontario public hospital holds authorization to prescribe. A patient's urine NAAT is positive for chlamydia, and the RN thinks the patient should start doxycycline. What should the RN do?

a. Write a prescription for doxycycline, because the RN prescribing list includes doxycycline.

b. Report the result to the physician or NP so that treatment can be ordered, and follow any medical directive in place.

c. Ask the RPN to give a dose of doxycycline from ward stock, then obtain the order later in the shift.

d. Tell the patient to buy doxycycline at a pharmacy after discharge, since it is available without a prescription.

Answer: b — RN prescribing does not apply in public hospitals, and the CNO list includes doxycycline only for malaria prevention, not for STBBI treatment, so the RN obtains an order or uses a medical directive (b; section 29.6, Scope in Practice). Prescribing here exceeds the RN's authority (a). Giving a drug without an order is outside every nurse's authority (c). Doxycycline needs a prescription (d).

36. [CORE] A patient in the emergency department says he has had a painful erection for 5 hours after taking a PDE5 inhibitor. What should the nurse do?

a. Recognize priapism as an emergency and notify the physician at once.

b. Ask him to walk around the department, because activity usually ends the erection within an hour.

c. Apply an ice pack, reassure him that the erection will settle on its own, and reassess in 2 hours.

d. Offer a nitroglycerin spray to relax the blood vessels and help the erection subside.

Answer: a — An erection lasting more than 4 hours needs immediate medical care, because delay can damage penile tissue and cause permanent loss of erections (a; section 29.6). Walking or waiting delays treatment (b, c). A nitrate is dangerous after a PDE5 inhibitor (d).

37. [CORE] A transgender woman is admitted for an appendectomy. She takes estradiol and spironolactone. Which actions by the nurse are appropriate? Select all that apply.

a. Ask privately for her name and pronouns and use them consistently.

b. Hold her estradiol on admission, since estrogen must always be stopped before surgery.

c. Ask the surgical team or prescriber for a plan for her hormones around surgery.

d. Share her gender history only with team members who need it for her care.

e. Ask about her past gender-affirming surgeries out of interest during the admission assessment.

f. Give VTE prophylaxis as ordered.

Answer: a, c, d, f — Using the patient's name and pronouns is fundamental to care (a). The nurse obtains a plan from the surgical team or prescriber rather than stopping hormones, because evidence does not show that holding hormones lowers VTE risk (c), protects privacy (d) and gives VTE prophylaxis as ordered (f; section 29.6). Stopping estradiol without an order is not supported (b). Questions are asked only when relevant to care, never out of curiosity (e).

38. [CORE] A 52-year-old man mentions new erectile dysfunction during a pre-operative visit. What is the nurse's best understanding of this finding?

a. ED at this age is a normal part of aging and needs no further follow-up from the health care team.

b. ED means his testosterone level is low, so the nurse should expect a testosterone prescription and hormone blood tests.

c. ED is almost always psychological at his age, so the nurse should refer him to a counsellor and avoid medical tests.

d. ED shares risk factors with heart disease and may be an early warning sign, so his heart health deserves attention.

Answer: d — The CUA notes that ED and cardiovascular disease share risk factors and that ED may be an early signal of later vascular events, and it suggests checking glucose and lipids (d; section 29.6). ED is common with age but still deserves attention (a). Low testosterone is only one possible cause (b). Psychological factors are possible, but the CUA lists many vascular and metabolic risk factors (c).

39. [RN] A 56-year-old patient with severe hot flashes asks about menopausal hormone therapy. Which finding in her history is a contraindication that the nurse should report to the prescriber?

a. A hysterectomy 10 years ago for uterine fibroids

b. Osteopenia found on her last bone density scan

c. A deep vein thrombosis 3 years ago after a long flight

d. Her last menstrual period was 3 years ago

Answer: c — A current or past venous thromboembolism is a contraindication to estrogen in the Canadian monograph (c; section 29.4). After a hysterectomy, estrogen can be used on its own (a). Preventing bone loss is a benefit of MHT, not a contraindication (b). She is under 60 and within 10 years of menopause, the group in which the benefit-risk balance is favourable (d).

40. [RN] A patient is treated with intramuscular ceftriaxone for gonorrhea found on a rectal NAAT and a throat NAAT. Which follow-up plan matches the national guide?

a. No follow-up testing, because ceftriaxone cures every gonorrhea infection when it is given correctly

b. A single repeat urine NAAT 3 days after treatment to confirm cure at all sites

c. A repeat test only if symptoms appear, because rectal and throat infections clear without retesting

d. A test of cure at both the rectum and the throat, by culture at least 3 days or NAAT 3 to 4 weeks or more after treatment

Answer: d — Because N. gonorrhoeae can quickly develop antimicrobial resistance, everyone needs a test of cure at each positive site; culture can be taken at least 3 days after treatment and NAAT should wait 3 to 4 weeks to avoid false positives (d; section 29.5). Treatment failure can occur (a). A urine test does not check the rectum or throat, and NAAT at 3 days may detect leftover genetic material (b). Rectal and throat infections are often silent, so waiting for symptoms is unsafe (c).

VIII Neurologic & Cerebrovascular Nursing Care

UNIT CLINICAL SCOPE & INTEGRATION

Focuses on high-acuity neurologic assessment (Glasgow Coma Scale, cranial nerves, pupillary and motor responses), pathophysiological management of increased intracranial pressure (ICP) and Cushing triad, Canadian Stroke Best Practice Recommendations for acute ischemic and hemorrhagic stroke, traumatic brain injury, spinal cord injury (autonomic dysreflexia), seizures, multiple sclerosis, Parkinson disease, myasthenia gravis, and Guillain–Barré syndrome.

Contents of UNIT VIII

Chapter	Chapter Title	Visual Assets	Page
Chapter 30	Neurologic Assessment and Increased Intracranial Pressure	6 Figs • 4 Tbls	p. 883
Chapter 31	Stroke	6 Figs • 4 Tbls	p. 913
Chapter 32	Traumatic Brain and Spinal Cord Injury and Chronic Neurologic Disorders	6 Figs • 4 Tbls	p. 943

30 Neurologic Assessment and Increased Intracranial Pressure

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Relate the structure and function of the nervous system, cerebral blood flow and cerebrospinal fluid to neurologic assessment findings.
2. Perform a focused neurologic assessment, including the Glasgow Coma Scale, pupils and motor checks, and report change from baseline.
3. Prepare and care for adults having neurologic diagnostic tests, including MRI safety screening and lumbar puncture.
4. Recognize early and late signs of increased intracranial pressure and provide nursing care that protects cerebral perfusion, using the CJMM.
5. Respond safely to seizures and status epilepticus and support adults living with epilepsy.
6. Recognize headache red flags, bacterial meningitis and brain tumours, and provide care after craniotomy.
7. Distinguish RN and RPN roles in neurologic care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5, 6	Clinician; Scholar	Foundations of Practice
2, 5	Educator; Advocate	Foundations of Practice; Ethical Practice
7	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

The brain and spinal cord shape every part of a person's life, from breathing and swallowing to speech, movement, memory and mood. When they are injured or under pressure, the first signs can be small: a patient who needs to be asked twice, a hand that drifts, a pupil that reacts a little more slowly than it did an hour ago. The nurse at the bedside is often the person who sees these changes first. A careful, repeatable neurologic assessment, compared with the patient's own baseline and reported without delay, can mean the difference between a problem found early and a brain injury that cannot be undone.

This chapter is the book's home for the nervous system. Section 30.1 reviews the structures and processes behind neurologic findings: neurons, the regions of the brain, the spinal cord, cerebral blood flow and cerebrospinal fluid. Section 30.2 teaches a focused neurologic assessment, including the Glasgow Coma Scale, pupils, limb strength, speech and how to report change. Section 30.3 covers common neurologic tests and the nursing care around them. The second half of the chapter covers increased intracranial pressure (30.4), seizures and status epilepticus (30.5), and headache red flags, central nervous system infections and brain tumours (30.6).

The chapter builds on earlier ones. Scope of practice for registered nurses (RNs) and registered practical nurses (RPNs) is taught in section 1.3 and the Clinical Judgment Measurement Model (CJMM) in section 1.4. Recognizing deterioration, the SBAR (situation, background, assessment, recommendation) format and rapid response are in Chapter 6, and delirium and dementia are in Chapter 8. Stroke is covered in Chapter 31, and traumatic brain injury, spinal cord injury and chronic neurologic disorders in Chapter 32. In other provinces and territories, practical nurses (PNs) are usually called licensed practical nurses (LPNs); this chapter uses "the nurse" unless the roles differ.

30.1 The Nervous System: A Focused Review

Cells, Brain and Spinal Cord

The basic working unit of the nervous system is the **neuron**, a nerve cell that receives, processes and sends signals. Each neuron has a cell body, branching dendrites that receive messages and a single axon that carries signals onward. Support cells, called glia, surround neurons; some wrap axons in myelin, a fatty layer that lets signals travel faster and farther. Where one neuron meets the next, at the synapse, chemical messengers called neurotransmitters cross a small gap and attach to receptors on the next cell (National Institute of Neurological Disorders and Stroke [NINDS], n.d.-a; Figure 30.1).

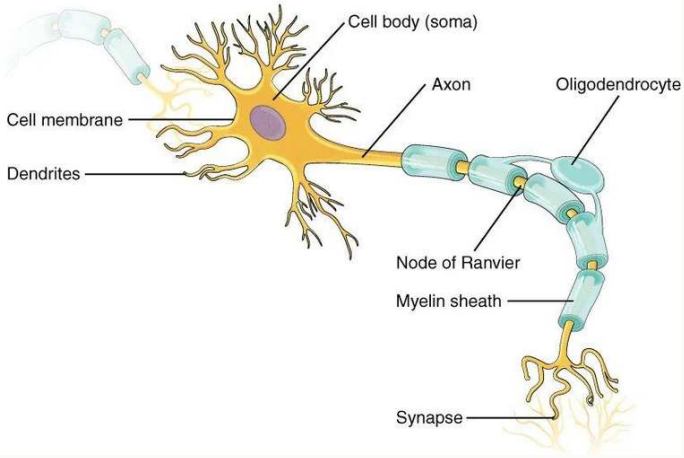

Figure 30.1 Structure of a multipolar neuron in the central nervous system, showing the cell body (soma), dendrites, axon, myelin sheath formed by an oligodendrocyte, nodes of Ranvier and synaptic terminals. (credit: "Figure 12.8, Parts of a Neuron" by J. Gordon Betts et al./OpenStax, Anatomy and Physiology 2e, CC BY-NC-SA 4.0)

The brain and spinal cord form the **central nervous system (CNS)**. The nerves outside them, including the 12 pairs of cranial nerves and the spinal nerves, form the peripheral nervous system. Part of the peripheral system, the autonomic nervous system, runs functions such as breathing and heartbeat that happen without conscious thought (NINDS, n.d.-b).

The **cerebrum** makes up most of the forebrain, the largest part of the brain, and is the source of conscious thought, memory and voluntary action. It has two hemispheres joined by a thick band of fibres, the corpus callosum. Each hemisphere has four lobes (NINDS, n.d.-a): (Figure 30.2)

- **Frontal lobe:** planning, reasoning and judgment; the motor cortex at its back plans and carries out voluntary movement.
- **Parietal lobe:** receives touch, temperature and position sense, and supports reading and arithmetic.
- **Temporal lobe:** hearing and the forming and recalling of memories.
- **Occipital lobe:** processes what the eyes see; damage here can cause loss of vision.

Language depends mainly on the left hemisphere in most people. Because the pathways between the brain and the body cross over, each hemisphere mainly controls the opposite side of the body: a tumour or stroke in the right hemisphere can weaken the left arm and leg (NINDS, n.d.-a). This crossing is why the nurse compares the two sides of the body at every check.

Deep in the brain, the thalamus acts as a relay station for information travelling between the spinal cord and the cerebrum, and the hypothalamus helps regulate emotions and waking (NINDS, n.d.-a). The **brainstem**, made up of the midbrain, pons and medulla, connects the brain to the spinal cord. It controls breathing and heart rate, carries reflex circuits, and helps control eye movements (NINDS, n.d.-a). A network of neurons in the upper brainstem, the ascending reticular activating system, sends signals through the thalamus to the cortex and keeps a person awake and alert (Taran et al., 2023).

This network explains a key idea in neurologic assessment. Consciousness needs both arousal (being awake) and awareness (knowing oneself and one's surroundings). Damage to the arousal network in the brainstem can cause coma, while widespread damage to the cortex or to both sides of the thalamus can leave a person with sleep-wake cycles but little or no awareness (Taran et al., 2023). A falling level of consciousness therefore suggests a problem in the brainstem or in large areas of both hemispheres, which is one reason it is treated as a serious cue.

The **cerebellum**, at the back of the brain below the cerebrum, coordinates movement and helps with learned, skilled actions (NINDS, n.d.-a). Problems here show up as clumsy, poorly aimed movements and an unsteady gait rather than weakness.

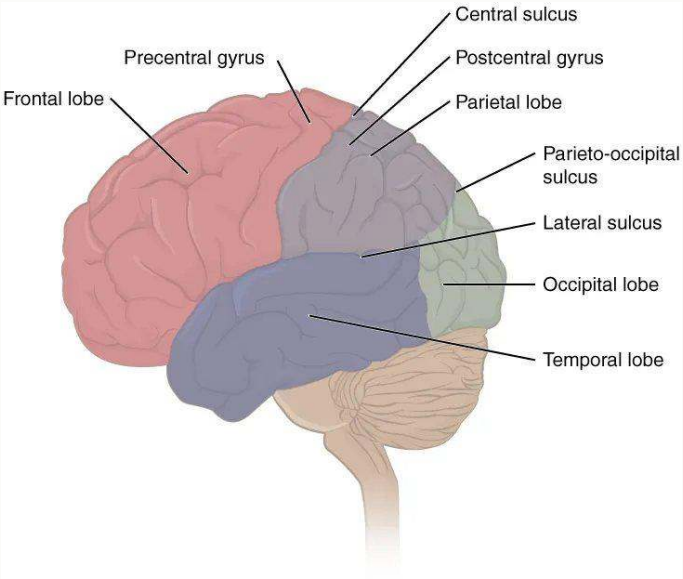

Figure 30.2 Lateral view of the cerebral cortex showing the frontal, parietal, occipital and temporal lobes and major sulci and gyri. (credit: "Figure 13.7, Lobes of the Cerebral Cortex" by J. Gordon Betts et al./OpenStax, Anatomy and Physiology 2e, CC BY-NC-SA 4.0)

The spinal cord carries long axons from the brain down to the nerves that move the body, and carries sensory messages back up (NINDS, n.d.-a). Spinal cord injury is covered in Chapter 32.

