OPENNURSING.CA • CANADIAN NURSING OPEN EDUCATIONAL RESOURCE

First Edition • 2026

Medical-Surgical Nursing

A Canadian Open Text

Evidence-Informed Adult Acute Care Across Canadian Health Systems

ARCHITECTURE OF THE TEXT — NINE CLINICAL UNITS • THIRTY-SIX CHAPTERS

Unit I • Ch. 1–6
Foundations, Indigenous Cultural Safety, Fluids, Sepsis, Pain & Shock

Unit II • Ch. 7–11
Perioperative Care, Older Adults, Oncology, Palliative Care & Substance Use

Unit III • Ch. 12–15
Respiratory Assessment, Oxygen Therapy, COPD, Asthma, ARDS & PE

Unit IV • Ch. 16–19
Cardiovascular Assessment, Dysrhythmias, ACS, Heart Failure & Vascular Care

Unit V • Ch. 20–23
Hematology, Transfusion, Immunity, HIV, Diabetes & Endocrine Disorders

Unit VI • Ch. 24–26
Upper & Lower Gastrointestinal, Hepatic, Biliary & Pancreatic Nursing Care

Unit VII • Ch. 27–29
Acute Kidney Injury, Chronic Kidney Disease, Dialysis, Urology & Reproductive Health

Unit VIII • Ch. 30–32
Neurologic Assessment, Increased ICP, Stroke, TBI, SCI & Chronic Neurologic Care

Unit IX • Ch. 33–36
Musculoskeletal Trauma, Orthopedics, Arthritis, Wounds, Burns, Eye & Ear Care

Andrew Lee, BEd, BN, MN, RN, CCN(C)
Professor of Nursing • Loyalist College, Belleville, Ontario

36 CHAPTERS • 245 FIGURES • 1,310 QUESTIONS

Canadian Clinical Practice & Medication Notice

Nursing practice, diagnostic protocols, and drug therapies evolve continuously. While every chapter has been verified against current Canadian clinical practice guidelines, provincial and territorial regulatory standards, and the Health Canada Drug Product Database as of October 2026, clinicians and students must always verify medication dosages, contraindications, reconstitution instructions, and infusion rates against current official Canadian product monographs, institutional formularies, and employer policies before administration.

Statement on Indigenous Health Data & OCAP® Principles

Whenever epidemiological or clinical studies involving First Nations, Inuit, or Métis peoples are discussed across this textbook, findings are contextualized within the historical and ongoing impacts of colonization, Indian hospitals, residential schools, and systemic racism in health care, and interpreted in respect of the First Nations principles of **Ownership, Control, Access, and Possession (OCAP®)** (OCAP® is a registered trademark of the First Nations Information Governance Centre [FNIGC]).

Indigenous Land Acknowledgement

This open textbook was authored in Belleville and Brighton, Ontario, on the traditional, ancestral, and treaty lands of the Anishinaabeg, Huron-Wendat, and Haudenosaunee peoples, adjacent to the Tyendinaga Mohawk Territory (Mohawks of the Bay of Quinte). As nurses and educators working across Turtle Island, we commit to enacting the Truth and Reconciliation Commission of Canada Calls to Action 18 through 24, Joyce's Principle, and culturally safe, anti-racist care at every bedside.

STATEMENT ON OPEN EDUCATION • OPENNURSING.CA *Author's Statement*

§ Why This Book Is Open

> *"Higher education shall be equally accessible to all on the basis of merit."*
>
> — *Universal Declaration of Human Rights*, Article 26 (United Nations, 1948)

Knowledge that heals belongs to everyone it might help. A patient never asks what their nurse could afford to learn; they hope only that the nurse knows enough to keep them safe. A barrier between a student and that knowledge is, in the end, a barrier between a patient and good care.

Nursing rests on a moral claim: every person has equal worth, and care should follow need rather than wealth or place. We cannot teach that principle honestly from a book only some students can afford. Cost falls hardest on those already carrying the most, and removing it is a matter of fairness, not charity.

For this reason, *Medical-Surgical Nursing: A Canadian Open Text* is free to read, download and print, under a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International licence (CC BY-NC-SA 4.0). Instructors may adapt it, provided what they build stays open. Openness also means access: the book is designed to meet Ontario's accessibility requirements (AODA) and WCAG 2.1 Level AA, so that no student is shut out by disability.

Open education rests on the belief that we learn best together. If you find an error, a barrier or a way to improve this book, please tell me (andrewleenl@gmail.com). Each correction is a small act of care for the next student, and for the patients that student will serve.

Andrew Lee, BEd, BN, MN, RN, CCN(C)

Preface & Pedagogical Architecture

For decades, Canadian Bachelor of Science in Nursing (BScN) and Practical Nursing (RPN/LPN) students have been asked to learn adult medical-surgical nursing from expensive commercial textbooks written for the United States health care market—or from lightly edited adaptations that retain US conventional laboratory units, FDA drug trade names, insurance-driven discharge models, and US scope-of-practice rules. **Medical-Surgical Nursing: A Canadian Open Text** was written from the ground up to give Canadian nursing students a rigorous, free, genuinely Canadian clinical text.

How This Textbook Supports Canadian Nursing Curricula

Architectural Feature	Clinical & Educational Design
100% Canadian SI Units & DPD Drugs	Every laboratory value uses Canadian SI units (mmol/L, µmol/L, g/L), and every medication is verified against the Health Canada Drug Product Database (recognizing Canadian generic names such as salbutamol, epinephrine, furosemide, and dimenhydrinate).
Dual-Track Core & Going Deeper Design	Core sections cover entry-to-practice competencies shared by all nursing students (NCLEX-RN, REx-PN, and CPNRE), while *Going Deeper* callouts and **[RN]** questions address complex multisystem titration and unstable acute care.
RN / RPN / LPN Scope in Practice	Applies CNO's Scope of Practice framework (authority, competence, and context) and BCCNM, CRNA, OIIQ, and Atlantic/Prairie regulatory standards to real bedside assignment and consultation decisions.
36 Unfolding Practice Stories	Each chapter follows a unique named Canadian nurse (18 RNs and 18 RPNs/LPNs) and adult patient from presentation through discharge across urban tertiary centres, rural community hospitals, and northern nursing stations.
1,310 Licensure Review Questions	Every chapter concludes with 30 to 40 NCLEX-RN, REx-PN, and CPNRE clinical judgment questions—including linked unfolding case studies—complete with option-by-option rationales.