Blood Flow, Cerebrospinal Fluid and the Skull

The brain makes up only 2% to 3% of body mass, yet under normal conditions it receives about 15% of the cardiac output and uses about 20% of the body's oxygen (Claassen et al., 2021). Because demand is so high, low oxygen or low blood pressure can harm brain tissue quickly.

Autoregulation is the ability of the brain's blood vessels to widen or narrow so that blood flow stays fairly steady when blood pressure changes. Older teaching described a flat, protected range of mean arterial pressure from about 50 to 150 mm Hg. A major review points out that this curve was built from group averages, and that in individual people the protected range is smaller and depends on how fast pressure changes; sudden swings reach the brain more directly (Claassen et al., 2021). When autoregulation is overwhelmed, low pressure leads to too little flow and ischemia, and severe high pressure pushes flow up (Claassen et al., 2021).

Carbon dioxide also controls cerebral blood flow. A rise in the arterial partial pressure of carbon dioxide ($PaCO_2$) widens cerebral vessels and increases blood flow, by roughly 3% to 6% for each 1 mm Hg rise; a fall in $PaCO_2$ narrows them and reduces flow (Claassen et al., 2021). This link matters for breathing and ventilation in brain injury (section 30.4; Chapter 15).

The **blood–brain barrier** is formed by tightly joined cells that limit which substances can pass from the blood into brain tissue, protecting the brain but also keeping out some drugs (Paszkowycz et al., 2025).

Cerebrospinal fluid (CSF) is a clear fluid that bathes the brain and spinal cord. A typical adult has about 150 mL of CSF at any time, but makes roughly 400 to 600 mL a day, mostly in the choroid plexus, a network of specialized tissue in the brain's fluid-filled chambers (ventricles). CSF flows from the lateral ventricles to the third ventricle, through a narrow channel (the cerebral aqueduct) to the fourth ventricle, and then into the space around the brain and spinal cord. It cushions the brain against shock, makes the brain buoyant and carries away waste. How CSF is absorbed back into the body is still being studied (Paszkowycz et al., 2025). Because production continues all day, anything that blocks flow or absorption can make fluid build up (hydrocephalus, section 30.4).

In an adult, the skull is a rigid, closed box. Brain tissue, blood and CSF share this fixed space, so when one of them grows, for example from swelling, bleeding or a tumour, the others must make room or the pressure inside the skull rises. Section 30.4 explains what happens next.

GOING DEEPER

Cranial Nerves at the Bedside

Required for RN students; optional for PN students.

The 12 pairs of cranial nerves leave the brain and brainstem directly. Each can be checked quickly, comparing the two sides (Larsen & Stensaas, n.d.-a):

- **I Olfactory:** smell; a familiar, non-irritating scent, one nostril at a time.
- **II Optic:** vision; the patient reads print or counts fingers. Nerve II carries the light signal for the pupil reflex; nerve III constricts the pupil.
- **III Oculomotor, IV Trochlear, VI Abducens:** eye movements; the patient follows a finger in all directions; watch whether the eyes move together and ask about double vision. Nerve III also lifts the eyelid, so a new drooping lid or a widening pupil on one

side can mean it is under threat (section 30.4).

- **V Trigeminal:** facial feeling and chewing; touch the forehead, cheek and jaw on both sides; feel the jaw muscles as the patient bites down.
- **VII Facial:** facial movement; the patient wrinkles the forehead, closes the eyes tightly and smiles; look for asymmetry.
- **VIII Vestibulocochlear:** hearing and balance; rub the fingers together beside each ear and compare.
- **IX Glossopharyngeal and X Vagus:** palate and gag reflex; the patient says "ah" while the nurse watches the palate rise evenly.
- **XI Accessory:** shoulder shrug and head turning against resistance.
- **XII Hypoglossal:** the patient sticks out the tongue and moves it side to side; a deviating tongue points toward the weak side.

30.2 Focused Neurologic Assessment

Level of Consciousness and the Glasgow Coma Scale

Level of consciousness describes how awake a person is (arousal) and how well the person understands self and surroundings (awareness). It is the core of every neurologic check. Vague words such as "drowsy" or "lethargic" mean different things to different people, so nurses describe what they see and use a shared scale.

The **Glasgow Coma Scale (GCS)** was described by Graham Teasdale and Bryan Jennett in 1974 to help clinicians communicate about consciousness after acute brain injury, and it is now used for impaired consciousness from many causes (Royal College of Physicians and Surgeons of Glasgow [RCPSG], n.d.-a; Teasdale et al., 2014). It rates three behaviours: eye opening, verbal response and motor response (Table 30.1). The authors' current structured approach has four steps (RCPSG, n.d.-c; Teasdale, 2015):

- **Check:** identify anything that could interfere with the assessment, such as a language difference, hearing loss, a prior neurologic deficit, sedation, a breathing tube or an injury.
- **Observe:** before speaking or touching, watch for spontaneous eye opening, speech and movement on both sides of the body.
- **Stimulate:** if there is no spontaneous response, speak in a normal voice and then a louder one; if there is still no response, apply physical pressure.
- **Rate:** score each component by the best response seen.

Physical stimulation follows a set order. Fingertip pressure on the nail bed is used first, and the finger pressed is changed over time. If a central stimulus is needed, the nurse uses a trapezius pinch at the top of the shoulder or pressure at the supraorbital notch above the eye. The authors advise against routine jaw pressure and strongly discourage rubbing the sternum with the knuckles, which can bruise and gives responses that are hard to interpret (RCPSG, n.d.-c).

Several details make the scale reliable:

- **Obeys commands** requires the patient to carry out a two-part request, such as "Squeeze my fingers, then let go" (Teasdale, 2015).
- **Localising** means the patient brings a hand above the collarbone toward a stimulus on the head or neck (Teasdale, 2015).
- **Orientated** means the patient correctly gives their name, the place and the date (Teasdale, 2015).
- **Not testable (NT):** when a factor prevents a valid rating, such as a breathing tube for the verbal response or swollen eyelids for eye opening, the nurse records "NT", never a score of 1 or 0. A total is not reported when a component is NT, because a falsely low total could mislead the team (RCPSG, n.d.-a; Teasdale, 2015).

The nurse reports the three components, not only the total. Written as E3V4M6, for example, the scores add to 13, but the same total of 8 could describe a patient who is E2V2M4 or one who is E1V1M6, and these patients are very different (RCPSG, n.d.-b). The nurse uses the words with the numbers, for example "opens eyes to voice, confused, obeys commands". The total ranges from 3 to 15, and the components carry more information than the sum (RCPSG, n.d.-a).

Interfering factors are handled rather than ignored. For a patient who speaks another language, the nurse adapts the check by using a professional interpreter (Chapter 2), written communication or, where possible, an assessor who shares the patient's language and

culture. When sedation or a paralyzing drug blocks the assessment, the prescriber may order a planned, brief pause in sedation so that responses can be seen. For a patient with a spinal cord injury who cannot move the hands, the nurse watches eye and tongue movements instead (RCPSG, n.d.-a). Each limitation is written in the record so the next nurse can repeat the check the same way.

Training and a standard method improve agreement between assessors, and nurses and physicians score the scale equally well (RCPSG, n.d.-a). The frequency of checks is set by the order or employer policy and is increased when the patient's condition changes.

Table 30.1 Glasgow Coma Scale components (Glasgow structured approach; original wording) (Teasdale, 2015; RCPSG, n.d.-a, n.d.-c)

Component	Responses from best to worst	Score	Practical tips
Eye opening	Spontaneous: eyes open before any stimulus	4	Watch first, before speaking or touching.
Eye opening	To sound: eyes open after a spoken or shouted request	3	Use a normal voice first, then a louder one.
Eye opening	To pressure: eyes open after fingertip pressure	2	Press the nail bed; change fingers over time.
Eye opening	None: no eye opening at any time, with nothing interfering	1	Record NT, not 1, if swelling or a dressing keeps the eyes closed.
Verbal response	Orientated: correctly states own name, current place and the date	5	Ask open questions, not yes-or-no questions.
Verbal response	Confused: speaks coherently but gets name, place or date wrong	4	Note which items are wrong.
Verbal response	Words: says only single, understandable words	3	Record the words heard.
Verbal response	Sounds: only moans or groans	2	Make sure hearing aids are in and the room is quiet.
Verbal response	None: no sound at all, with nothing interfering	1	Record NT if a breathing tube or other factor prevents speech.
Motor response	Obeys commands: follows a two-part request	6	Ask the patient to squeeze and then let go.
Motor response	Localising: brings a hand above the collarbone toward a stimulus on the head or neck	5	Use a trapezius pinch or supraorbital pressure.
Motor response	Normal flexion: bends the arm at the elbow quickly, moving it away from the body	4	Score the best response of either arm.
Motor response	Abnormal flexion: slow, stereotyped bending with the arm across the chest, forearm turning and thumb clenched	3	Describe the posture in the notes; report at once if new.
Motor response	Extension: straightens the arm at the elbow	2	A new extension response is an emergency.
Motor response	None: no movement of arms or legs, with nothing interfering	1	Record NT if paralysis or sedation prevents testing.

Pupils, Movement and Sensation

Pupil checks are done in dim light. The nurse estimates each pupil's size in millimetres against a pupil gauge, notes its shape, and shines a light into each eye to see whether the pupil constricts briskly, sluggishly or not at all. Manual checks are subjective. In one study of neurocritical care patients, nurses using a penlight and gauge missed half of the cases of unequal pupils (a difference of 1 mm or more) that an automated pupillometer detected, and the two methods disagreed about light reaction in 18% of checks (Couret et al., 2016). Where automated pupillometers are available, policy guides their use.

A **pupillary response** that changes, for example a pupil that becomes larger than the other or reacts sluggishly, is an urgent cue, especially with a falling level of consciousness, because it can signal brain herniation pressing on the brainstem (Couret et al., 2016; section 30.4). The nurse first checks the record for a known baseline difference or eye condition, but does not delay reporting a new finding.

Limb strength is compared side to side. The Medical Research Council scale grades power from 0 (no contraction) through 1 (flicker of contraction), 2 (movement with gravity eliminated), 3 (movement against gravity) and 4 (movement against gravity and resistance) to 5 (normal power). Within grade 4, the subgrades 4−, 4 and 4+ describe slight, moderate or strong resistance overcome (Medical Research Council, 1976). Many units use simpler words, such as "strong", "weak" or "no movement", for each limb.

Subtle one-sided weakness is easy to miss with strength testing alone. **Pronator drift** is a quick screen: the patient holds both arms straight out in front with palms up and eyes closed, and the nurse watches whether one forearm turns palm-down and drifts downward, a sign of a problem in the motor pathway from the brain (Larsen & Stensaas, n.d.-b). In a Canadian study of 170 patients suspected of having mild one-sided brain lesions, arm drift testing (pronator drift and a related straight-arm test) detected 92% of the lesions confirmed by CT, while muscle-by-muscle strength testing detected only 39% (Teitelbaum et al., 2002).

When a patient cannot follow commands, the motor response to pressure gives vital information. **Abnormal flexion** is a slow, stereotyped bending of the arm across the chest, with the forearm turning, the thumb clenched and the leg extending; it differs from normal flexion, a quick withdrawal of the arm away from the body. **Abnormal extension** is a straightening of the arm at the elbow (Teasdale, 2015). These postures show severe brain dysfunction, and extension ranks lower on the GCS than abnormal flexion. Any new posturing is reported at once.

The nurse also checks sensation by touching both arms and legs lightly, asking whether the feeling is the same on each side, and asks about new numbness or tingling. Simple coordination tests, such as touching a finger to the nose, help detect cerebellar problems in a patient who is alert enough to take part.

Speech, Orientation and Cranial Nerve Screening

Orientation to person, place and date is part of the verbal score. The nurse also listens to how the patient speaks. **Aphasia** is a disorder of language, caused by damage to the language areas of the brain; it can affect speaking, understanding, reading and writing (National Institute on Deafness and Other Communication Disorders [NIDCD], n.d.). **Dysarthria** is a disorder of speech caused by weakness or poor control of the muscles used for talking, so speech sounds slurred, slow, soft or mumbled, but the person's language is intact (American Speech-Language-Hearing Association [ASHA], n.d.). A patient with aphasia may seem confused when the real problem is language, so the nurse records the speech problem and treats it as a factor that affects the verbal score (RCPSG, n.d.-a). New aphasia or dysarthria may signal a stroke (Chapter 31). New facial weakness, slurred speech or a wet, gurgly voice also raise concern about safe swallowing; the patient takes nothing by mouth until a swallowing screen is done (Chapter 31) (Figure 30.3).

Recognizing and Reporting Change

A single neurologic check means little on its own. Serial findings are recorded on a neurologic observation chart so that a trend can be seen at a glance (RCPSG, n.d.-b). Their value comes from comparison with the patient's baseline: the findings recorded at the previous check, and the patient's usual state as described by the family or the record. At handover, the outgoing and incoming nurses can check the patient together so that both agree on the starting point.

The GCS authors give no fixed number of points that defines a significant change. They advise the team to weigh the earlier pattern, the starting level, which component changed (a fall in the motor score usually needs a faster response) and whether the change persists or is confirmed by a colleague (RCPSG, n.d.-a). Any decline calls for urgent medical review to look for treatable causes, which may include imaging of the head, usually a computed tomography (CT) scan (RCPSG, n.d.-b).

The nurse also asks what kind of change it is. Delirium (Chapter 8) usually causes fluctuating attention and confusion without a new one-sided sign. A new focal sign, such as pronator drift, one-sided weakness, a new pupil difference or new aphasia, points to a structural problem in the brain. Both need reporting, but a focal sign is an emergency. Low blood glucose can also lower consciousness and cause focal signs; a point-of-care glucose check is part of the response (section 22.4). Late signs of rising pressure inside the skull, such as posturing, a fixed and dilated pupil and the Cushing triad, are covered in section 30.4.

When the nurse finds a decline, the nurse stays with the patient, rechecks the airway, breathing, circulation and glucose, and calls the most responsible provider or the rapid response team using SBAR (Chapter 6). An RPN reports to the RN at the same time but does not wait for the RN to reassess before calling for help when the patient is deteriorating (section 1.3). The record states the time, each GCS component in words and numbers, pupil size and reaction, limb strength on each side, who was told, when and what was done (Chapter 1).