MEDICAL-SURGICAL NURSING: A CANADIAN OPEN TEXT *Section Guide*

§ Detailed Table of Contents & Section Guide

UNIT I — Foundations of Canadian Medical-Surgical Practice p. 1

01 Medical-Surgical Nursing in Canada p. 2
Introduction • 1.1 What Medical-Surgical Nursing Is • 1.2 Where Adults Receive Care in Canada • 1.3 The Medical-Surgical Team and Scope of Practice • 1.4 Clinical Judgment: The Clinical Judgment Measurement Model • 1.5 Professional, Legal and Ethical Foundations • 1.6 Safety and Quality in Medical-Surgical Care • 1.7 Partnering with Patients Across Transitions • 1.8 Using This Book

02 Equity, Cultural Safety and Indigenous Health in Adult Care p. 35
Introduction • 2.1 Health Equity and the Determinants of Health • 2.2 Cultural Safety, Humility and Trauma- and Violence-Informed Care • 2.3 First Nations, Inuit and Métis Health • 2.4 Rights, Policy and Data • 2.5 Caring for Other Equity-Deserving Adults • 2.6 Equity in Everyday Medical-Surgical Practice

03 Fluids, Electrolytes and Acid–Base Balance p. 67
Introduction • 3.1 Body Fluids and How They Are Regulated • 3.2 Fluid Volume Deficit and Excess • 3.3 IV Fluids and Fluid Management • 3.4 Sodium Imbalances • 3.5 Potassium Imbalances • 3.6 Calcium, Magnesium and Phosphate • 3.7 Acid–Base Balance

04 Inflammation, Infection and Sepsis p. 97
Introduction • 4.1 Inflammation and Healing • 4.2 Infection: Recognition and Diagnostics • 4.3 Infection Prevention and Control on the Unit • 4.4 Antibiotic-Resistant Organisms and C. difficile • 4.5 Antimicrobial Stewardship and the Nurse • 4.6 Sepsis

05 Pain p. 125
Introduction • 5.1 Understanding Pain • 5.2 Pain Assessment • 5.3 Multimodal and Non-Opioid Analgesia • 5.4 Opioids: Safe Use in Hospital • 5.5 Patients Living With Chronic Pain or Opioid Use Disorder

06 Recognizing Deterioration and Shock p. 152
Introduction • 6.1 Recognizing Clinical Deterioration • 6.2 Early Warning Scores and Escalation • 6.3 Shock: How It Develops • 6.4 Hypovolemic and Cardiogenic Shock • 6.5 Distributive and Obstructive Shock • 6.6 Nursing Care of the Patient in Shock

UNIT II — Cross-Cutting Clinical Priorities in Adult Care p. 178

07 Perioperative Nursing p. 179
Introduction • 7.1 The Perioperative Journey • 7.2 Preoperative Assessment and Preparation • 7.3 Consent and the Day of Surgery • 7.4 Anesthesia and Sedation • 7.5 Care After Anesthesia (PACU) • 7.6 Postoperative Care and Complications

08 Older Adults in Acute Care p. 206
Introduction • 8.1 Aging, Frailty and Acute Care • 8.2 Delirium • 8.3 Dementia and Depression in Hospital • 8.4 Falls and Functional Decline • 8.5 Medications in Older Adults • 8.6 Restraints, Capacity and Transitions

09 Cancer Care p. 234
Introduction • 9.1 Cancer Biology • 9.2 Cancer in Canada: Risk, Prevention and Screening • 9.3 Cancer Treatments • 9.4 Oncologic Emergencies • 9.5 Safe Handling of Hazardous Drugs • 9.6 Living With Cancer: Support and Survivorship

10 Palliative and End-of-Life Care p. 264
Introduction • 10.1 The Palliative Approach • 10.2 Advance Care Planning and Goals of Care • 10.3 Managing Symptoms • 10.4 Medical Assistance in Dying • 10.5 The Last Days and Care After Death • 10.6 Grief and Caring for Ourselves

11 Substance Use in Acute Care p. 290
Introduction • 11.1 Substance Use, Stigma and Health • 11.2 Screening and Brief Intervention in Hospital • 11.3 Alcohol Withdrawal • 11.4 Opioid Toxicity and Withdrawal • 11.5 Stimulants, Cannabis and Other Substances • 11.6 Harm Reduction and Transitions

UNIT III — Respiratory Nursing Care p. 317

12 Respiratory Assessment and Oxygen Therapy p. 318
Introduction • 12.1 Breathing and Gas Exchange: A Brief Review • 12.2 Focused Respiratory Assessment • 12.3 Pulse Oximetry and Other Measures • 12.4 Oxygen Therapy • 12.5 Airway Clearance • 12.6 Artificial Airways and Tracheostomy Care

13 Lower Respiratory Infections and Lung Cancer p. 349
Introduction • 13.1 Community-Acquired Pneumonia • 13.2 Hospital-Acquired and Aspiration Pneumonia • 13.3 Influenza, COVID-19 and RSV • 13.4 Tuberculosis • 13.5 Lung Cancer • 13.6 Pleural Effusion and Empyema

14 Obstructive and Restrictive Lung Disease p. 380
Introduction • 14.1 Obstructive and Restrictive Patterns • 14.2 Asthma • 14.3 Inhaled Medications and Devices • 14.4 Chronic Obstructive Pulmonary Disease • 14.5 Smoking and Vaping Cessation • 14.6 Bronchiectasis, Interstitial Lung Disease and Sleep Apnea

15 Acute Respiratory Failure and Pulmonary Embolism p. 409
Introduction • 15.1 Acute Respiratory Failure • 15.2 Acute Respiratory Distress Syndrome • 15.3 Non-invasive and Mechanical Ventilation • 15.4 Pneumothorax and Chest Injury • 15.5 Chest Tubes and Chest Drainage • 15.6 Pulmonary Embolism

UNIT IV — Cardiovascular & Vascular Nursing Care p. 438

16 Cardiac Assessment and Dysrhythmias p. 439
Introduction • 16.1 The Heart and Its Rhythm: A Brief Review • 16.2 Focused Cardiovascular Assessment • 16.3 Cardiac Tests • 16.4 Cardiac Monitoring and Reading a Rhythm Strip • 16.5 Common Dysrhythmias and How to Respond • 16.6 Atrial Fibrillation and Flutter • 16.7 Heart Blocks, Pacemakers and Implantable Devices

17 Coronary Artery Disease and Acute Coronary Syndromes p. 476
Introduction • 17.1 Atherosclerosis and Cardiovascular Risk • 17.2 Stable Angina and Chronic Coronary Disease • 17.3 Recognizing Acute Coronary Syndromes • 17.4 Early Treatment and Complications of ACS • 17.5 Care Around PCI and CABG • 17.6 Cardiac Rehabilitation and Living With Coronary Disease

18 Heart Failure, Valvular and Inflammatory Heart Disease p. 504
Introduction • 18.1 Heart Failure: How It Develops • 18.2 Recognizing and Managing Worsening Heart Failure • 18.3 Medications and Devices • 18.4 Self-Management and Transitions • 18.5 Valvular Heart Disease • 18.6 Infective Endocarditis • 18.7 Pericarditis, Myocarditis and Cardiomyopathies

19 Hypertension and Vascular Disorders p. 538
Introduction • 19.1 Hypertension: Measurement and Risk • 19.2 Treating Hypertension • 19.3 Hypertensive Emergencies and Acute Aortic Syndromes • 19.4 Peripheral Arterial Disease • 19.5 Abdominal Aortic Aneurysm • 19.6 Venous Disease and VTE • 19.7 Anticoagulation

UNIT V — Hematologic, Immunologic & Endocrine Care p. 568

20 Hematologic Disorders and Transfusion p. 569
Introduction • 20.1 Blood and Its Tests • 20.2 Anemias • 20.3 Sickle Cell Disease and Thalassemia • 20.4 Bleeding and Clotting Disorders • 20.5 Leukemia, Lymphoma and Myeloma • 20.6 Blood Components and Transfusion

21 Immunity, Allergy and HIV p. 601
Introduction • 21.1 The Immune System: A Focused Review • 21.2 Hypersensitivity and Allergy • 21.3 Immunodeficiency and the Immunocompromised Patient • 21.4 HIV: Infection, Testing and Prevention • 21.5 Living With HIV: Treatment and Nursing Care • 21.6 Autoimmunity and Adult Immunization