LIFESPAN CONSIDERATIONS

Neurologic Assessment in Older Adults

- **Know the baseline.** Many older adults have some memory loss, hearing loss or slowed movement before admission. The nurse asks family members or caregivers what is usual for the person and records it, so that a new change stands out.
- **Remove barriers to communication.** Hearing loss, a language difference and a prior neurologic deficit can all interfere with the GCS (RCPSG, n.d.-a). The nurse makes sure hearing aids and glasses are in place and uses a professional interpreter when needed.
- **Review medications.** Sedation is a known interfering factor (RCPSG, n.d.-a). New sedating drugs, such as opioids or sleep medicines, are a common reason for drowsiness, but the nurse does not assume a drug is the cause until a structural problem has been considered.
- **Think of delirium.** Older adults are at high risk of delirium, which can mask or mimic other neurologic changes (Chapter 8).
- **Take falls seriously.** A fall in an older adult who takes an anticoagulant is reported promptly even when the person seems well, and neurologic checks follow the order or policy (Chapter 32).

30.3 Neurologic Diagnostics

Table 30.2 summarizes the common neurologic tests and the nursing care before and after each.

Imaging

Computed tomography (CT) uses an X-ray beam that rotates around the body to build cross-sectional images. It is fast and good at showing bleeding, clots, injuries and tumours in the head, which makes it the usual first test when a patient's neurologic status declines suddenly (National Institute of Biomedical Imaging and Bioengineering [NIBIB], n.d.-a; RCPSG, n.d.-b). CT uses ionizing radiation; the cancer risk from a single scan is generally small, but it grows with repeated exposure (NIBIB, n.d.-a).

Iodine-based contrast is injected into a vein to highlight blood vessels and some lesions, as in CT angiography. Some patients react to contrast agents, so the nurse asks about previous reactions (NIBIB, n.d.-a). The Canadian Association of Radiologists advises screening kidney risk with a short questionnaire, not delaying an emergency scan to wait for a creatinine result, considering preventive measures only when the estimated glomerular filtration rate (eGFR) is below 30 mL/min/1.73 m², and holding no medicines routinely except metformin at that eGFR (Macdonald et al., 2022). The nurse follows the local protocol. Catheter angiography, which images vessels by threading a catheter into an artery, is discussed with stroke (Chapter 31).

Magnetic resonance imaging (MRI) uses a strong magnet and radio waves and involves no ionizing radiation. It shows the brain, spinal cord and nerves in much more detail than CT (NIBIB, n.d.-b). The machine is loud, and the patient must lie very still in a

narrow tube, which can be hard for people with claustrophobia or pain; options include preparation, music and, when ordered, sedation (NIBIB, n.d.-b). Gadolinium-based contrast may be given; in people with severe kidney failure on dialysis, some of these agents have been linked to a rare but serious condition called nephrogenic systemic fibrosis (NIBIB, n.d.-b). The magnet is always on, so every person and object entering the scanner room must be screened (see Clinical Safety box).

Electroencephalography

Electroencephalography (EEG) records the brain's electrical activity through small electrodes attached to the scalp. It is a key test in diagnosing epilepsy and can help identify other brain disorders (The Ottawa Hospital, 2021). Before a routine EEG, the patient washes the hair and leaves out conditioners, creams, sprays and gels; eats a normal meal; avoids caffeine on the day of the test; and takes usual medicines unless told otherwise. When sleep is needed during the test, the patient may be asked to sleep less the night before. The recording usually lasts up to an hour; the patient may be asked to breathe deeply or look at a flashing light, which can bring on a seizure in a person with epilepsy, so staff are ready to respond (The Ottawa Hospital, 2021). Ambulatory EEG records for hours or days.

In intensive care, continuous EEG monitoring is recommended to diagnose seizures and status epilepticus that cause no obvious movements, and to judge whether seizure treatment is working; it may also help detect ischemia, assess consciousness during sedation and guide prognosis after cardiac arrest (Herman et al., 2015). Seizures and their care are covered in section 30.5.

Lumbar Puncture

A **lumbar puncture (LP)** is a procedure in which a thin needle is passed between two vertebrae in the lower back into the space that holds CSF. The CSF pressure is measured and fluid is collected for tests that look for infection, bleeding or abnormal cells; less often, fluid is removed to lower high pressure (Brain & Spine Foundation, 2022; Figure 30.4).

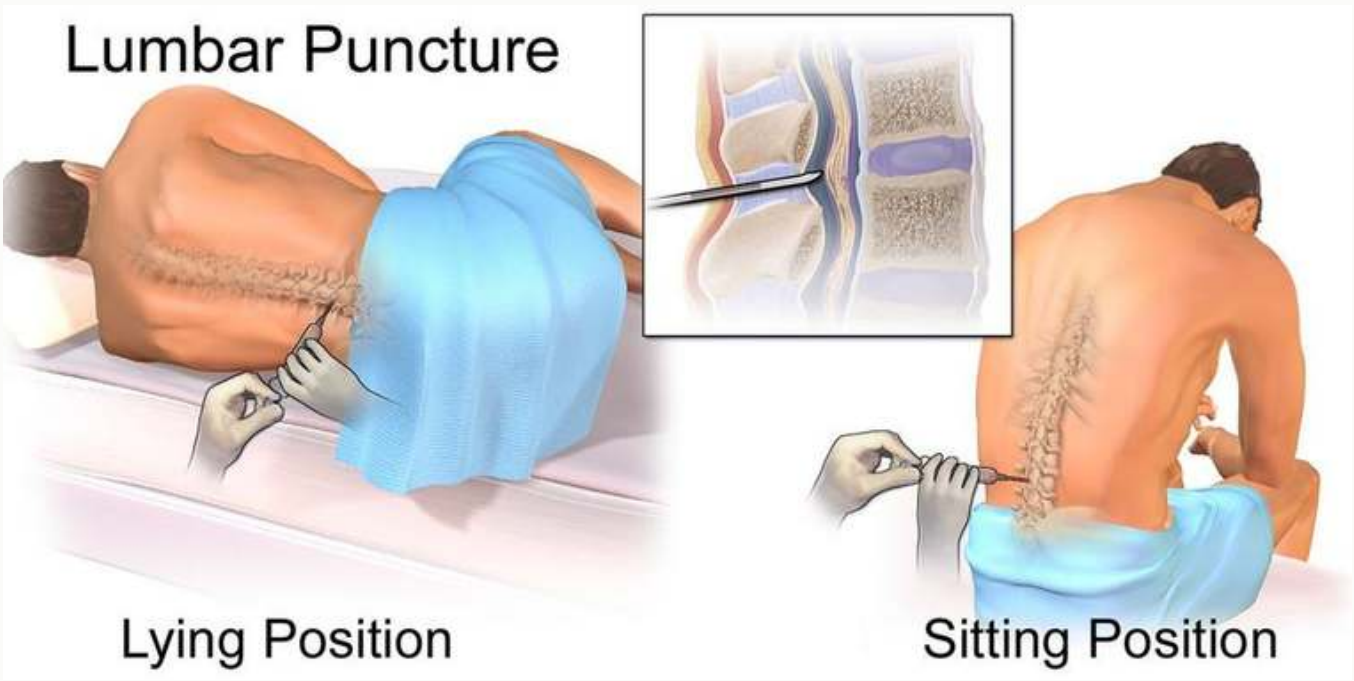

Figure 30.4 Lateral recumbent and seated positions for lumbar puncture, flexing the lumbar spine to widen the interspinous space for needle entry into the subarachnoid space. (credit: “Blausen 0617 LumbarPuncture” by BruceBlaus/Wikimedia Commons, CC BY 3.0)

When pressure inside the skull may be high or a mass may be present, removing CSF from below can be dangerous, so a head CT is done first. For adults with suspected bacterial meningitis, the Infectious Diseases Society of America (IDSA) recommends CT before LP for patients with features linked to abnormal head CT findings: age 60 years or older, a history of central nervous system disease, a weakened immune system, a seizure in the week before presentation, or abnormal neurologic findings such as a reduced level of consciousness, arm or leg drift, or abnormal language. In these patients, blood cultures are drawn and antibiotics are started before

the CT, so that imaging does not delay treatment (Tunkel et al., 2004; section 30.6). The nurse also tells the team if the patient takes an anticoagulant (Brain & Spine Foundation, 2022), and the prescriber decides whether to hold it.

Before the test, the nurse confirms consent (Chapter 1), explains what will happen and helps the patient into position: lying on one side, curled with knees drawn to the chest and the back at the edge of the bed, or sitting and leaning forward so that the back curves outward (Brain & Spine Foundation, 2022). During the test, the nurse supports the position, offers reassurance and watches the patient's response. A sudden sharp pain down a leg can occur if the needle touches a nerve; the clinician adjusts the needle (Brain & Spine Foundation, 2022). The nurse labels the CSF tubes in order and sends them promptly.

Afterward, the nurse checks the puncture site, vital signs and neurologic status. Routines such as lying flat for a time vary between facilities; the nurse follows the order and local policy. The most common problem is **post–dural puncture headache**, which begins within 5 days, is caused by CSF leaking through the puncture and usually comes with neck stiffness or hearing symptoms. It is usually worse when sitting or standing and better lying down, and it usually settles within 2 weeks or after an epidural blood patch seals the leak (Headache Classification Committee of the International Headache Society, 2018). Up to 35% of patients may develop this headache. A Canadian-led clinical practice guideline strongly recommends atraumatic (pencil-point) needles, which cut the risk by more than half compared with conventional needles without making the test less likely to succeed (Rochwerg et al., 2018). Patients are taught to report a headache that persists or comes with vomiting, fever or new neurologic symptoms.

Table 30.2 Neurologic tests and nursing care (NIBIB, n.d.-a, n.d.-b; Macdonald et al., 2022; Mhatre, n.d.; The Ottawa Hospital, 2021; Herman et al., 2015; Tunkel et al., 2004; Brain & Spine Foundation, 2022)

Test	What it shows	Before	After
CT of the head	Bleeding, clots, injury, swelling and tumours; fast in emergencies	Ask about pregnancy when relevant; keep the patient safe and monitored during transfer	Resume neurologic checks; report results as they arrive
CT with iodine-based contrast or CT angiography	Blood vessels and some lesions	Ask about past contrast reactions; complete the kidney risk questionnaire; follow the protocol for metformin when eGFR is below 30	Watch for delayed reactions; follow the local protocol
MRI of the brain or spine	Detailed images of brain, spinal cord and nerves	Complete the MRI safety screen; remove all metal and medication patches as directed; prepare for noise and confined space	Check that devices removed or reprogrammed for the scan are restored as directed
Routine EEG	Electrical activity; seizure patterns	Clean hair without products; regular meal; no caffeine; usual medicines unless told otherwise; less sleep if ordered	Wash out electrode paste; watch for drowsiness if a sedative was given
Continuous EEG	Seizures without movements; response to treatment	Explain the purpose to patient and family; protect the scalp and electrodes	Check the skin under electrodes; report events and seizures promptly
Lumbar puncture	CSF pressure; infection, bleeding or abnormal cells	Confirm consent; report anticoagulant use; ensure CT first when criteria apply; position the patient	Check the site, vital signs and neurologic status; teach about post–dural puncture headache

CLINICAL SAFETY

Screening Before MRI

The MRI magnet is always on. Metal objects can be pulled into the scanner as dangerous projectiles, and heating from the scanner can cause burns, among the most common MRI injuries. Careful screening prevents both (Mhatre, n.d.).

- Screen before every MRI, even if a previous scan went well. Every question on the form is answered, and every "yes" is explained.
- A nurse may complete the first screening form; trained MRI staff review it and do a final check before the scan.
- For a patient who cannot answer, ask a family member or substitute decision-maker, review the chart and imaging, and look for scars from implanted devices; X-rays may be needed when no reliable history exists.

- Record the type, make and model of any implant or device. An "MR Conditional" device is safe only under the conditions its maker specifies.
- Ask about past injuries with metal fragments, especially near the eyes.
- Remove jewellery, phones, external pumps and devices, and medication patches with metal as directed; dress the patient in a gown with no metal.
- Take only equipment labelled MR Safe or MR Conditional into the scanner room; ordinary metal oxygen tanks, monitors and pumps can become projectiles.

30.4 Increased Intracranial Pressure

Intracranial pressure (ICP) is the pressure inside the skull. A rise in ICP is one of the most dangerous problems in neurologic care, because it can reduce blood flow to the brain and push brain tissue out of place. Many conditions in this chapter and in Chapters 31 and 32 share this final pathway. This section explains why ICP rises, how the nurse recognizes the rise early, and which nursing measures protect the brain while the team treats the cause.

What Raises ICP

In an adult, the skull is a closed, rigid box. It holds three things: brain tissue, blood and cerebrospinal fluid (CSF; section 30.1). Because the box cannot expand, the total volume of these three stays the same (Wilson, 2016). When something new takes up space, such as a blood clot or a growing tumour, the body first makes room by moving CSF out of the skull and then by pushing venous blood out of the head. While this buffer lasts, the pressure changes very little. Once it is used up, even a small added volume makes the pressure climb steeply (Wilson, 2016). This explains why a patient can look stable for hours and then deteriorate within minutes.

Common causes of raised ICP include:

- **Bleeding:** a hemorrhage in or around the brain, including bleeding after surgery (Chapters 31 and 32).
- **Swelling: Cerebral edema** is swelling of brain tissue. It can surround a tumour or an abscess or accompany some infections (Bhalla et al., 2024), and it can follow a brain injury or a stroke (Chapters 31 and 32).
- **Tumours:** a growing mass plus the edema around it (section 30.6).
- **Hydrocephalus: Hydrocephalus** is a buildup of CSF in the ventricles. In obstructive hydrocephalus, something blocks the flow of CSF, and the ventricles enlarge (Bhalla et al., 2024).
- **Infection:** meningitis, encephalitis or a brain abscess (section 30.6).

The brain needs a steady supply of oxygen and glucose. **Cerebral perfusion pressure** (CPP) is the pressure that drives blood into the brain. In plain terms, it is the blood pressure pushing blood in minus the pressure inside the skull pushing back. When ICP rises, or when blood pressure falls, CPP drops and parts of the brain may not get enough blood. Section 30.1 described autoregulation, which keeps blood flow fairly steady as blood pressure changes. That protection works only within limits, and when it fails on the low-pressure side the result is poor perfusion and possible ischemia (Claassen et al., 2021). The calculation for CPP appears in the Going Deeper box at the end of this section.

Carbon dioxide also matters. A rise in the blood level of carbon dioxide widens brain blood vessels and increases blood flow; a fall narrows them and reduces flow (Claassen et al., 2021). In a tight skull, extra blood volume raises the pressure, while too little flow starves the tissue. For this reason, the team manages breathing and ventilation with care (Chapter 15).

Recognizing Rising ICP and Herniation

The nurse's most useful tool is a careful neurologic assessment, repeated as ordered and compared with the patient's own baseline (section 30.2). Early signs are often subtle and easy to blame on something else.

Raised ICP can cause headache, nausea and vomiting, pupil changes and a change in mental status (Bhalla et al., 2024). The first change is often in level of consciousness. The patient becomes restless or irritable, answers more slowly, is newly confused, or is harder to wake. A family member may say, "She isn't herself." In a patient at risk, the nurse treats new restlessness as a possible

neurologic cue, completes a neurologic assessment before giving any sedative, which could mask further change, and reports the finding.

As pressure rises further, the Glasgow Coma Scale (GCS) score falls, a pupil may enlarge and react slowly or not at all, and abnormal flexion or extension posturing may appear (section 30.2). The **Cushing triad** is a combination of high blood pressure, a slow heart rate and an irregular breathing pattern or apnea. All three together are uncommon and often appear late (Bhalla et al., 2024). The nurse never waits for the triad before acting.

Herniation is the displacement of brain tissue, under pressure, from one compartment of the skull into another or down through the opening at the base of the skull. It can occur under the fold between the two hemispheres, across the tentorium (uncal herniation) or through the foramen magnum (tonsillar herniation) (Bhalla et al., 2024). In uncal herniation, consciousness drops suddenly, the pupil on the same side as the lesion dilates, and weakness appears on the opposite side of the body (Bhalla et al., 2024). Herniation is an emergency. The nurse calls for immediate help through the hospital's process (Chapter 6), stays with the patient, supports the airway and breathing, and prepares for urgent imaging and treatment. Table 30.3 groups early and late signs with the nursing response (Figure 30.5).

Figure 30.5 Non-contrast head CT showing an acute left-sided subdural hematoma (solid arrows) with mass effect, ventricular compression and midline shift to the right (open arrows). (credit: “Trauma subdural arrows” by Glitzy queen00/Wikimedia Commons, Public domain)

Table 30.3 Early and late signs of increased intracranial pressure and the nursing response (Bhalla et al., 2024; sections 30.2 and 30.4)

Area assessed	Early signs	Late signs	Nursing action
Level of consciousness	Restlessness, irritability, slower answers, new confusion, drowsiness	Falling GCS score; responds only to pressure or not at all	Compare with baseline; report any decline at once; do not sedate before assessing
Pupils	Subtle change in size or a slightly slower reaction on one side	One pupil dilated and sluggish or fixed; both pupils fixed	Treat a new unequal or sluggish pupil as urgent; escalate immediately
Movement	New weakness or pronator drift on one side	Abnormal flexion or extension posturing; no movement	Check both sides each time; describe exactly what is seen
Vital signs	May be unchanged early	High blood pressure, slow heart rate, irregular breathing or apnea (Cushing triad)	Do not wait for these signs; call for immediate help if they appear
Other	New or worsening headache; nausea or vomiting	Seizures; airway at risk as consciousness falls	Protect the airway; report vomiting and headache; follow seizure care (section 30.5)

Nursing Care

Nursing care aims to keep oxygen and blood flowing to the brain and to avoid anything that pushes ICP higher while the team treats the cause. The measures below follow the Neurocritical Care Society's basic measures for anyone at risk of raised ICP (Bhalla et al., 2024) and an international consensus algorithm for severe traumatic brain injury (Hawryluk et al., 2019). The patient's own orders always guide care.

Figure 30.6 An external ventricular drain (EVD) system mounted on a bedside pole with the pressure transducer levelled at the external auditory meatus and blood-tinged cerebrospinal fluid in the collection chamber. (credit: "EVD-ICH" by Rmosler2100/Wikimedia Commons, CC BY-SA 3.0)

- **Position:** The Neurocritical Care Society protocol advises raising the head of the bed above 30° and keeping the head in the midline to help venous blood drain from the head (Bhalla et al., 2024). The nurse avoids sharp bending or turning of the neck and checks that collars, tube ties and dressings do not press on the neck. Some patients need a different position, so the nurse follows the order (Figure 30.6).
- **Oxygen and breathing:** The nurse keeps oxygen saturation (SpO_2) above 94% (Bhalla et al., 2024), protects the airway and reports noisy or irregular breathing. Deliberate fast breathing to lower carbon dioxide is used only briefly, as a bridge ordered by the team, because prolonged use may worsen ischemia (Bhalla et al., 2024).
- **Blood pressure:** Low blood pressure lowers CPP, so the nurse reports hypotension promptly.
- **Temperature:** Fever increases the brain's demands. The aim is a normal temperature (Bhalla et al., 2024), and the severe brain injury algorithm defines fever to avoid as a core temperature above 38 °C (Hawryluk et al., 2019).
- **Sodium and glucose:** The protocol calls for correcting low sodium (Bhalla et al., 2024; section 3.4). The nurse watches sodium and glucose results as ordered and reports values outside the ranges the team has set; low glucose is managed as described in section 22.4.
- **Comfort and calm:** The protocol advises keeping painful or distressing stimuli to a minimum and giving analgesia and sedation as ordered (Bhalla et al., 2024). The nurse plans care so that the patient has rest periods, keeps the room quiet and explains each step.
- **Avoiding strain:** The nurse helps the patient avoid straining, gives stool softeners as ordered and reports constipation.
- **Seizures:** The nurse gives antiseizure medicines on time as ordered and reports any seizure activity (section 30.5).
- **Osmotherapy: Osmotherapy** is the use of a concentrated solution to draw water out of brain tissue into the bloodstream and lower ICP. Mannitol and hypertonic saline are described as equally effective, and both depend on an intact blood–brain barrier (Bhalla et al., 2024). The nurse gives them as ordered or per protocol and monitors the laboratory values the order sets (Table 30.4). Corticosteroids are reserved for edema around tumours, abscesses and certain infections and are otherwise avoided (Bhalla et al., 2024); routine steroids are not recommended for severe traumatic brain injury (Hawryluk et al., 2019).
- **Escalation:** Any decline in level of consciousness, a new pupil change or new weakness is reported at once using SBAR (Chapter 6). The Neurocritical Care Society suggests that handovers include the patient's worst, best and current neurologic examination, the steps taken and the response (Bhalla et al., 2024).

Families are often the first to notice that something has changed. The nurse explains why the head of the bed stays raised, why checks continue through the night, and why the patient should avoid straining. The nurse asks the family to report any change in alertness, speech or behaviour, however small. For older adults, the family's description of the person's usual thinking, hearing and vision helps the nurse set an accurate baseline (section 30.2). An older adult who takes an anticoagulant and has a fall needs prompt assessment as the employer's policy directs (Chapter 32). When the patient moves to another unit or goes home, the nurse hands over the latest neurologic findings and the warning signs the patient and family should watch for.

GOING DEEPER

ICP Monitoring and External Ventricular Drains

Required for RN students; optional for PN students.

In critical care, ICP can be measured with a monitor placed in the brain or a ventricle. CPP is calculated as mean arterial pressure (MAP) minus ICP: a MAP of 80 mm Hg and an ICP of 25 mm Hg give a CPP of 55 mm Hg.

- **Thresholds:** The Brain Trauma Foundation's fourth edition, a guideline for severe traumatic brain injury, recommends treating ICP above 22 mm Hg (Carney et al., 2017). The Neurocritical Care Society defines adult intracranial hypertension as ICP above 22 mm Hg for more than 5 minutes and gives a CPP target of 60 to 70 mm Hg (Bhalla et al., 2024). These numbers come from brain injury research; for other conditions, the team sets the targets.
- **External ventricular drain:** An **external ventricular drain** (EVD) is a catheter placed through the skull into a ventricle that measures ICP and drains CSF into a closed system. It is used to treat raised ICP (Hawryluk et al., 2019) and obstructive hydrocephalus (Bhalla et al., 2024).
- **Nursing care:** The drain is levelled and set at the height that the neurosurgical order and employer policy specify, re-levelled whenever the patient's position changes, and clamped only as ordered or as policy allows. The nurse records CSF volume, colour and clarity and reports sudden changes.
- **Infection:** CSF infection is a recognized complication of an EVD (Fried et al., 2016), so the nurse handles the system only as policy allows and uses aseptic technique.

CLINICAL JUDGMENT

Restless After Surgery

Names and details are fictional; this is a composite story.

Lorraine Bouchard, 63, is on a neurosurgery unit on day 2 after removal of a brain metastasis from her right frontal lobe. At 02:00 the RPN caring for her finds her trying to climb out of bed and pulling at her intravenous (IV) line. At 22:00 her GCS score was 15, her pupils were equal and brisk, and she had no drift. She is on dexamethasone and levetiracetam.

- **Recognize cues:** She is restless and says her head "is pounding." She vomited once. Her GCS score is now 14 because she is confused about the date. Her pupils are equal and brisk, and she has no drift. Blood pressure is 158/88 mm Hg, up from 132/76; heart rate is 84. The head of her bed has slid down to about 15°.
- **Analyze cues:** The RPN considers delirium (Chapter 8), pain, a full bladder, low sodium and high glucose from dexamethasone (Table 30.4). New confusion with headache and vomiting after brain surgery could also mean rising ICP.
- **Prioritize hypotheses:** Rising ICP from postoperative edema or bleeding is the most dangerous possibility and must be ruled out first.
- **Generate solutions:** Hold the as-needed sedative, raise the head of the bed as ordered, check capillary glucose, recheck the neurologic assessment within minutes, and involve the RN and the neurosurgery resident.
- **Take action:** The RPN raises the head of the bed to the ordered 30°, keeps her head midline and calls the RN to the bedside. Capillary glucose is 9.2 mmol/L. The RN calls the resident using SBAR. The resident orders an urgent CT scan, sodium and glucose levels, and neurologic checks every 15 minutes.
- **Evaluate outcomes:** The CT shows more edema but no new bleeding. After the dexamethasone order is changed, her headache eases, and by 06:00 her GCS score is 15.

30.5 Seizures and Status Epilepticus

Seizures and Epilepsy

A **seizure** is a short-lived event of signs or symptoms caused by abnormal, excessive or synchronized electrical activity of neurons in the brain (Fisher et al., 2014). A seizure is a symptom, not a diagnosis. **Epilepsy** is a brain disease marked by a lasting tendency to have seizures. The International League Against Epilepsy (ILAE) diagnoses epilepsy when a person has two unprovoked seizures more than 24 hours apart, or one unprovoked seizure and a high chance of more (at least 60% over the next 10 years), or a recognized epilepsy syndrome (Fisher et al., 2014). A **provoked seizure**, also called an acute symptomatic seizure, is caused by a temporary problem acting on an otherwise normal brain, such as a concussion, a fever or alcohol withdrawal. A provoked seizure does not on its own count toward a diagnosis of epilepsy (Fisher et al., 2014).

The ILAE updated its seizure classification in 2025, building on its 2017 framework. The update keeps four classes (Beniczky et al., 2025):

- **Focal:** A **focal seizure** starts in networks limited to one hemisphere. Focal seizures are further described by whether consciousness, meaning both awareness and responsiveness, is preserved or impaired.
- **Generalized:** A **generalized seizure** starts in networks spread across both hemispheres. Examples are absence seizures and generalized tonic-clonic seizures.
- **Unknown:** The information available is not enough to say whether the seizure was focal or generalized.
- **Unclassified:** No information is available to describe the seizure, but the clinician is confident it was epileptic.

A **tonic-clonic seizure** has a stiffening (tonic) phase followed by rhythmic jerking (clonic) of the limbs. It may be generalized from the start, or it may begin as a focal seizure that spreads to both hemispheres, called a focal-to-bilateral tonic-clonic seizure (Beniczky et al., 2025). The update also asks clinicians to describe signs in the order they appeared, not just the first sign (Beniczky et al., 2025). The nurse's careful description of what happened first, and what followed, therefore helps the team classify the seizure.

Seizures in hospital have many possible causes. Stopping an antiseizure medicine abruptly can increase seizure frequency (BGP Pharma, 2023), so the nurse treats missed or vomited doses as a possible trigger. Low blood glucose (section 22.4) and alcohol withdrawal (Chapter 11) are possible causes of prolonged seizures (National Institute for Health and Care Excellence [NICE], 2022). Other causes include low sodium (section 3.4), brain tumours (National Cancer Institute, n.d.), encephalitis (Tunkel et al., 2008) and injury to the brain (Fisher et al., 2014). The nurse looks for a cause the team can correct and asks people with epilepsy about their own triggers, such as lack of sleep.

Care During and After a Seizure

Most seizures stop on their own within seconds to a few minutes (Epilepsy Ontario, 2018). The nurse's role during a seizure is to stay with the patient, keep the patient safe and observe closely. Epilepsy Ontario's first aid advice, adapted to the hospital, is:

- **Stay and call:** Stay calm and with the patient, and call for help with the call bell or the unit's emergency process.
- **Time it:** Note the time the seizure started and the time it ended (Epilepsy Ontario, 2018).
- **Make the space safe:** Move hard or sharp objects away, cushion the head and lower the bed. Once the jerking eases, turn the patient onto the side so that saliva can drain (Epilepsy Ontario, 2018).
- **Nothing in the mouth, no restraint:** Never place anything in the mouth, including a tongue blade or a finger, and never hold the person down (Epilepsy Ontario, 2018).
- **Oxygen and suction:** Give oxygen and suction the mouth as employer policy and the patient's orders direct.
- **Watch for emergency cues:** Epilepsy Ontario advises calling for emergency help when a seizure lasts more than 5 minutes, when seizures repeat without full recovery in between, when consciousness or normal breathing does not return, or when the person is injured, pregnant or has diabetes (Epilepsy Ontario, 2018). In hospital, the nurse activates the rapid response or code process (Chapter 6).

During the seizure, the nurse observes and later records the details: what the patient was doing beforehand; any warning the patient describes; where the movements started and how they spread; the eyes and head; skin colour; breathing; incontinence or tongue biting; and how long the seizure lasted. Colour changes such as cyanosis can be harder to see on darker skin (Chapter 12), so the nurse also looks at the lips and inside the mouth and checks SpO_2.