22 Diabetes p. 635
Introduction • 22.1 Glucose Regulation and Types of Diabetes • 22.2 Monitoring Glucose • 22.3 Insulin and Non-Insulin Medications • 22.4 Hypoglycemia • 22.5 Hyperglycemic Emergencies: DKA and HHS • 22.6 Diabetes in Hospital, Complications and Living Well

23 Thyroid, Parathyroid, Adrenal and Pituitary Disorders p. 665
Introduction • 23.1 Endocrine Feedback and Testing • 23.2 Thyroid Disorders • 23.3 Thyroid and Parathyroid Surgery • 23.4 Adrenal Disorders • 23.5 Pituitary Disorders and Water Balance

UNIT VI — Gastrointestinal, Hepatic, Biliary & Pancreatic Care p. 695

24 Upper Gastrointestinal Disorders and Nutrition p. 696
Introduction • 24.1 Digestion and Nutrition Assessment • 24.2 Enteral and Parenteral Nutrition • 24.3 Dysphagia and Texture-Modified Diets • 24.4 GERD, Gastritis and Peptic Ulcer Disease • 24.5 Upper Gastrointestinal Bleeding • 24.6 Obesity and Bariatric Surgery

25 Lower Gastrointestinal Disorders p. 727
Introduction • 25.1 Bowel Function, Constipation and Diarrhea • 25.2 Inflammatory Bowel Disease • 25.3 Diverticular Disease and Appendicitis • 25.4 Bowel Obstruction and Ileus • 25.5 Colorectal Cancer Care • 25.6 Ostomy Care and Teaching

26 Liver, Biliary and Pancreatic Disorders p. 759
Introduction • 26.1 The Liver, Biliary Tree and Pancreas • 26.2 Viral Hepatitis and Steatotic Liver Disease • 26.3 Cirrhosis and Its Complications • 26.4 Alcohol-Related Liver Disease, Acute Liver Failure and Transplant • 26.5 Gallbladder and Biliary Disease • 26.6 Acute and Chronic Pancreatitis

UNIT VII — Renal, Urologic & Reproductive Health Care p. 790

27 Acute Kidney Injury and Chronic Kidney Disease p. 791
Introduction • 27.1 Kidney Function and Kidney Tests • 27.2 Acute Kidney Injury • 27.3 Chronic Kidney Disease • 27.4 Dialysis • 27.5 Kidney Transplant • 27.6 Kidney Health in Canada and Living Well With CKD

28 Urinary Tract and Prostate Disorders p. 822
Introduction • 28.1 Urinary Tract Infection • 28.2 Urinary Catheters and CAUTI Prevention • 28.3 Urinary Retention and Incontinence • 28.4 Kidney Stones • 28.5 Benign Prostatic Hyperplasia and Prostate Surgery • 28.6 Prostate and Bladder Cancer

29 Reproductive and Breast Health in Adult Care p. 852
Introduction • 29.1 Sexual Health in Medical-Surgical Care • 29.2 Breast Cancer Care • 29.3 Gynecologic Conditions and Surgery • 29.4 Menopause and Midlife Health • 29.5 Sexually Transmitted and Blood-Borne Infections • 29.6 Erectile Dysfunction and Gender-Affirming Care

UNIT VIII — Neurologic & Cerebrovascular Nursing Care p. 882

30 Neurologic Assessment and Increased Intracranial Pressure p. 883
Introduction • 30.1 The Nervous System: A Focused Review • 30.2 Focused Neurologic Assessment • 30.3 Neurologic Diagnostics • 30.4 Increased Intracranial Pressure • 30.5 Seizures and Status Epilepticus • 30.6 Headache, Central Nervous System Infections and Brain Tumours

31 Stroke p. 913
Introduction • 31.1 Understanding Stroke • 31.2 Recognizing Stroke and Code Stroke • 31.3 Hyperacute Treatment • 31.4 Hemorrhagic Stroke • 31.5 Stroke Unit Care • 31.6 Rehabilitation, Transitions and Living After Stroke

32 Traumatic Brain and Spinal Cord Injury and Chronic Neurologic Disorders p. 943
Introduction • 32.1 Traumatic Brain Injury and Concussion • 32.2 Spinal Cord Injury • 32.3 Multiple Sclerosis • 32.4 Parkinson Disease • 32.5 Myasthenia Gravis and Guillain–Barré Syndrome • 32.6 Amyotrophic Lateral Sclerosis and Living With Progressive Neurologic Disease

UNIT IX — Musculoskeletal, Integumentary & Sensory Care p. 975

33 Musculoskeletal Trauma and Orthopedic Surgery p. 976
Introduction • 33.1 Fractures and Their Care • 33.2 Complications After Musculoskeletal Injury • 33.3 Osteoporosis and Bone Health • 33.4 Hip Fracture in Older Adults • 33.5 Joint Replacement and Spine Surgery • 33.6 Amputation • 33.7 Mobility and Safe Patient Handling

34 Arthritis and Connective Tissue Disorders p. 1008
Introduction • 34.1 Joints, Inflammation and Arthritis in Canada • 34.2 Osteoarthritis • 34.3 Rheumatoid Arthritis • 34.4 Gout • 34.5 Lupus and Other Connective Tissue Disorders • 34.6 Medicines for Inflammatory Arthritis • 34.7 Living Well With Chronic Arthritis

35 Skin, Wounds and Burns p. 1040
Introduction • 35.1 Skin Structure and Assessment • 35.2 Pressure Injuries • 35.3 Wound Healing and Wound Care • 35.4 Surgical Wounds and Skin Infections • 35.5 Burns • 35.6 Skin Cancer and Other Common Skin Conditions

36 Eye and Ear Disorders p. 1075
Introduction • 36.1 Vision and Eye Assessment • 36.2 Cataract, Glaucoma and Other Causes of Vision Loss • 36.3 Eye Emergencies, Trauma and Eye Surgery • 36.4 Hearing and Ear Assessment • 36.5 Communication Access, Hearing Aids and Cochlear Implants • 36.6 Ear Disorders and Ear Surgery

I Foundations of Canadian Medical-Surgical Practice

UNIT CLINICAL SCOPE & INTEGRATION

Establishes the legal, ethical, regulatory, and physiological foundations of adult acute-care nursing across Canada. Chapters 1 through 6 examine the Canada Health Act, provincial and territorial RN/RPN/LPN scopes of practice, Indigenous cultural safety and TRC Calls to Action 18–24, fluid/electrolyte and acid–base balance in SI units, infectious disease and sepsis, acute and chronic pain stewardship, and early recognition of clinical deterioration and shock.