The **post-ictal state** is the recovery period after a seizure. The patient may be drowsy or confused for a time and may not recall the seizure. The nurse keeps the patient on the side, checks vital signs, SpO_2 and capillary glucose, completes a neurologic assessment and looks for injury. The nurse stays until the patient is fully aware again and offers calm reassurance (Epilepsy Ontario, 2018). A patient who does not wake as expected, or who has new weakness, needs prompt reassessment by the team. **Seizure precautions** are the safety measures the employer's policy sets for patients at risk, such as a low bed, suction and oxygen ready at the bedside, and IV access.

Status Epilepticus

Status epilepticus is a seizure that lasts too long, or seizures that follow one another without recovery, because the mechanisms that normally stop a seizure have failed (Trinka et al., 2015). For a convulsive (tonic-clonic) seizure, the ILAE defines two time points. After 5 minutes, the seizure is treated as continuous seizure activity that is unlikely to stop on its own. After 30 minutes, it carries a risk of long-term harm to the brain. The authors note that the evidence behind these times is incomplete (Trinka et al., 2015).

This chapter uses the American Epilepsy Society (AES) guideline (Glauser et al., 2016) for treatment timing. The guideline divides care into phases:

- **Stabilization (0 to 5 minutes):** standard initial first aid for seizures.
- **Initial therapy (from 5 minutes):** a benzodiazepine, such as intramuscular midazolam, intravenous lorazepam or intravenous diazepam.
- **Second therapy (from 20 minutes):** if the seizure continues, an intravenous second-line medicine, such as fosphenytoin, valproic acid or levetiracetam.
- **Third therapy (from 40 minutes):** further medicines or anesthetic drugs, with continuous electroencephalography (EEG), in critical care.

Medicines are given as ordered or per protocol. A UK guideline also advises a second benzodiazepine dose when the seizure has not stopped 5 to 10 minutes after the first, and asks clinicians to consider causes such as low blood glucose and alcohol withdrawal (NICE, 2022). The nurse checks capillary glucose as soon as it can be done safely and treats a low value per protocol (section 22.4). The nurse calls for help early, before the 5-minute mark if the patient is struggling to breathe or is injured. Benzodiazepines can cause dangerous respiratory depression, so equipment to support the airway and breathing is kept ready, and after a dose the nurse watches breathing, SpO_2 and level of consciousness closely (Sandoz Canada, 2022).

Living With Epilepsy

Many people with epilepsy live full lives with good seizure control. The nurse supports this goal in several ways:

- **Taking medicines as prescribed:** The phenytoin monograph warns that stopping an antiseizure medicine suddenly can increase seizures, including status epilepticus, and that changes should be made gradually under a prescriber's direction (BGP Pharma, 2023). On admission, the nurse confirms each antiseizure medicine, the dose and the timing, and makes sure doses are not missed when the patient cannot take anything by mouth.
- **Drug levels and interactions:** For phenytoin, the monograph states that the effective serum level is usually 40 to 80 µmol/L, that early signs of toxicity are involuntary eye movements (nystagmus), unsteadiness and slurred speech, and that many drugs raise or lower phenytoin levels (BGP Pharma, 2023). The nurse reports these signs, and the pharmacist reviews new medicines for interactions (Table 30.4).
- **Mood:** Antiseizure medicines can raise the chance of suicidal thinking and behaviour, so every patient taking them is monitored (BGP Pharma, 2023). The nurse asks about mood and provides crisis resources.
- **Driving:** In Ontario, physicians and nurse practitioners must report patients with certain high-risk medical conditions to the Ministry of Transportation under the *Highway Traffic Act* (Government of Ontario, 2026). For seizures, the main concern is that the driver could suddenly become incapacitated. The ministry reviews each report against national medical standards and may suspend a licence (Ministry of Transportation, 2019). The nurse teaches the patient not to drive until the prescriber and the ministry say it is safe. Each province and territory sets its own driver fitness policies, and only some make reporting by health professionals mandatory (Canadian Council of Motor Transport Administrators [CCMTA], 2021).
- **Safety and stigma:** The nurse asks about safety at home and work, helps the patient plan for seizures, and links the patient to Epilepsy Ontario or a local epilepsy agency. Epilepsy still carries stigma; the nurse uses person-first language, such as "a person with epilepsy."

Table 30.4 Medicines for seizures and raised intracranial pressure (Canadian product monographs and sources cited)

Drug or class	Canadian examples	Used for	Nursing points

Drug or class	Canadian examples	Used for	Nursing points
Benzodiazepines	lorazepam, midazolam, diazepam	First treatment for status epilepticus (Glauser et al., 2016)	Give as ordered or per protocol; record the time; watch breathing, SpO_2 and level of consciousness; have airway equipment ready (Sandoz Canada, 2022)
Antiseizure medicines	levetiracetam, phenytoin, fosphenytoin, valproic acid, lacosamide, carbamazepine	Second-line treatment of status epilepticus (levetiracetam, fosphenytoin, valproic acid); long-term seizure control	Give on time; do not stop suddenly; for phenytoin, levels as ordered (usually 40 to 80 µmol/L), report nystagmus, unsteadiness or slurred speech, teach good dental hygiene; monitor mood (BGP Pharma, 2023)
Osmotherapy	mannitol, hypertonic saline	Lowering ICP (Bhalla et al., 2024)	Give as ordered or per protocol; for hypertonic saline, check sodium as ordered (the protocol suggests every 4 to 6 hours); for mannitol, follow the osmolality or osmolar gap results the order sets; report results outside the set limits
Corticosteroid	dexamethasone	Edema around brain tumours; adjunct in some bacterial meningitis	Monitor glucose (may unmask diabetes or raise insulin needs); watch for signs of infection, which steroids can mask, and mood change; do not stop suddenly (Sandoz Canada, 2026)

CANADIAN CONTEXT

Epilepsy in Canada

The Public Health Agency of Canada (PHAC) tracks epilepsy through the Canadian Chronic Disease Surveillance System. In 2021–2022, almost 1 in 100 Canadians were living with epilepsy: 13% were children and youth aged 1 to 19, 63% were adults aged 20 to 64, and 24% were older adults aged 65 and older. New cases were most frequent in older adults, at 87 per 100,000, compared with 51 per 100,000 adults aged 20 to 64 and 66 per 100,000 children and youth. After adjustment for population aging, the share of Canadians living with epilepsy rose by about 2% a year, from 0.78% in 2011–2012 to 0.95% in 2021–2022. The data do not include Quebec or the Northwest Territories, and PHAC advises caution with 2021–2022 figures because of the COVID-19 pandemic (PHAC, 2024).

Care is not equally easy to reach. In the Kivalliq region of Nunavut, for example, EEG is not available locally, and treating prolonged seizures beyond first- and second-line medicines can mean air transfer more than a thousand kilometres away (Ng, 2024). Ng notes that local epilepsy care falls short of what is recommended and names the lasting effects of cultural and socioeconomic trauma as part of the challenge. Losing a driver's licence after a seizure can make travel to appointments harder. The nurse asks how the patient will reach follow-up care and connects the patient with virtual care and community epilepsy agencies where they are available.

30.6 Headache, Central Nervous System Infections and Brain Tumours

Headache Red Flags

Most headaches are primary headaches, such as migraine or tension-type headache. Only a minority are secondary headaches, caused by another condition (Do et al., 2019). The nurse's task is to notice the features that suggest a dangerous cause and to report them. One widely used list, called SNNOOP10, names these red flags (Do et al., 2019):

- **Systemic symptoms,** including fever.
- **Neoplasm** (cancer) in the person's history.
- **Neurologic deficit,** including decreased consciousness.
- **Onset that is sudden or abrupt.** A **thunderclap headache** is a severe headache that reaches its peak almost at once; it can signal bleeding around the brain and needs emergency assessment (Chapter 31).
- **Older age,** with headache that begins after age 65.
- **A change in pattern** or a recent new headache.

- **Position** that changes the headache, or headache **precipitated** by sneezing, coughing or exercise.
- **Papilledema,** a swelling of the optic disc seen on eye examination.
- **Progressive** headache or an unusual presentation.
- **Pregnancy** or the period after giving birth.
- **A painful eye** with features such as tearing or a red eye.
- **Posttraumatic** onset, after a head injury (Chapter 32).
- **Pathology of the immune system,** for example human immunodeficiency virus (HIV) infection.
- **Painkiller overuse** or a new drug started when the headache began.

The authors note that the evidence for many red flags is limited (Do et al., 2019). The nurse therefore reports any red flag, together with vital signs and a neurologic assessment, and does not decide alone that a headache is harmless. A headache with fever and neck stiffness points to meningitis.

Meningitis and Encephalitis

Bacterial meningitis is a bacterial infection of the meninges, the membranes covering the brain and spinal cord. It is a medical emergency. In a large Dutch study of adults with community-acquired bacterial meningitis, the most common causes were *Streptococcus pneumoniae* (51% of episodes) and *Neisseria meningitidis* (37%) (van de Beek et al., 2004).

In meningococcal meningitis, PHAC lists sudden fever, severe headache and neck stiffness, sometimes with nausea, vomiting, sensitivity to light and a change in consciousness (Public Health Agency of Canada [PHAC], 2026). Not every patient has all the classic signs. In the Dutch study, only 44% of episodes showed all three of fever, a stiff neck and altered mental status, yet almost every patient had two or more of headache, fever, neck stiffness and altered mental status (van de Beek et al., 2004).

Infection with *N. meningitidis* can cause a petechial rash, sometimes with pink spots or blisters, and a rash that does not blanch with pressure in meningococcal sepsis. The rash is harder to see on darker skin, so the nurse checks paler areas such as the palms, the soles and the inside of the eyelids, as well as the palate (PHAC, 2026). A non-blanching rash with fever is reported at once. Sepsis is covered in Chapter 4.

Care moves fast:

- **Cultures and antibiotics:** Blood cultures are drawn at once. When the lumbar puncture will be delayed or a CT is needed first, antibiotics and adjunctive therapy are given before the lumbar puncture or before the patient goes for CT (Tunkel et al., 2004). Antibiotics are never delayed for testing. The prescriber chooses intravenous antibiotics based on the patient's age and risk factors; examples are ceftriaxone, often with vancomycin, and ampicillin in some patients (Tunkel et al., 2004). The nurse gives them as ordered and without delay.
- **Dexamethasone:** When an adult has suspected or confirmed pneumococcal meningitis, the first dose of dexamethasone is given 10 to 20 minutes before, or at the same time as, the first antibiotic dose (Tunkel et al., 2004).
- **CT before lumbar puncture:** CT is done first in some adults: those aged 60 or older and those with a weakened immune system, a history of central nervous system disease, a seizure in the past week, or abnormal neurologic findings such as a reduced level of consciousness or a focal deficit (Tunkel et al., 2004; section 30.3).
- **Precautions:** Ontario public health guidance calls for droplet precautions for a hospitalized patient with invasive meningococcal disease until 24 hours of antibiotic therapy have been given (Thunder Bay District Health Unit, 2026). Infection prevention and control are covered in Chapter 4.
- **Public health:** Invasive meningococcal disease is nationally notifiable, and suspected cases must be reported by health care providers to the local public health unit (PHAC, 2026), in Ontario immediately by phone (Thunder Bay District Health Unit, 2026). Public health staff find close contacts, who are offered preventive antibiotics whatever their vaccination status (PHAC, 2026).
- **Monitoring:** The nurse watches for rising ICP, seizures, shock and changes in the rash, and reports them at once.

In Canada, 104 of 738 people with invasive meningococcal disease and a known outcome died between 2012 and 2021, and 15% to 20% of survivors have lasting effects such as hearing loss, seizures or limb loss (PHAC, 2026). Vaccines protect against several

serogroups (Chapter 21).

Encephalitis is inflammation of the brain tissue itself, with signs of neurologic dysfunction. It shares many features with meningitis, and some patients have both (meningoencephalitis). Encephalitis can cause confusion, behaviour change, focal weakness and seizures (Tunkel et al., 2008). In the IDSA guideline, herpes simplex virus is among the most commonly identified causes. Acyclovir is started in every patient with suspected encephalitis while test results are pending (Tunkel et al., 2008). Because a change in mental status cannot reliably separate encephalitis from bacterial meningitis, the team considers both at first (Tunkel et al., 2008).

Brain Tumours and Craniotomy Care

A **primary brain tumour** starts in the brain or its coverings. A metastatic (secondary) brain tumour spreads to the brain from cancer elsewhere. The Brain Tumour Foundation of Canada (2025) states that each day, 27 people in Canada learn they have a brain tumour, and for 8 of them it is brain cancer. Of all primary brain tumours, 62% are non-malignant, and brain metastases develop at some point in 20% to 40% of people with cancer (Brain Tumour Foundation of Canada, 2025). For 2026, the Canadian Cancer Society (2026) projects 3,300 new diagnoses of brain and other nervous system cancer in Canada and 2,700 deaths from it.

Symptoms depend on the size and location of the tumour (National Cancer Institute, n.d.). General symptoms include persistent headache, vomiting, drowsiness and subtle changes in personality, memory or thinking. Other symptoms reflect the area involved (section 30.1), such as weakness on one side, or problems with speech, vision or coordination. A new seizure in an adult with no history of seizures can be a sign of a brain tumour (National Cancer Institute, n.d.). Edema around the tumour can raise ICP (section 30.4).

Dexamethasone may be used to treat cerebral edema, including edema around brain tumours (Sandoz Canada, 2026). It can unmask diabetes or raise insulin needs, mask signs of infection, cause mood changes and stomach ulcers, and must not be stopped suddenly (Sandoz Canada, 2026). The nurse checks glucose as ordered and teaches the patient to taper only as directed. Cancer treatment is covered in Chapter 9, and palliative care in Chapter 10.

A **craniotomy** is surgery in which part of the skull is opened to reach the brain. General perioperative care is in Chapter 7. After a craniotomy, the nurse:

- completes neurologic checks as ordered and compares each with the last, reporting any decline at once (section 30.2);
- keeps the head of the bed at the angle the surgeon orders;
- watches the incision for bleeding, swelling and infection, and reports any clear fluid from the wound, nose or ear, which can be a sign of a CSF leak;
- monitors sodium and fluid balance, because sodium problems can follow brain surgery (section 3.4; section 23.5);
- gives antiseizure medicines on time and follows seizure precautions as ordered;
- manages pain and nausea as ordered (Chapter 5) and helps the patient avoid straining (section 30.4); and
- supports the patient and family facing a new cancer diagnosis, and involves palliative care early when goals call for it (Chapter 10).

> **SCOPE IN PRACTICE**
>
> **Neurologic Care and Who Does What**
>
> The College of Nurses of Ontario's (CNO's) Scope of Practice standard asks whether a nurse has the **authority**, the **competence** and the right **context** for an activity (Chapter 1, section 1.3).
>
> - **Neurologic checks:** RNs and RPNs both complete neurologic assessments, including the GCS, pupils and limb strength, for patients in their care.
> - **Escalation is every nurse's duty:** Any nurse who finds a falling GCS score, a new pupil change or new weakness acts at once and escalates. The RPN does not wait for the next scheduled check; the RPN informs the RN and the physician or nurse practitioner immediately.
> - **Competence:** EVD care, continuous EEG monitoring and titrated infusions, such as hypertonic saline, need specialized education. Many employers limit them to RNs, often in critical care or on neurosurgical units. A nurse who has not been educated for these activities does not perform them and asks for help.

- **Context:** The RPN consults the RN when a patient's needs grow more complex, such as rising ICP, status epilepticus or suspected meningitis. Assigning patients by stability is a common employer practice, not a CNO rule.
- **Standards:** CNO's revised Scope of Practice and Medication standards take effect March 1, 2027.

Employer policy and the province or territory shape these roles.

PRACTICE STORY

Thirty Degrees

Names and details are fictional; this is a composite story.

Nurse: Deepa Nair, RN. Years in practice: 3. Setting: neurosurgery unit, Ontario.

Mr. Delorme was 71, the day after a craniotomy to remove a meningioma. At 08:00 he was chatty, telling me about his grandson's hockey team. GCS 15. Pupils 3 mm, equal and brisk. Strong grips on both sides.

At 11:30, after physiotherapy, I found him lying almost flat. The order said thirty degrees. I raised the bed and started my checks, and something felt off. He still knew where he was, but he answered in short phrases and kept closing his eyes. "Just tired," he said. His GCS was still 15 when I scored it. Then I looked at his pupils. The left one was 4 mm and slower than the right.

It was a millimetre. I could have talked myself out of it. I asked my charge nurse to look, and she saw it too. His blood pressure was higher than at 08:00, and his heart rate was a little lower.

I called the neurosurgery resident and gave it to her in SBAR: day 1 after a left frontal craniotomy; new left pupil, 4 mm and sluggish; drowsier than at 08:00, though still scoring 15; blood pressure up. I told her I was worried. She came within minutes, ordered an urgent CT scan and asked me to repeat his checks every 15 minutes. The scan showed a small collection of blood under the bone flap, and he went back to the operating room that afternoon.

Two days later, he was telling me about hockey again. What stays with me is that the total score had not changed. The pupil, and the way he talked, told me more than the number did.

Reflect: Which cues did Priya act on, even though the GCS total had not changed? If an RPN on the same unit had noticed the pupil change first, what should the RPN have done, and who should the RPN have told?

Chapter 30 Summary

Introduction

- Early neurologic changes are often small, and the bedside nurse is often the first to notice them; careful, repeatable checks compared with baseline allow early action.

30.1 The Nervous System: A Focused Review

- Neurons send signals along axons, sped by myelin, and pass them to the next cell with neurotransmitters; the brain and spinal cord form the central nervous system.
- The four lobes of each cerebral hemisphere have distinct roles, and pathways cross so that each hemisphere mainly controls the opposite side of the body.
- The brainstem controls breathing, heart rate and arousal; consciousness needs both arousal and awareness, so a falling level of consciousness suggests a brainstem or widespread hemispheric problem.
- The brain uses about 20% of the body's oxygen; autoregulation keeps blood flow fairly steady over a narrower range than once taught, and rising carbon dioxide widens cerebral vessels.
- An adult has about 150 mL of CSF but makes 400 to 600 mL a day; the skull is a closed box shared by brain, blood and CSF (section 30.4).

30.2 Focused Neurologic Assessment

- The GCS is done with the structured approach (check, observe, stimulate, rate), using fingertip pressure first and avoiding a sternal rub.

- Each component is reported in words and numbers; untestable components are recorded as NT, not 1, and no total is reported when a component is NT.
- A new unequal or sluggish pupil, new pronator drift, new posturing or a falling motor score is an urgent cue; pronator drift detects subtle weakness better than strength testing alone.
- Aphasia is a language disorder and dysarthria a muscle-control speech disorder; both can affect the verbal score and swallowing safety.
- Change is judged against baseline; a new focal sign points to a structural problem and is escalated at once with SBAR, with precise documentation.

30.3 Neurologic Diagnostics

- CT is fast and the usual first test for sudden decline; Canadian guidance limits kidney precautions for iodine contrast to an eGFR below 30 mL/min/1.73 m² and does not delay emergency scans.
- MRI gives more detail without ionizing radiation but needs a full safety screen before every scan, because the magnet is always on.
- Routine EEG needs clean hair without products and usual medicines; continuous EEG in intensive care detects seizures without movements.
- Lumbar puncture is preceded by CT when criteria such as reduced consciousness or a focal deficit are present, without delaying antibiotics in suspected meningitis.
- Post–dural puncture headache is positional and usually resolves; atraumatic needles reduce it by more than half.

30.4 Increased Intracranial Pressure

- The skull is a closed box holding brain, blood and CSF; once the body's buffer is used up, a small added volume makes ICP rise steeply.
- Bleeding, cerebral edema, tumours, hydrocephalus and infection can all raise ICP and lower cerebral perfusion pressure.
- Early signs are subtle changes in level of consciousness, restlessness, headache and vomiting; a falling GCS score, pupil changes, posturing and the Cushing triad are late signs.
- Herniation is an emergency: the nurse calls for immediate help and stays with the patient.
- Nursing care includes raising the head of the bed above 30° with the head midline as ordered, keeping SpO_2 above 94%, avoiding fever and low blood pressure, limiting distressing stimuli and giving osmotherapy as ordered or per protocol.

30.5 Seizures and Status Epilepticus

- Epilepsy is a lasting tendency to have seizures; a provoked seizure caused by a temporary problem does not on its own count toward the diagnosis.
- The ILAE's 2025 classification keeps four classes (focal, generalized, unknown and unclassified) and asks for signs to be described in the order they appeared.
- During a seizure, the nurse stays, times it, protects the head, turns the patient to the side as it eases and never restrains or puts anything in the mouth.
- A convulsive seizure lasting 5 minutes is status epilepticus; the AES guideline gives a benzodiazepine from 5 minutes and a second-line medicine from 20 minutes, as ordered or per protocol.
- Antiseizure medicines are never stopped suddenly; phenytoin toxicity shows as nystagmus, unsteadiness and slurred speech.
- In Ontario, physicians and nurse practitioners must report high-risk conditions to the Ministry of Transportation; the nurse teaches the patient not to drive until cleared.

30.6 Headache, Central Nervous System Infections and Brain Tumours

- Headache red flags include fever, a history of cancer, neurologic deficits, sudden onset, onset after 65, a changed pattern and immune system disease.
- Bacterial meningitis is an emergency; the classic triad is often incomplete, and antibiotics are never delayed for testing.

- A petechial rash is harder to see on darker skin, so the nurse checks the palms, soles, eyelids and palate.
- In Ontario, patients with invasive meningococcal disease are on droplet precautions for 24 hours after antibiotics start, and suspected cases are reported to public health at once.
- Acyclovir is started for suspected encephalitis while tests are pending.
- After a craniotomy, the nurse compares each neurologic check with the last, watches for CSF leak and sodium problems, monitors glucose on dexamethasone, and escalates any decline at once.

Key Terms (44)

abnormal extension: A motor response in which the arm straightens at the elbow in response to a stimulus; it ranks lower on the GCS than abnormal flexion.

abnormal flexion: A slow, stereotyped motor response with the arm bent across the chest, forearm turning, thumb clenched and leg extended; a sign of severe brain dysfunction.

antiseizure medication: A medicine used to prevent or stop seizures, such as levetiracetam, phenytoin or lacosamide.

aphasia: A disorder of language from damage to the brain's language areas that can affect speaking, understanding, reading and writing.

autoregulation: The ability of cerebral blood vessels to widen or narrow to keep brain blood flow fairly steady when blood pressure changes.

bacterial meningitis: A bacterial infection of the meninges that cover the brain and spinal cord; a medical emergency.

blood–brain barrier: Tightly joined cells that limit which substances pass from the blood into brain tissue.

brainstem: The midbrain, pons and medulla, which link the brain to the spinal cord and control breathing, heart rate, many reflexes and arousal.

central nervous system (CNS): The brain and spinal cord.

cerebellum: The part of the brain at the back, below the cerebrum, that coordinates movement and learned motor skills.

cerebral edema: Swelling of brain tissue, for example around a tumour or after an injury.

cerebral perfusion pressure: The pressure that drives blood into the brain; mean arterial pressure minus intracranial pressure.

cerebrospinal fluid (CSF): The clear fluid made mainly in the choroid plexus of the ventricles that cushions the brain and spinal cord and carries away waste.

cerebrum: The main part of the forebrain, the largest part of the brain, made of two hemispheres and four lobes; it controls conscious thought, memory, language and voluntary movement.

computed tomography (CT): An imaging test that uses a rotating X-ray beam to build cross-sectional images; fast and useful for finding bleeding in the head.

craniotomy: Surgery in which part of the skull is opened to reach the brain.

Cushing triad: A late sign of raised intracranial pressure: high blood pressure, a slow heart rate and an irregular breathing pattern or apnea.

dysarthria: A speech disorder caused by weakness or poor control of the muscles used for talking, producing slurred, slow or soft speech with intact language.

electroencephalography (EEG): A test that records the brain's electrical activity through electrodes on the scalp.

encephalitis: Inflammation of the brain tissue itself, with signs of neurologic dysfunction such as confusion, behaviour change or seizures.

epilepsy: A brain disease marked by a lasting tendency to have seizures, diagnosed by the ILAE's practical definition.

external ventricular drain: A catheter placed through the skull into a ventricle that measures intracranial pressure and drains cerebrospinal fluid into a closed system.

focal seizure: A seizure that starts in networks limited to one hemisphere of the brain.

generalized seizure: A seizure that starts in networks spread across both hemispheres of the brain.

Glasgow Coma Scale (GCS): A standard scale that rates eye opening, verbal response and motor response to describe level of consciousness; the components are reported separately, and the total ranges from 3 to 15.

herniation: The displacement of brain tissue, under pressure, from one compartment of the skull into another or through the opening at the base of the skull.

hydrocephalus: A buildup of cerebrospinal fluid in the ventricles of the brain, often because its flow is blocked.

intracranial pressure: The pressure inside the skull, produced by the brain tissue, blood and cerebrospinal fluid it contains.

level of consciousness: How awake a person is (arousal) and how well the person understands self and surroundings (awareness).

lumbar puncture (LP): A procedure in which a needle is passed between lower back vertebrae into the CSF space to measure pressure and collect fluid.

magnetic resonance imaging (MRI): An imaging test that uses a strong magnetic field and radio waves to make detailed images of soft tissues such as the brain and spinal cord.

neuron: A nerve cell that receives, processes and sends signals; it has a cell body, dendrites and an axon.

osmotherapy: The use of a concentrated solution, such as mannitol or hypertonic saline, to draw water out of brain tissue and lower intracranial pressure.

post-ictal state: The recovery period after a seizure, when the person may be drowsy or confused.

post–dural puncture headache: A headache that starts in the 5 days after a lumbar puncture, caused by CSF leaking through the puncture, often worse upright and better lying down.

primary brain tumour: A tumour that starts in the brain or its coverings, as opposed to one that spreads to the brain from elsewhere.

pronator drift: A sign of subtle arm weakness in which one outstretched arm, held palm up with the eyes closed, turns palm-down and drifts downward.

provoked seizure: A seizure caused by a temporary problem, such as a concussion, a fever or alcohol withdrawal, acting on an otherwise normal brain.

pupillary response: The size, shape and reaction to light of the pupils; a new unequal or sluggish pupil is an urgent cue.

seizure: A short-lived event of signs or symptoms caused by abnormal, excessive or synchronized electrical activity of neurons in the brain.

seizure precautions: Safety measures set by employer policy for patients at risk of seizures.

status epilepticus: A seizure that lasts too long, or repeated seizures without recovery between them; for a convulsive seizure, treatment starts at 5 minutes.

thunderclap headache: A severe headache that reaches its peak almost at once; it needs emergency assessment.

tonic-clonic seizure: A seizure with a stiffening phase followed by rhythmic jerking of the limbs.

Licensure Review & Clinical Judgment Questions (40)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Margaret Okafor (Questions 1–4): Margaret Okafor, 58, has a known left frontal brain tumour and is on a neurosurgery unit in Ontario awaiting surgery. She is on hourly neurologic checks, which were unchanged all morning. At 1000 her GCS was 15 (E4V5M6), her pupils were 3 mm, round and brisk, and both arms were strong with no drift. At 1100 the RPN assigned to her finds that she opens her eyes only when spoken to, knows her name but says it is 2019 and that she is "at the bank", and still squeezes and releases on request. When she holds her arms out with palms up and eyes closed, her right forearm turns palm-down and drifts. Vital signs are unchanged from 1000.

1. [CORE] Which action should the RPN take next to complete the assessment of Ms. Okafor?

a. Ask Ms. Okafor to rest for half an hour and then repeat the Glasgow Coma Scale to see whether the change persists.

b. Check the size, shape and light reaction of both pupils and compare strength and sensation on both sides of her body.

c. Apply a firm sternal rub to see whether Ms. Okafor can localize the stimulus before scoring her motor response.

d. Review the medication record to find a sedating drug given this morning that could explain why she has become drowsy and confused.

Answer: b — A new change in level of consciousness with a new focal sign calls for a complete, focused check, including pupils and side-to-side motor and sensory comparison (section 30.2, Pupils, Movement and Sensation). Option a delays action; a decline with a focal sign is not left for 30 minutes. Option c uses a stimulus the GCS authors strongly discourage, and she already obeys commands, so her motor score is 6. Option d assumes a drug cause; a new one-sided sign points to a structural problem and is reported first.