Contents of UNIT I

Chapter	Chapter Title	Visual Assets	Page
Chapter 1	Medical-Surgical Nursing in Canada	11 Figs • 6 Tbls	p. 2
Chapter 2	Equity, Cultural Safety and Indigenous Health in Adult Care	3 Figs • 5 Tbls	p. 35
Chapter 3	Fluids, Electrolytes and Acid–Base Balance	6 Figs • 4 Tbls	p. 67
Chapter 4	Inflammation, Infection and Sepsis	4 Figs • 4 Tbls	p. 97
Chapter 5	Pain	2 Figs • 4 Tbls	p. 125
Chapter 6	Recognizing Deterioration and Shock	4 Figs • 4 Tbls	p. 152

01 Medical-Surgical Nursing in Canada

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Describe medical-surgical nursing and the settings and transitions in which adults receive care in Canada.
2. Explain how the Canada Health Act and provincial and territorial delivery shape adults' access to hospital and community care, using Ontario as the example.
3. Compare the roles of registered nurses, practical nurses, nurse practitioners and unregulated care providers on a medical-surgical team, using authority, competence and context.
4. Apply the six cognitive skills of the Clinical Judgment Measurement Model to a change in an adult patient's condition.
5. Explain how the CNO Code of Conduct, the CNA Code of Ethics for Nurses (2025), and consent, privacy and documentation requirements guide daily practice.
6. Describe the patient safety systems that protect adults in hospital and the nurse's part in them.
7. Use teach-back, professional interpreters and discharge planning to partner with patients and families across transitions in care.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2	Clinician; Coordinator	Foundations of Practice
3	Coordinator; Collaborator; Professional	Collaborative Practice; Legal Practice
4	Clinician; Scholar	Foundations of Practice
5	Professional; Advocate	Ethical Practice; Legal Practice; Professional Practice
6	Leader; Clinician	Professional Practice; Foundations of Practice
7	Educator; Communicator; Collaborator	Collaborative Practice

Introduction

Every day, adults arrive on hospital units across Canada with pneumonia, a flare of chronic obstructive pulmonary disease (COPD), a new hip or a failing heart. In 2024–2025, Canadian hospitals recorded about 3.14 million acute inpatient stays. After giving birth, the most common reasons for a stay were COPD and bronchitis, then pneumonia (Canadian Institute for Health Information [CIHI], 2026a). Caring for these adults before, during and after hospital is the work of medical-surgical nursing.

The people in those beds are older than they once were. On July 1, 2026, one in five people in Canada (20.0%) was 65 or older (Statistics Canada, 2026). In 2021, people 65 and older made up 18.5% of the population but accounted for 43.2% of health spending (CIHI, 2023). Many live with **multimorbidity**, meaning two or more chronic conditions at once. In the 2017–2018 Canadian Community Health Survey, about 37% of seniors living in the community reported at least two of ten common chronic diseases, a figure the Public Health Agency of Canada (PHAC) calls a conservative estimate (PHAC, 2020). A British Columbia study that used health administrative records and counted 25 conditions found that more than 60% of adults 65 and older met this definition in 2019/2020 (Ferris et al., 2025).

For the nurse, this means a patient admitted for one problem usually brings several others, a long medication list, a family who wants to help and questions about what happens after discharge. This chapter sets the foundation for that work: what medical-surgical nursing is, where adults receive care in Canada, and the legal and ethical rules that guide every nurse.

1.1 What Medical-Surgical Nursing Is

Adult Health Across Acute and Chronic Illness

Medical-surgical nursing is the nursing care of adults who are acutely ill, who are living through a flare-up (exacerbation) of a chronic illness, or who need surgery and support to recover from it. The name comes from two kinds of hospital units. On a medical unit, patients are treated mainly with medications, monitoring and other non-surgical therapies for problems such as heart failure or infection. On a surgical unit, patients are preparing for or recovering from an operation.

In practice, the line blurs. An older adult recovering from bowel surgery may also have heart failure, diabetes and early dementia. Medical-surgical nurses therefore need broad knowledge of every body system and strong skills in noticing when a patient's condition is changing. The same knowledge is used outside hospital wards, in day surgery, rehabilitation, home care and virtual care.

The Illness Trajectory

The **illness trajectory** is the path a health condition takes over time and the care a person needs along the way. This book uses five broad phases:

- **Prevention and health promotion:** lowering risk before disease starts or worsens, such as through vaccination or smoking cessation.
- **Acute illness:** a new problem, a sudden worsening of a chronic one, or planned surgery.
- **Recovery and rehabilitation:** regaining strength, function and independence.
- **Chronic disease management:** living well with a long-term condition through self-management and follow-up.
- **End of life:** comfort and support for the person and family when cure is no longer the goal (Chapter 10).

The path is rarely straight. A person with COPD may go from stable self-management to an emergency admission and back home several times in a year, and each admission is a chance to prevent the next one. The condition chapters of this book follow the same order: prevention, acute care, recovery and discharge, long-term management and, where relevant, palliative needs.

Patient- and Family-Centred Care

Patient- and family-centred care is a way of working in which patients, the people they call family, and health care providers act as partners as care is planned, given and evaluated (Institute for Patient- and Family-Centered Care [IPFCC], n.d.; Registered Nurses' Association of Ontario [RNAO], 2015). It sees the patient as a whole person with values and goals, not as a diagnosis. The patient decides who counts as family, whether a spouse, friend or chosen family member, and how much each person takes part. Its core ideas are respect and dignity, sharing complete and usable information, supporting participation at the level the patient chooses, and collaboration (IPFCC, n.d.).

Figure 1.1 A nurse measures a patient's blood pressure at the bedside. Regular, careful assessment underlies every other part of medical-surgical nursing care. (credit: “Blood Pressure Monitoring” by NIH Clinical Center/Flickr, CC BY 2.0)

Healthcare Excellence Canada (HEC) uses the term **essential care partner** for a person the patient (or substitute decision-maker; see section 1.5) names to give the physical, psychological and emotional support the patient considers important; this role differs from that of a visitor (HEC, n.d.-a). HEC also involves patients and caregivers with lived experience as partners in improving services (HEC, n.d.-b). On a unit, this looks like bedside shift report that includes the patient, asking "What matters most to you?", and inviting the named partner to discharge teaching.

The Nurse's Work on a Medical-Surgical Unit

The nurse's core work includes the following (Figure 1.1):

- **Assessment:** gathering and interpreting physical, mental, social and spiritual data, and learning what the patient wants.
- **Surveillance:** watching for small changes over time so that deterioration is caught early (Chapter 6).
- **Medication administration:** giving medications safely, monitoring effects and reconciling lists at each transition.
- **Teaching:** preparing patients and families for self-care, starting on admission.
- **Coordination:** connecting care across shifts, the interprofessional team and community services.
- **Advocacy:** speaking up for the patient's wishes, safety and rights.

Registered nurses (RNs) and practical nurses (PNs), who are called registered practical nurses (RPNs) in Ontario and **licensed practical nurses (LPNs)** in most other provinces and territories (see section 1.3), share much of this work. How it is divided on a unit depends on each nurse's authority, competence and the practice context, including employer policy and provincial or territorial rules.

1.2 Where Adults Receive Care in Canada

The Canada Health Act

The **Canada Health Act** is the federal law that sets the conditions provinces and territories must meet to receive full federal cash contributions for health care. The Act declares that the main objective of Canadian health care policy is to protect, promote and restore residents' physical and mental well-being and to make reasonable access to health services possible without cost or other obstacles getting in the way (Canada Health Act, 1985, s. 3). It deals mainly with **insured health services**: medically necessary hospital services, medically required physician services, and surgical-dental procedures that need a hospital. Hospital services include a standard ward bed, nursing care, diagnostic tests, drugs given in hospital, and operating room and anesthesia services (s. 2). Provincial and territorial plans must meet five criteria (Table 1.1) and must not allow extra-billing or user charges for insured services (ss. 7–12, 18–19).

Table 1.1 The five criteria of the Canada Health Act in plain language (Canada Health Act, 1985)

Criterion	What it means	What it means for patients
Public administration	A public authority accountable to the government runs the plan on a non-profit basis and is subject to audit.	Insured hospital and physician care is paid by a public plan, not a for-profit insurer.
Comprehensiveness	The plan covers all insured services provided by hospitals and physicians, and surgical-dental services that need a hospital.	Medically necessary hospital and physician care, including tests and drugs given in hospital, is covered.
Universality	All insured residents are entitled to insured services on the same terms.	Every eligible resident has the same basic coverage.
Portability	New residents wait no more than three months for coverage, and the plan keeps paying when residents are temporarily away.	A resident who falls ill while visiting another province is covered by the home plan.
Accessibility	Services are offered on uniform terms, and charges or other barriers must not block reasonable access.	Patients are not billed at the point of care for insured hospital and physician services.