2. [CORE] Which statement by the RPN best compares Ms. Okafor's 1100 findings with her baseline?

a. "Her GCS fell from 15 to 13: her eyes now open only to voice, she is confused, her motor score is unchanged, and her right arm newly drifts."

b. "Her GCS is 13, which is within the expected range for a person with a known brain tumour, and her vital signs have not changed at all since 1000."

c. "Her GCS has dropped by two points since 1000, which is too small a change to report until it has fallen by at least three points."

d. "Her GCS has fallen from 15 to 13 because her motor score has dropped, and the new weakness in her right arm accounts for the lower total this morning."

Answer: a — The nurse reports each component and the direction of change, not only the total (E3V4M6 = 13 compared with E4V5M6 = 15), plus the new focal sign (section 30.2, Level of Consciousness and the Glasgow Coma Scale; Recognizing and Reporting Change). Option b is wrong; there is no "normal" GCS for a diagnosis, and a decline from baseline matters. Option c is wrong because the GCS authors give no fixed point threshold for reporting. Option d misreads the scores; her motor score is still 6, since she obeys a two-part command.

3. [CORE] The RPN calls the RN and the neurosurgery resident. Which statement is the best recommendation in the RPN's SBAR report?

a. "I am going to keep checking her every hour as ordered, and I will let you know at the end of my shift if anything else about her changes."

b. "I think she is just tired from not sleeping well last night, so I would like an order for something to help her sleep tonight."

c. "I am concerned her tumour is causing a new deficit. Please come and assess her now; do you want neurologic checks every 15 minutes and a CT?"

d. "Could you review her chart sometime when you have a moment today? Her daughter mentioned that she seemed a little more forgetful than usual this morning."

Answer: c — The recommendation names the concern and asks for prompt bedside assessment and clear orders, such as more frequent checks and imaging (section 30.2, Recognizing and Reporting Change; Chapter 6). Option a delays escalation. Option b attributes a focal sign to fatigue and requests a sedative, which could mask further decline. Option d understates an urgent change and gives no clear request or timeline.

4. [CORE] Which entry best documents the RPN's 1100 assessment of Ms. Okafor?

a. "1100: Patient more lethargic and confused than earlier. GCS 13. Will continue to monitor. Resident aware."

b. "1100: Neuro status changed. Patient appears drowsy. Right arm weak. Pupils fine. Will reassess at 1200 as ordered."

c. "1100: GCS 13. Pupils equal and reactive. Patient confused and drowsy. Pronator drift noted on testing. MD to be called if she gets any worse; will reassess at 1200."

d. "1100: Eyes open to voice (E3), confused, gives year as 2019 (V4), obeys commands (M6), GCS 13; pupils 3 mm, round, brisk; right pronator drift, new. RN and neurosurgery resident informed 1105; resident to assess."

Answer: d — The record states the time, each GCS component in words and numbers, pupil size and reaction, the side and type of motor change, who was told and when, and the plan (section 30.2, Recognizing and Reporting Change). Options a and b use vague words such as "lethargic", "drowsy" and "fine" and give no components or side. Option c omits the side of the drift and the components, and it delays reporting a change that is already significant.

5. [CORE] A patient has a tumour in the right parietal and frontal region of the brain. Where would the nurse most expect to find new weakness?

a. In the right arm and right leg, because each hemisphere controls the same side of the body.

b. In the left arm and left leg, because pathways cross so each hemisphere controls the opposite side.

c. In both legs equally, because the frontal lobe controls movement of the lower body on both sides at once.

d. In the face only, because tumours in the frontal region affect the cranial nerves before the limbs.

Answer: b — Pathways between the brain and body cross over, so a right hemisphere lesion can weaken the left arm and leg (section 30.1, Cells, Brain and Spinal Cord). Option a reverses the crossing. Option c is wrong; each motor cortex mainly controls the opposite side, not both legs. Option d is wrong; frontal lesions commonly cause limb weakness, and there is no rule that the face is affected first.

6. [CORE] A patient with a brain injury is breathing slowly and shallowly, and the arterial partial pressure of carbon dioxide is rising. How does this affect blood flow to the brain?

a. Cerebral vessels narrow, so blood flow to the brain falls and the brain becomes ischemic.

b. Cerebral vessels are not affected by carbon dioxide, only by changes in blood pressure.

c. Cerebral vessels widen, so blood flow and blood volume inside the skull increase.

d. Cerebral vessels widen at first, then narrow again within minutes as autoregulation corrects them.

Answer: c — A rise in $PaCO_2$ widens cerebral vessels and increases blood flow, adding volume inside the closed skull (section 30.1, Blood Flow, Cerebrospinal Fluid and the Skull; section 30.4). Option a describes the effect of a fall in $PaCO_2$. Option b is wrong; carbon dioxide is a strong regulator of cerebral blood flow. Option d is not described by the source; autoregulation responds to blood pressure changes, not by reversing the carbon dioxide effect.

7. [CORE] A patient on a medical unit was intubated an hour ago for respiratory failure. The patient opens the eyes to voice and obeys commands. How should the nurse record the GCS?

a. E3 V1 M6, total 10

b. E3 VNT M6, total 13 out of 15

c. E3 V5 M6, total 14, assuming the patient is oriented

d. E3 VNT M6, with no total reported

Answer: d — When a breathing tube prevents speech, the verbal component is recorded as not testable (NT), not 1, and a total is not reported because it could mislead the team (section 30.2, Level of Consciousness and the Glasgow Coma Scale). Option a gives a falsely low score. Option b adds a total that cannot be calculated. Option c guesses a score that was not observed.

8. [CORE] A patient does not open the eyes when spoken to in a normal or loud voice. Which physical stimulus should the nurse use first?

a. Fingertip pressure on the nail bed

b. A knuckle rub on the sternum

c. Firm pressure at the angle of the jaw

d. A pinch on the inner thigh

Answer: a — The structured approach uses fingertip pressure first, and trapezius or supraorbital pressure when a central stimulus is needed (section 30.2, Level of Consciousness and the Glasgow Coma Scale). Option b is strongly discouraged because it bruises and gives hard-to-read responses. Option c is not recommended for routine use. Option d is not part of the standard method.

9. [CORE] At 0200, the nurse finds that a patient's right pupil is 5 mm and sluggish, while the left is 3 mm and brisk. At 0100 both pupils were 3 mm and brisk. The patient is harder to rouse. What should the nurse do first?

a. Document the finding and recheck both pupils at the next scheduled check in one hour.

b. Ask the patient whether they use any eye drops and wait for the answer before acting.

c. Stay with the patient and escalate at once to the most responsible provider or rapid response team.

d. Dim the lights further and repeat the pupil check several times to make sure the finding is accurate.

Answer: c — A new unequal, sluggish pupil with a falling level of consciousness can signal herniation and needs immediate escalation (section 30.2, Pupils, Movement and Sensation; section 30.4). Option a delays action for an hour. Option b is reasonable background, but it does not come before getting help for a patient who is harder to rouse. Option d repeats checks instead of acting; confirming a finding must not delay reporting it.

10. [CORE] A patient with a new left temporal lesion answers "yes" to every question, speaks fluently in sentences that make little sense and cannot follow simple requests. The patient's face and limbs move normally. Which interpretation by the nurse is most accurate?

a. The patient has dysarthria from weakness of the muscles that are used for both speaking and swallowing.

b. The patient has aphasia, a language problem that can make the verbal score look like confusion.

c. The patient has delirium, so a full neurologic check is not needed until the delirium resolves.

d. The patient is hard of hearing, so the nurse should raise their voice, face the patient and repeat each of the questions.

Answer: b — Fluent speech with little meaning and poor understanding, after damage to a language area, fits aphasia, which affects the verbal score and is recorded as a factor (section 30.2, Speech, Orientation and Cranial Nerve Screening). Option a is wrong; dysarthria causes slurred speech with intact language, and the patient's face moves normally. Option c is wrong; a new focal lesion is not assumed to be delirium, and checks continue. Option d mislabels a language problem as a hearing problem.

11. [CORE] Which factors can interfere with an accurate Glasgow Coma Scale assessment? Select all that apply.

a. Hearing loss without hearing aids in place

b. Sedating medication given in the past hour

c. An endotracheal tube

d. Severe swelling of both eyelids

e. A language different from the nurse's, with no interpreter

f. A blood pressure of 142/88 mm Hg

g. Age over 75 years

Answer: a, b, c, d, e — The GCS authors list pre-existing factors (language differences, hearing loss, prior deficits), current treatment (sedation, intubation) and injuries, such as eyelid swelling, as factors that can prevent a valid rating (section 30.2, Level of Consciousness and the Glasgow Coma Scale). A blood pressure of 142/88 mm Hg (f) does not itself prevent a rating. Age (g) is not an interfering factor; the nurse compares the older adult with their own baseline.

12. [CORE] An RPN on a medical unit is caring for a patient on neurologic checks every 2 hours. The patient's GCS has fallen from 14 to 11, and the right arm now drifts. What should the RPN do?

a. Notify the RN and wait for the RN to repeat the assessment before anyone calls the physician.

b. Recheck the patient in 2 hours as ordered, because an RPN cannot report changes in a patient's condition directly to a physician.

c. Stay with the patient, call the rapid response team or physician per policy, and inform the RN at the same time.

d. Ask a colleague to repeat the GCS in an hour and report only if both nurses agree that the score has changed.

Answer: c — Every nurse who notices deterioration acts at once and escalates; the RPN involves the RN but does not wait for a reassessment before calling for help (section 30.2, Recognizing and Reporting Change; section 1.3; Chapter 6). Options a and d delay escalation. Option b is wrong; the RPN can and must report a deteriorating patient directly according to employer policy.

13. [CORE] An RPN is assigned a patient whose care began with neurologic checks every 4 hours. Overnight the patient's condition becomes less predictable and checks are increased to every 15 minutes. Which action best reflects CNO's Scope of Practice standard?

a. The RPN keeps the patient because performing neurologic checks is within the RPN's authority in every situation.

b. The RPN transfers the patient's care to an RN, because CNO rules state that RPNs may care only for patients who are stable and predictable.

c. The RPN considers authority, competence and context, consults the RN, and follows employer policy about who should be assigned.

d. The RPN continues care without consulting anyone, because the frequency of checks does not affect the nursing role.

Answer: c — CNO's standard asks nurses to consider authority, competence and context, and the RPN consults the RN as the patient's needs change; employer policy also matters (section 1.3; section 30.2). Option a ignores competence and context. Option b presents a common employer practice as a CNO rule, which it is not. Option d ignores the change in context and the duty to consult.

14. [CORE] A 79-year-old patient was alert and oriented on admission. Today the patient is restless, says it is night when it is noon, and pulls at the intravenous line. The left arm drifts downward when held out. Which interpretation should guide the nurse's action?

a. The restlessness and disorientation are typical of delirium, so the nurse can address sleep and hydration first.

b. Disorientation is common in older adults in hospital, so the findings can be reported at the next routine round.

c. The arm drift is likely due to the IV line, so the nurse should check the line and reassess later in the shift.

d. The new one-sided arm drift points to a structural brain problem, so the nurse escalates urgently.

Answer: d — A new focal sign, such as one-sided drift, points to a structural cause and is an emergency, even if delirium is also present (section 30.2, Recognizing and Reporting Change; Chapter 8). Option a addresses delirium but misses the focal sign. Option b treats a new change as expected and delays reporting. Option c blames the intravenous line and delays assessment of a serious sign.

15. [CORE] A patient scheduled for an MRI of the brain says, "I have a pacemaker, but my cardiologist said it is MRI-safe." What should the nurse do?

a. Record that the patient has an MRI-safe pacemaker and send the patient for the scan as scheduled.

b. Record the device's make and model, find the device card or notes, and alert the MRI team before the scan.

c. Cancel the MRI, because no patient with a pacemaker can ever have an MRI scan.

d. Ask the patient to sign a waiver accepting the risk, and then send the patient for the scan.

Answer: b — Implants are identified by type, make and model with written documentation, and an MR Conditional device is safe only under the maker's conditions, which the MRI team must confirm (section 30.3, Clinical Safety box). Option a accepts a verbal report without checking the device. Option c is wrong; some pacemakers are MR Conditional. Option d does not replace screening.

16. [CORE] A patient is booked for a routine outpatient EEG tomorrow morning. Which instruction should the nurse give?

a. "Do not eat or drink anything after midnight, and skip all of your morning medicines."

b. "Apply conditioner after washing your hair so the electrodes slide on easily."

c. "Drink a strong coffee before the test so that you stay awake the whole time."

d. "Wash your hair the night before or that morning, and do not use any hair products."

Answer: d — Clean hair without conditioners, creams, sprays or gels helps the electrodes attach (section 30.3, Electroencephalography). Option a is wrong; the patient eats a normal meal to keep blood glucose stable and takes usual medicines unless told otherwise. Option b adds a product that interferes with the electrodes. Option c is wrong; caffeine is avoided on the day of the test.

17. [CORE] A patient had a lumbar puncture yesterday. Today the patient reports a headache that is worse when sitting up and eases when lying down, with mild neck stiffness. The patient has no fever. Which explanation by the nurse is most accurate?

a. "This sounds like a headache from a small CSF leak at the puncture site. It usually settles, and I will let your team know."

b. "This headache means the test has caused meningitis, so you will need antibiotics and another lumbar puncture."

c. "This is a migraine, which is common after any procedure, so you should take a migraine tablet and rest."

d. "This headache is a warning sign of bleeding inside your skull, so you will need an emergency CT scan of your head right away."

Answer: a — A headache that starts in the 5 days after a lumbar puncture and is worse upright and better lying down, often with neck stiffness, fits post–dural puncture headache from a CSF leak; it usually resolves, and the team is informed (section 30.3, Lumbar Puncture). Option b is not supported; there is no fever, and the pattern is positional. Option c mislabels the cause. Option d overstates the risk; the positional pattern after a puncture points to a leak, although a headache with fever or new neurologic signs would be escalated.

18. [RN] An RN assesses a patient. The patient's eyes open only to fingertip pressure. The patient says single words such as "stop" and "no" but no sentences. With a trapezius pinch, the patient's right hand moves up to the shoulder and pushes the nurse's hand away. How should the RN record the GCS?

a. E2 V3 M5, GCS 10

b. E3 V3 M5, GCS 11

c. E2 V2 M4, GCS 8

d. E2 V4 M6, GCS 12

Answer: a — Eyes opening to pressure score 2, single understandable words score 3, and moving a hand above the collarbone toward a stimulus at the head or neck is localising, which scores 5 (section 30.2, Table 30.1). Option b scores eye opening as "to sound". Option c treats words as sounds and localising as normal flexion. Option d treats single words as confused speech and localising as obeying commands.

19. [RN] During a neurologic check, an RN applies a trapezius pinch to a patient who does not respond to voice. Both arms bend slowly at the elbows and lie across the chest, the forearms rotate, the thumbs clench and the legs extend. Fifteen minutes ago, the patient withdrew the arm quickly away from the body. What does this change indicate?

a. An improvement, from normal flexion to localising, showing the patient is becoming more aware.

b. A change from normal flexion to abnormal flexion, a sign of serious brain dysfunction that needs immediate escalation.

c. A change from abnormal extension to abnormal flexion, which is an expected pattern as the effects of sedating medicines gradually wear off.

d. A seizure, so the RN should time the movements and wait for them to stop before reporting.

Answer: b — Slow, stereotyped flexion with the arm across the chest, forearm rotation, thumb clenching and leg extension is abnormal flexion (M3); the earlier quick withdrawal was normal flexion (M4), so the motor response has fallen, which needs urgent escalation (section 30.2, Pupils, Movement and Sensation). Option a is wrong; localising means reaching toward the stimulus. Option c misreads the earlier response. Option d confuses posturing provoked by a stimulus with a seizure and delays action.

20. [RN] Four adults with suspected bacterial meningitis are waiting for a lumbar puncture in the emergency department. For which patient should the RN expect a head CT before the lumbar puncture?

a. A 32-year-old patient with fever, headache and neck stiffness who is alert, oriented and has a normal neurologic exam.

b. A 45-year-old patient with fever and headache who has a history of migraine and a normal neurologic exam.

c. A 28-year-old patient with fever, rash and headache whose only medicine is an oral contraceptive.

d. A 51-year-old patient with fever, headache, a reduced level of consciousness and new left arm drift.

Answer: d — The IDSA features that call for a CT before lumbar puncture include an abnormal level of consciousness and abnormal neurologic findings such as arm drift, which may signal a mass or raised pressure; blood cultures and antibiotics are not delayed for the CT (section 30.3, Lumbar Puncture; section 30.6). Options a, b and c describe patients under 60 with no criteria; migraine and oral contraceptives are not on the list.

Case: Marc Belanger (Questions 21–26): Marc Belanger, 46, has had epilepsy since age 20 and takes levetiracetam twice daily. He was admitted to a medical unit 2 days ago with pneumonia. He vomited his last two doses of levetiracetam. At 14:10 the nurse finds him having a generalized tonic-clonic seizure. At 14:16 he is still seizing. SpO_2 is 88% on room air, heart rate 128, temperature 38.1 °C, and capillary blood glucose 5.6 mmol/L. He has a working IV, and his orders include intravenous lorazepam per the unit's seizure protocol.

21. [CORE] Which findings should the nurse recognize as cues that need immediate attention? Select all that apply.

a. The seizure has lasted more than 5 minutes

b. SpO_2 of 88% on room air

c. Capillary blood glucose of 5.6 mmol/L

d. Two vomited doses of levetiracetam

e. A history of epilepsy since age 20

f. A working IV line

Answer: a, b, d — A convulsive seizure lasting longer than 5 minutes meets the ILAE time point for status epilepticus and needs treatment now (a; section 30.5). An SpO_2 of 88% shows that oxygenation is falling during the seizure (b). Missed antiseizure doses can increase seizures and are a likely trigger to report (d). A glucose of 5.6 mmol/L is not low, so it does not explain the seizure (c). A long history of epilepsy is background information, not an immediate cue (e). The working IV is useful for treatment but is not a problem that needs attention (f).

22. [CORE] Why is the time of 14:16 important in Mr. Belanger's care?

a. Seizures that last 6 minutes usually stop by themselves within the next few minutes, so the nurse can keep watching for now.

b. After 5 minutes, a convulsive seizure is unlikely to stop on its own and is treated as status epilepticus.

c. After 5 minutes, the risk of permanent brain harm is already established, so treatment will no longer change the outcome.

d. The time matters mainly for documentation, because the seizure protocol starts only after 30 minutes of seizure activity.

Answer: b — The ILAE treats a convulsive seizure lasting 5 minutes as continuous seizure activity that needs treatment, and the AES guideline starts initial therapy at 5 minutes (b; section 30.5). Waiting for the seizure to stop is unsafe after 5 minutes (a). The 30-minute time point, not the 5-minute one, marks the risk of long-term harm, and treatment is urgent precisely because it can prevent harm (c). Treatment begins at 5 minutes, not 30 (d).

23. [RN] Which hypothesis should the nurse treat as the priority?

a. Convulsive status epilepticus with low oxygen, possibly triggered by missed levetiracetam doses and fever

b. Hypoglycemia causing a prolonged seizure that will stop as soon as intravenous dextrose is given by the nurse

c. A non-epileptic event related to anxiety about his pneumonia, his fever and the long hospital stay

d. Alcohol withdrawal seizures that need a withdrawal protocol started before any other treatment is given

Answer: a — The seizure has lasted more than 5 minutes with an SpO_2 of 88%, and he missed two doses of his antiseizure medicine while febrile, so convulsive status epilepticus with hypoxemia is the priority (a; section 30.5). His glucose is 5.6 mmol/L, so hypoglycemia is not the cause (b). Calling the event non-epileptic could delay life-saving treatment (c). Nothing in the case suggests alcohol use, and withdrawal is managed as described in Chapter 11 (d).

24. [CORE] Which action should the nurse take first at 14:16?

a. Place a padded tongue blade between his teeth to protect his tongue and keep his airway open.

b. Hold his arms and legs firmly to prevent injury until the seizure team arrives at the bedside.

c. Leave the room to get the seizure protocol binder and check the lorazepam order before calling anyone.

d. Call for help at once, turn him to his side when it is safe and give oxygen per policy.

Answer: d — The nurse stays with the patient, activates help, protects the airway by positioning him on his side and gives oxygen as policy directs while the benzodiazepine is prepared (d; section 30.5). Nothing is ever placed in the mouth (a), and the person is never restrained (b). Leaving the patient alone during status epilepticus delays help and is unsafe (c).

25. [CORE] Lorazepam is given at 14:18. At 14:28 Mr. Belanger is still seizing. What should the nurse expect next?

a. The team will wait until 14:40 before giving any more medicine, because lorazepam needs about 20 minutes to work.

b. The nurse will give a second dose of levetiracetam by mouth once the jerking slows enough for him to swallow.

c. The team will give a repeat benzodiazepine dose or a second-line intravenous medicine as the protocol directs.

d. The nurse will stop all medicines and wait for an EEG to confirm the diagnosis before treatment continues.

Answer: c — Guidance supports a second benzodiazepine dose when a seizure continues 5 to 10 minutes after the first, and the AES guideline moves to a second-line intravenous medicine, such as levetiracetam, fosphenytoin or valproic acid, from 20 minutes (c; section 30.5). Waiting longer delays treatment (a). Nothing is given by mouth during a seizure (b). Treatment does not wait for an EEG (d).

26. [CORE] At 14:45 the seizure has stopped. Which finding best shows that care is working?

a. He is breathing regularly, SpO_2 is 95% with oxygen, and he opens his eyes to his name, though he is still confused.

b. He is breathing regularly but does not respond to voice or pressure, and his eyes stay closed 30 minutes later.

c. He has no jerking, but his left arm and leg are newly weak, and his speech is slurred compared with this morning.

d. He is sleeping on his back, SpO_2 is 90% on oxygen, and his breathing is noisy with gurgling sounds.

Answer: a — Regular breathing, a safe SpO_2 and early return of response, with expected post-ictal confusion, show that the plan is working (a; section 30.5). Not responding 30 minutes later is not expected recovery and needs prompt reassessment (b). New one-sided weakness and slurred speech need urgent assessment for another cause (c). Lying on his back with noisy breathing and a low SpO_2 suggests airway compromise; he should be on his side (d).

27. [CORE] A patient is on day 1 after a craniotomy. Which finding is most likely an early sign of rising intracranial pressure?

a. A blood pressure of 176/70 mm Hg with a heart rate of 48 and irregular breathing

b. A fixed, dilated right pupil with no response to light on either side

c. New restlessness and slower answers to questions compared with 2 hours earlier

d. Abnormal extension of both arms and legs in response to pressure on a nail bed

Answer: c — A subtle change in level of consciousness, such as restlessness or slower answers, is often the first sign of rising ICP (c; section 30.4, Table 30.3). High blood pressure with a slow heart rate and irregular breathing (Cushing triad) is a late sign (a). A fixed, dilated pupil is a late sign (b). Abnormal extension posturing is a late sign (d).

28. [CORE] A patient with a brain tumour has a blood pressure of 184/72 mm Hg (previously 136/78), a heart rate of 46 (previously 82) and irregular breathing. What should the nurse do?

a. Recheck the vital signs in 1 hour and report them at the next scheduled update to the physician.

b. Give the as-needed antihypertensive and recheck the blood pressure in 30 minutes before calling anyone.

c. Lower the head of the bed flat to improve blood flow to the brain and recheck the heart rate.

d. Call for immediate help, stay with the patient and support the airway, because these are late signs of raised pressure.

Answer: d — High blood pressure, a slow heart rate and irregular breathing form the Cushing triad, a late sign of raised ICP and possible herniation; the nurse calls for immediate help and stays with the patient (d; section 30.4). Waiting an hour is unsafe (a). Treating the blood pressure alone misses the emergency and could lower cerebral perfusion (b). Lying flat can impair venous drainage from the head (c).

29. [CORE] Which position best supports a patient at risk of increased intracranial pressure, unless the orders say otherwise?

a. Head of bed raised above 30°, with the head in the midline and the neck not bent or turned

b. Head of bed flat, with a pillow under the shoulders to extend the neck and open the airway

c. Head of bed raised to 15°, with the head turned toward the window to keep the patient calm

d. Head of bed flat, with the knees and hips sharply bent to reduce pressure in the abdomen

Answer: a — The Neurocritical Care Society advises raising the head of the bed above 30° with the head midline to help venous drainage (a; section 30.4). Lying flat with the neck extended can impair venous drainage (b). Turning the head can compress the veins of the neck (c). Lying flat with sharp hip flexion can raise abdominal and chest pressure and does not help venous drainage (d).

30. [CORE] During a generalized tonic-clonic seizure, which action is correct?

a. Hold the patient's shoulders down firmly so that the jerking movements stop sooner.

b. Note the start time, cushion the head and turn the patient onto the side as the jerking eases.

c. Insert an oral airway between the teeth as soon as the seizure begins to protect the tongue.

d. Give the patient a sip of water once the jerking slows so that the throat does not become dry.

Answer: b — Epilepsy Ontario advises timing the seizure, cushioning the head and rolling the person onto the side as the seizure eases (b; section 30.5). Restraint can cause injury and does not stop a seizure (a). Nothing is placed in the mouth during a seizure (c). Nothing is given by mouth until the patient is fully awake and can swallow safely (d).

31. [CORE] A patient with epilepsy says, "My seizures have been gone for a year, so I'm going to stop my medicine this week." What is the nurse's best response?

a. "That sounds reasonable after a full year without seizures, so you can stop it this week."

b. "Stopping suddenly can bring on seizures, so any change needs to be planned with your prescriber."

c. "You can stop it if you take half the dose this week and none at all after that."

d. "You should stop it only if your next blood test shows a low level of the medicine."

Answer: b — The phenytoin monograph warns that stopping an antiseizure medicine suddenly can increase seizures, including status epilepticus, and that changes should be gradual and directed by the prescriber (b; section 30.5). Stopping on one's own is unsafe (a). A self-made taper is still not directed by the prescriber (c). A drug level does not decide whether to stop treatment (d).

32. [CORE] A patient taking phenytoin has new unsteadiness, slurred speech and jerking eye movements when looking to the side. What should the nurse do?

a. Encourage the patient to walk more often to improve balance before the next dose.

b. Give the next dose early to prevent a seizure, because these signs suggest a low level.

c. Hold the next dose until the patient's symptoms improve and document the findings.

d. Report the findings to the prescriber, because they are signs of phenytoin toxicity.

Answer: d — The monograph lists nystagmus, unsteadiness and slurred speech as early signs of phenytoin toxicity, so the nurse reports them promptly and expects a serum level (d; section 30.5, Table 30.4). Walking more increases the risk of falls (a). These are signs of a high level, not a low one (b). The nurse does not decide alone to hold or change an antiseizure dose; the prescriber decides (c).

33. [CORE] In Ontario, a patient has a first seizure and asks the nurse whether he can drive home from the hospital. Which statement is accurate?

a. "Physicians and nurse practitioners must report certain conditions, so do not drive until you are told it is safe."

b. "Only the police can report a seizure to the Ministry of Transportation, so you may drive until the ministry contacts you."

c. "Reporting is optional in Ontario, so your licence is not affected unless you decide to tell the ministry yourself."

d. "You can drive as long as you feel well, because a single seizure does not count as a reportable medical condition."

Answer: a — Ontario's Highway Traffic Act requires physicians and nurse practitioners to report high-risk medical conditions, and the ministry reviews seizure reports against national standards; the nurse teaches the patient not to drive until cleared (a; section 30.5). Physicians, nurse practitioners and others report; reporting is not left to police (b). Reporting is mandatory for these clinicians (c). A seizure is a form of sudden incapacitation, the main concern the ministry names, so feeling well does not make driving safe (d).

34. [CORE] Which headache features should the nurse report as red flags? Select all that apply.

a. A sudden, severe headache that reached its peak within moments

b. A new headache in a 72-year-old with no previous headaches

c. A headache with a temperature of 38.9 °C and a stiff neck

d. A familiar migraine pattern that the patient has had for 15 years

e. A headache in a patient receiving treatment for lung cancer

f. A headache that eases with the patient's usual acetaminophen dose

Answer: a, b, c, e — The SNNOOP10 list includes sudden onset (a), onset after age 65 (b), systemic symptoms such as fever (c) and a history of cancer (e) (section 30.6). A long-standing, unchanged migraine pattern is not a red flag on its own (d). A headache that responds to usual treatment is not a red flag, although new painkiller overuse would be (f).

35. [CORE] A patient admitted with suspected meningococcal meningitis started antibiotics 6 hours ago. Which precautions should the nurse use?

a. Airborne precautions in a negative-pressure room until the patient's CSF culture becomes negative

b. Droplet precautions until 24 hours after antibiotics started, in addition to routine practices

c. Contact precautions only, because the infection spreads mainly through contaminated surfaces