Many services adults need after discharge fall outside the Act. Each province and territory decides whether and how to cover outpatient prescription drugs, home care, dental care, vision care and ambulance services, often for groups such as seniors, children and people receiving social assistance; others pay themselves or use private insurance (Health Canada, 2025). The federal Canadian Dental Care Plan now also helps with dental costs for eligible residents who have no access to dental insurance and an adjusted family net income under $90,000 (Employment and Social Development Canada, 2026). In Ontario, the Ontario Drug Benefit program covers people 65 and older and some younger groups, with deductibles and co-payments for some (Government of Ontario,

2026a). A drug given free in hospital may cost money at the pharmacy, so the nurse asks early whether the patient can afford discharge prescriptions.

Provincial, Territorial and Federal Roles

Provinces and territories run their insurance plans, decide eligibility and covered services, deliver most care and regulate health professions, including nursing. The federal government administers the Canada Health Act, funds care through transfers and serves certain groups directly, including First Nations people living on reserve, Inuit, eligible veterans and serving Canadian Armed Forces members (Health Canada, 2025). Three federal bodies matter most to nurses:

- **Health Canada:** administers the Canada Health Act and regulates health products such as drugs.
- **Public Health Agency of Canada:** promotes health, works to prevent chronic and infectious disease and injury, and prepares for and responds to public health emergencies (PHAC, 2025).
- **Indigenous Services Canada (ISC):** employs nurses in nursing stations and health centres, mostly in First Nations communities that are remote or isolated (ISC, n.d.-b), and runs the **Non-Insured Health Benefits (NIHB)** program. NIHB covers registered First Nations and recognized Inuit for pharmacy, vision, dental, mental health counselling, medical supplies and equipment, and medical transportation not covered by other plans (ISC, n.d.-a). Chapter 2 discusses Indigenous health services further.

Ontario as an Example

Each province and territory organizes care differently, so agency names will vary. Ontario's main parts are:

- **Ontario Health:** a provincial agency created in 2019 that oversees health care delivery and performance (Government of Ontario, 2025b). Its six regions plan, fund and monitor local care (Ontario Health, 2026a).
- **Ontario Health Teams (OHTs):** groups of local providers, such as hospitals, primary care, home care and long-term care, that work as one team; 58 OHTs cover the province (Government of Ontario, 2026c; Ontario Health, 2026b).
- **Public hospitals:** each is a separate, independent corporation with its own governing board, operating under the Public Hospitals Act, 1990 (Government of Ontario, 2023a).
- **Ontario Health atHome:** formed June 28, 2024, from the 14 Home and Community Care Support Services organizations; it coordinates home and community care and long-term care placement (Government of Ontario, 2024; Ontario Public Appointments Secretariat, n.d.).
- **Long-term care homes:** 24-hour nursing and personal care for adults who need it, governed by the Fixing Long-Term Care Act, 2021 (Government of Ontario, 2025a).
- **Primary care:** family physicians and nurse practitioners (NPs), often in teams (Ontario Ministry of Health, 2025).
- **Public health units:** 29 boards of health that deliver local programs such as immunization and infectious disease control (Government of Ontario, 2026d).

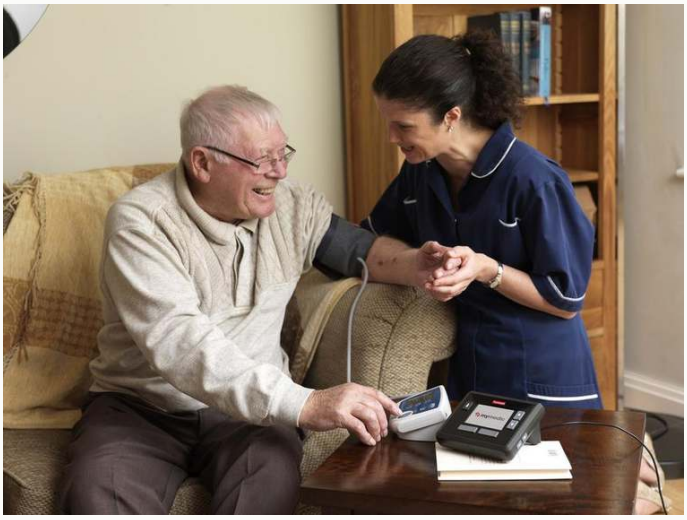

Figure 1.2 A nurse checks an older man's blood pressure in his home. Medical-surgical nursing continues after discharge through home care, telephone follow-up and remote monitoring. (credit: “Telehealth - Older man and nurse using blood pressure” by Tunstall Telehealthcare/Flickr, CC BY 2.0)

Where Medical-Surgical Nurses Work

Settings include medical and surgical inpatient units; step-down units for patients who need closer monitoring but not intensive care; day surgery and ambulatory clinics; the emergency department, where admitted patients may be held while waiting for a bed; rehabilitation; home care; and virtual care, such as telephone follow-up or remote monitoring after discharge (Figure 1.2).

Transitions and Alternate Level of Care

A **transition in care** is any move between settings or teams: admission, transfer or discharge. Information, medications and plans can be lost at each one, so the nurse confirms changes and makes sure the next team and the patient know the plan. Discharge planning begins at admission.

Alternate level of care (ALC) describes a patient who still occupies a hospital bed but no longer needs acute care and is waiting for a better-suited setting, such as long-term care, rehabilitation or home with supports. In Ontario, a physician (or another designated professional) makes the designation (Ontario Health, 2021). In 2024–2025, 6.1% of hospital stays in Canada included ALC days (CIHI, 2026a). These waits reduce beds for new admissions; Chapter 8 discusses how nurses protect older adults during them.

CANADIAN CONTEXT

Care Far from Home

Because surgical, specialist and hospital services are concentrated in larger centres, adults in rural, remote and northern communities often travel to a regional or southern centre for surgery, specialist care or admission. A nurse in a remote nursing station may stabilize a patient and arrange transfer by air or road (Figures 1.3 and 1.4). For registered First Nations and recognized Inuit, the NIHB medical transportation benefit can cover travel to the nearest appropriate facility for care not available at home, along with meals, lodging and, when a medical or legal need exists, an approved escort. Prior approval may be required (ISC, 2019, 2025). Ontario's Northern Health Travel Grant partly repays eligible northern residents who travel at least 100 km one way to the nearest specialist or ministry-funded health facility for care not available locally (Government of Ontario, 2026b).

Travel separates people from family, language, food and community. Inuit patients travelling from Nunavut to Ottawa for cancer care reported having little say or support in decisions and leaned on their escorts for everyday choices (Jull et al., 2021). The nurse can ask who is travelling with the patient, include the escort in teaching, arrange an interpreter and plan the trip home early. Chapter 2 explores these issues further.

1.3 The Medical-Surgical Team and Scope of Practice

On a medical-surgical unit, no nurse works alone. A patient recovering from bowel surgery may see a registered nurse, a practical nurse, a personal support worker, a physician, a physiotherapist and a pharmacist before lunch. Safe care depends on each person knowing what they may do, what they are able to do well, and what the setting allows. This section introduces the team and then explains how Ontario nurses decide whether an activity is within their scope.

The Nursing Team

In Ontario, the College of Nurses of Ontario (CNO) regulates three categories of nurse: RNs, RPNs and NPs. All three practise nursing, and all three must meet CNO's practice standards. They differ in entry education, in the controlled acts the law gives them, and in the depth of knowledge that underpins their practice.

An RN enters practice with a baccalaureate degree in nursing, and an RPN with a practical nursing diploma (CNO, n.d.-g). Outside Ontario, most provinces and territories call the practical nurse an LPN (see section 1.1). The letters RPN also mean something else in much of the country. In the four western provinces, Yukon and several other jurisdictions, RPN stands for **registered psychiatric nurse**, a separate regulated profession (CIHI, 2026c). This book uses "PN" for the general role and "RPN" only for Ontario's registered practical nurse.

An NP is an RN with graduate-level education who has added legislated authority to diagnose, order tests and prescribe. Since July 1, 2026, Ontario has registered NPs in a single class instead of by specialty (CNO, n.d.-i). On a medical-surgical unit, an NP may manage a group of inpatients alongside physicians, depending on the hospital.

The nursing team also includes **unregulated care providers (UCPs)**, people who give care but are not regulated under the Regulated Health Professions Act, 1991 (RHPA). UCPs have no legally defined scope of practice. Their employer sets their role and the tasks they may do (CNO, n.d.-k). In Ontario, the most common UCP is the **personal support worker (PSW)** (Figure 1.5). Since

December 1, 2024, PSWs can choose to register with the Health and Supportive Care Providers Oversight Authority (HSCPOA). Registration is voluntary, the title is not protected, and the authority sets no scope of practice. A nurse's accountability is the same whether or not a PSW is registered (CNO, 2024). Other provinces differ. Since February 2, 2026, Alberta has regulated health care aides under its Health Professions Act, through the College of Licensed Practical Nurses and Health Care Aides of Alberta, and the title "health care aide" is now protected (College of Licensed Practical Nurses and Health Care Aides of Alberta [CLHA], n.d.; Government of Alberta, n.d.). The nurse therefore checks the rules where they work. Table 1.2 summarizes the Ontario nursing team.

Figure 1.5 A health care assistant helps a patient with fluids. Unregulated care providers, such as PSWs in Ontario, give much of the personal care on medical-surgical units, within the role their employer sets. (credit: “A healthcare assistant pouring water for a patient” by Adrian Wressell, Heart of England NHS FT/Wellcome Collection, CC BY 4.0)

Table 1.2 Members of the medical-surgical nursing team in Ontario (CNO, n.d.-g, n.d.-i, n.d.-k, 2024)

Role	Regulated by (Ontario)	Entry education	Typical medical-surgical responsibilities
Registered nurse (RN)	College of Nurses of Ontario	Baccalaureate degree in nursing	Assesses and plans care for an assigned group of patients, including those whose condition is complex or changing; leads or coordinates care; acts as a resource for RPNs and other team members; may be charge nurse
Registered practical nurse (RPN)	College of Nurses of Ontario	Practical nursing diploma	Assesses, plans, gives and evaluates care for an assigned group of patients; consults the RN or another team member as a patient's needs change; may lead and direct UCPs
Nurse practitioner (NP)	College of Nurses of Ontario	RN plus graduate-level NP education	Assesses, diagnoses, orders tests and treatments, and prescribes within NP scope; collaborates with physicians and nurses in managing inpatients
Personal support worker (PSW), an unregulated care provider	Not regulated under the RHPA; voluntary registration with HSCPOA	Set by the employer	Helps with hygiene, mobility, eating and toileting; measures and reports findings when the employer's role description allows; reports changes to the nurse

The Interprofessional Team

Nurses are at the bedside around the clock, so they often notice change first and connect the team. Physicians, including hospitalists (physicians who care for hospital inpatients) and surgeons, diagnose and direct medical and surgical treatment. Pharmacists review medication orders, check for interactions and advise on dosing. Physiotherapists and occupational therapists help patients regain mobility and daily function and plan for safe discharge. Dietitians assess nutrition and plan feeding. Social workers support patients and families with coping, finances and discharge arrangements. Respiratory therapists manage airways, oxygen and ventilation and often attend urgent calls. Spiritual care providers support patients and families of any faith or none. Good collaboration means sharing findings early and respecting each person's expertise.

Scope of Practice: Authority, Competence and Context

Scope of practice is the range of activities a nurse is permitted and able to perform safely. CNO's Scope of Practice standard, in effect since July 1, 2023, asks every nurse to consider three things before acting: authority, competence and context (CNO, 2025e). A nurse needs all three. Having legal authority does not make an activity safe if the nurse lacks the skill, and having the skill does not help if the setting does not allow it.

Authority comes from law. The RHPA sets the framework for all regulated health professions in Ontario and lists **controlled acts**, activities that can cause harm if done by someone without the right training and that only authorized people may perform. The Nursing Act, 1991 describes nursing practice and authorizes RNs and RPNs to perform five controlled acts. These include a procedure below the dermis or a mucous membrane, giving a substance by injection or inhalation, and putting an instrument, hand or finger beyond specified body openings (CNO, 2025e). For most controlled acts, a nurse needs an **authorizing mechanism**. An order may be a **direct order**, given for one patient (usually in writing), or a **directive**, written by an authorized provider in advance to apply to any patient who meets set conditions. Through **delegation**, a professional who holds the authority for a controlled act, and can perform it competently, passes that authority to someone who does not hold it. Through **initiation**, a regulation under the Nursing Act, 1991 lets RNs and RPNs decide on their own to perform certain acts, such as some wound care. Initiation is not available everywhere. Nurses cannot initiate controlled acts in public hospitals, because the Public Hospitals Act, 1990 requires orders for treatment there (CNO, 2025e). Since December 4, 2023, RNs who complete CNO-approved education may prescribe certain medications. This authority is not part of entry-level practice and cannot be used in public hospitals (CNO, n.d.-d; Government of Ontario, 2023b). Finally, an employer may narrow a nurse's scope through policy but can never widen it beyond what the law and CNO allow.

Competence is the knowledge, skill and judgment needed to perform an activity safely. It belongs to the individual nurse and changes over time. Two nurses with the same title may have different competence. Each nurse reflects on their practice, identifies learning needs and takes part in CNO's Quality Assurance Program, which the RHPA requires (CNO, 2025e). A nurse who is not competent to perform an activity does not perform it. Instead, the nurse seeks help, learns the skill or transfers care.

Context is the setting in which care happens: the patient's needs, the unit, employer policy, staffing, equipment and the support available. A nurse may be authorized and competent to do something that is still unsafe on a particular unit at a particular time. When an employer policy conflicts with a CNO standard, the nurse's first accountability is to the standard (CNO, 2025e). Table 1.3 turns the three elements into questions.

Table 1.3 Authority, competence and context: questions the nurse asks before acting (CNO, 2025e)

Element	Questions to ask	Example on a surgical unit
Authority	Is this a controlled act? Is it authorized to my category of nurse? Do I have an order, a directive or delegation? Does setting-specific law apply?	An RPN finds that a surgical wound needs irrigation and packing. This is a controlled act the RPN is authorized to perform, but in a public hospital the RPN needs an order and cannot initiate it.
Competence	Do I know why this is being done, its risks and what to watch for? Have I done it before and kept my skill current? Can I manage what might go wrong?	An RN has never cared for a patient with a new epidural infusion. The RN asks the educator for teaching and a colleague's support before taking the assignment.
Context	Do employer policies allow it here? Are the right equipment, staff and backup available? Has the patient's condition changed what is needed?	An RPN's patient becomes unstable at night. Policy requires the RN to assume care when a patient meets rapid response criteria, so the RPN consults the RN at once.

Assignment, Consultation and Escalation

CNO's Scope of Practice standard applies to every nurse, whatever the category. It does not divide patients into "RN patients" and "RPN patients." It asks every nurse to judge whether the patient's condition calls for the activity and to consult or transfer care when that is needed for safety (CNO, 2025e). Many hospitals build assignment rules on top of this. A common employer practice is to assign patients whose condition is unstable or changing quickly to RNs and to expect RPNs to consult the RN as a patient's needs change. These are employer decisions, not CNO rules, and they vary between hospitals.

One rule applies to everyone. Any nurse who sees a patient deteriorating acts at once and escalates. The RPN who notices a falling blood pressure does not wait for the RN to discover it. The RPN begins care within their scope, tells the RN and calls for help using the unit's escalation process. Chapter 6 covers early warning scores, structured communication and rapid response in full.

Nurses also assign work to UCPs. When assigning a task, the nurse is accountable for assessing the patient, the environment and the risks, and for confirming that the UCP can do the task. If the task is new to the UCP, the nurse teaches or supervises, and afterward the nurse follows up (CNO, n.d.-k). A nurse may also delegate a controlled act the nurse is authorized and competent to perform, such as an injection, if the delegation requirements are met. The nurse remains responsible for the decision and for the patient's ongoing nursing care (CNO, 2025e, 2026b).

Standards change. On September 24, 2026, CNO's Council approved revised Scope of Practice and Medication standards that take effect March 1, 2027. Under the revisions, an authorized provider must assess a patient before writing an order for that patient, and the rules for delegation are spelled out more clearly. Aesthetic services get their own rules: a nurse who delegates an aesthetic procedure must be on site for all of it, and any treatment there that involves a prescription drug or a controlled act needs an order for the individual patient, not a directive. Some things do not change. A nurse who delegates is still accountable for the patient's ongoing care, and RNs and RPNs still need no delegation to carry out the controlled acts the law already gives them (CNO, 2026b, 2026d). Students should check CNO's website for the current version of any standard.

SCOPE IN PRACTICE

Who Cares for Mr. Desjardins Now?

Mr. Desjardins, 68, is on postoperative day 1 after an open colectomy. At 0200, the RPN assigned to him finds a heart rate of 128, a blood pressure of 88/52, cool hands and a urine output of 10 mL in the last hour.

- **Authority:** The RPN is authorized to give intravenous (IV) fluids and injections when they are ordered, so authority is not the barrier. In a public hospital, though, every new treatment still needs an order.
- **Competence:** The RPN can recognize that this is shock until proven otherwise. Depending on the RPN's own knowledge and experience, managing a patient whose condition is changing minute by minute, while also caring for four other patients, may be more than the RPN can safely do alone.
- **Context:** The hospital's policy says that a patient who meets rapid response criteria is cared for by an RN, with the RPN's help. The surgeon is in the operating room.

The RPN stays with Mr. Desjardins, checks that his IV is running as ordered and calls the RN to the bedside. The RN takes over his care and calls the rapid response team. The RPN gives an SBAR (Situation, Background, Assessment, Recommendation) handover, then continues to help. In another hospital or province, the policy might divide the work differently. In every setting, the nurse who sees the change acts and escalates.

PRACTICE STORY

The Night Mrs. Kowalski Changed

Names and details are fictional; this is a composite story.

Nurse: Danielle Thériault, RPN. Years in practice: 7. Setting: medical unit, community hospital, eastern Ontario.

Mrs. Kowalski, 86, was on day 2 of treatment for pneumonia. At the start of my night shift she was chatty and told me about her great-grandchildren. She was on 2 L/min of oxygen by nasal prongs.

At 0300 I went in for vital signs. She was picking at her blanket and asked me why her late husband had not come to visit. I knew from her daughter that this was not her normal. Her respiratory rate was 28, up from 18 at 2300. Her oxygen saturation was 89%, her heart rate 108 and her temperature 38.3 °C. Her blood pressure was 112/64, lower than her usual.

On their own, none of these numbers looked dramatic. Together, they worried me. I checked her prongs, sat her up and went to find Marco, the RN on our side of the unit.

I used SBAR. "Situation: Mrs. Kowalski in room 14 has new confusion and her respiratory rate has gone from 18 to 28 since 2300. Background: she's 86, day 2 of treatment for pneumonia, on 2 litres. Assessment: her sats are 89%, heart rate 108, temperature 38.3, and her pressure is lower than her baseline. I think she's getting worse, maybe sepsis. Recommendation: I'd like you to see her now, and I think she meets our rapid response criteria."

Marco came straight away and called the rapid response team. The respiratory therapist increased her oxygen, and the physician ordered blood work and a chest X-ray. Under our unit's policy, Marco took over her care, and I helped while keeping up with my

other patients.

In the morning, Mrs. Kowalski was more settled. Her daughter thanked me for noticing. I told her that noticing is part of the job, but so is knowing when to bring in someone else.

Reflect: Which of the three elements of scope (authority, competence or context) led Danielle to consult the RN rather than keep managing Mrs. Kowalski's care alone? What would she do if the RN was busy with another emergency?

1.4 Clinical Judgment: The Clinical Judgment Measurement Model

Every chapter of this book asks the same question: what should the nurse notice, think and do next? This section introduces the framework the book uses to answer it.

What Clinical Judgment Is

Clinical judgment is the reasoning a nurse uses to make sense of a patient's situation and decide how to respond. It draws on knowledge, experience and what the nurse observes. The National Council of State Boards of Nursing (NCSBN), the organization that develops the National Council Licensure Examination (NCLEX), describes clinical judgment as the observable result of critical thinking and decision-making, and as a repeating process rather than a single act (NCSBN, 2026). A nurse who notices that a postoperative patient is more restless, links it to a rising heart rate, considers bleeding and acts on that concern is using clinical judgment. So is the nurse who later checks whether the action worked.

Clinical judgment matters on medical-surgical units because patients' conditions change, sometimes slowly and sometimes fast. A single abnormal value may mean little, but a pattern of small changes can signal serious trouble. Good judgment links the signs and turns them into timely action.

The NCSBN Clinical Judgment Measurement Model

NCSBN created the **Clinical Judgment Measurement Model (CJMM)** to measure clinical judgment in a licensing exam. The work grew from NCSBN's 2013–2014 practice analysis, which found that newly licensed nurses were increasingly expected to make complex decisions (NCSBN, n.d.-c). The model drew on research in nursing, cognitive psychology and decision science. Building it took the work of over 100 nursing experts and response data from over 200,000 NCLEX candidates (NCSBN, n.d.-a). After more than a decade of research, NCSBN launched the **Next Generation NCLEX (NGN)**, built on the model, on April 1, 2023 (NCSBN, 2023).

The CJMM is a measurement tool. NCSBN states that the model does not define or redefine clinical judgment and does not replace the nursing process (NCSBN, n.d.-a). Its value for students is that it breaks clinical judgment into six skills that can be practised and assessed one at a time.

Figure 1.6 A nurse records a patient's vital signs, including oxygen saturation from a finger probe. Recognizing cues begins with accurate, regular assessment. (credit: “A nurse carrying out observations on a patient” by Adrian Wressell, Heart of England NHS FT/Wellcome Collection, CC BY 4.0)

The Six Cognitive Skills

- **Recognize cues:** The nurse identifies which information matters. A **cue** is any piece of patient data, such as a vital sign, a laboratory value, a symptom or a family member's comment, that may signal a problem. The nurse separates normal from abnormal and relevant from irrelevant (Figure 1.6).

- **Analyze cues:** The nurse groups related cues and links them to the patient's condition. Fever, a productive cough and crackles in one lung base belong together. The nurse begins to form a **hypothesis**, a possible explanation that fits the cues.
- **Prioritize hypotheses:** The nurse ranks the possible explanations by how likely and how dangerous each is, and how urgently each must be addressed.
- **Generate solutions:** The nurse names the outcomes they want and identifies actions that would achieve them, including actions that would rule a hypothesis in or out.
- **Take action:** The nurse carries out the chosen actions, which include interventions, communication with the team and documentation.
- **Evaluate outcomes:** The nurse compares what happened with what was expected and decides whether to continue, change or escalate the plan.

The six skills form a cycle, not a straight line. New cues appear during evaluation, and the nurse begins again. Table 1.4 applies each skill to one patient.

Table 1.4 The six cognitive skills of the CJMM applied on a medical unit (NCSBN, 2026)

Skill	What the nurse does	Example
Recognize cues	Picks out the findings that matter from everything available	A 74-year-old admitted with heart failure has gained 1.8 kg since yesterday, has new ankle edema and is short of breath lying flat
Analyze cues	Links findings to each other and to the patient's history	The nurse connects weight gain, edema and orthopnea with fluid overload from worsening heart failure
Prioritize hypotheses	Ranks explanations by likelihood, risk and urgency	Fluid overload affecting breathing is ranked above a less urgent concern such as poor appetite
Generate solutions	Sets expected outcomes and plans actions within scope	Raise the head of the bed, check oxygen saturation, review fluid intake and the medication record, and plan to notify the physician
Take action	Carries out the plan, communicates and documents	The nurse positions the patient, reports findings using SBAR, carries out new orders and records assessments
Evaluate outcomes	Compares results with expected outcomes and adjusts	Two hours later, breathing is easier and urine output has risen; the nurse continues to monitor and reports that the plan is working

Clinical Judgment and the Nursing Process

Students often ask how the CJMM fits with the nursing process (assessment, analysis or diagnosis, planning, implementation and evaluation). The two are closely related. NCSBN built the model on a nursing process and did not intend it to replace one (NCSBN, n.d.-a). NCSBN does not publish a step-by-step match, but the two line up roughly as follows. Recognizing and analyzing cues happen during assessment and analysis. Prioritizing hypotheses and generating solutions happen during planning. Taking action is implementation, and evaluating outcomes is evaluation. The CJMM adds detail inside the nursing process. It makes the thinking between the steps visible, especially the step of ranking possible explanations before choosing what to do.

How This Book and the Licensing Exams Use the Model

This book uses the six skills as its teaching framework for nursing care. In every clinical chapter, the nursing care sections move from cues, through possible explanations and priorities, to actions and evaluation. Clinical Judgment boxes work through one patient step by step.

Each licensing exam assesses this kind of reasoning in its own way. The NCLEX for RNs (NCLEX-RN) is built on the CJMM. Every candidate answers three case studies of six linked items, one item for each skill in order, along with stand-alone items (NCSBN, 2021, 2026). Practical nursing exams test the same reasoning in traditional formats. The Regulatory Exam – Practical Nurse (REx-PN), which practical nursing graduates write to register in Ontario and British Columbia, uses multiple-choice, multiple-response, calculation, exhibit and graphic items. Its 2027 test plan expects candidates to apply clinical decision-making and critical thinking (NCSBN, 2027). The Canadian Practical Nurse Registration Examination (CPNRE), used in the other provinces and territories except Quebec, presents 40% to 60% of its multiple-choice questions as case-based items tied to a scenario, and it tests

critical thinking as one of three cognitive levels (CLHA, 2026). Whichever exam a student writes, practising the six skills on real patient situations is good preparation.

CLINICAL JUDGMENT

Postoperative Day 1 After a Bowel Resection

Ms. Okonkwo, 58, weighs 75 kg and is on postoperative day 1 after a sigmoid resection. Her orders say to notify the surgeon if urine output is below 30 mL/h for two hours.

- **Recognize cues:** At 1000, her heart rate is 118 (76 before surgery), blood pressure 104/66 (130/80 before surgery), respiratory rate 22, temperature 37.8 °C and oxygen saturation (SpO2) 95% on room air. Urine output has been 15 mL/h for the past two hours. She rates her abdominal pain 7/10. Her abdomen is more distended than at 0600. Her hemoglobin this morning was 104 g/L, down from 131 g/L before surgery.
- **Analyze cues:** Tachycardia, a lower blood pressure and low urine output suggest reduced circulating volume. The fall in hemoglobin, rising pain and distension raise further concerns.
- **Prioritize hypotheses:** Hypovolemia, from bleeding or from fluid shifts, is the most urgent hypothesis. Anastomotic leak and early sepsis are less likely on day 1 but dangerous, so they stay on the list. Uncontrolled pain can raise heart rate but does not explain the falls in blood pressure and hemoglobin.
- **Generate solutions:** Expected outcomes are a heart rate below 100, urine output at or above the ordered minimum and stable hemoglobin. Planned nursing actions: reassess vital signs, the wound and any drain; check that the IV is patent and running at the ordered rate; check for urinary retention as policy allows; and notify the surgeon now.
- **Take action:** The nurse calls the surgical resident using SBAR and asks for an assessment. The resident orders a fluid bolus and blood work, and the nurse carries out the orders and documents. The nurse also treats her pain as ordered.
- **Evaluate outcomes:** One hour later, her heart rate is 102, her blood pressure 114/70 and her urine output 35 mL for that hour. Repeat hemoglobin is 101 g/L. She is improving but not stable. The nurse continues close monitoring and will call again if her heart rate climbs, her urine output falls or her abdomen worsens.

GOING DEEPER

Inside the CJMM and Next Generation NCLEX Items

Required for RN students; optional for PN students.

The CJMM is drawn in layers, from the broadest context to the most specific factors (Muntean & Betts, 2026; NCSBN, n.d.-a).

- **Layer 0:** The context. A patient has needs, and the nurse must make decisions about them.
- **Layer 1:** Clinical judgment as a whole, which is too broad to measure directly.
- **Layer 2:** A repeating loop of forming hypotheses, refining hypotheses, and acting and evaluating.
- **Layer 3:** The six cognitive skills. This is the level at which NCLEX items are written and classified.
- **Layer 4:** Factors that shape judgment. Some are in the environment (such as time pressure, resources or the medical record) and some are in the person (such as knowledge, skills or level of experience) (Betts et al., 2019; NCSBN, 2020).

NGN items appear in two ways. A **case study** presents one patient whose information unfolds over six items, ordered from recognizing cues to evaluating outcomes (NCSBN, 2021, 2026). **Stand-alone items** stand on their own. Two stand-alone formats, the bow-tie and the trend item, each ask the candidate to use several skills at once (NCSBN, 2021; Simpson et al., 2023). Item formats include extended multiple response, matrix or grid, drag and drop, drop-down (both with cloze, or fill-in-the-blank, versions), highlight, bow-tie and trend (Betts et al., 2019; Boev, 2022; NCSBN, 2022). Items with more than one correct answer can earn partial credit. NCSBN uses three rules (Muntean & Betts, 2026; NCSBN, n.d.-b). Under plus/minus scoring, a point is gained for each correct choice and lost for each incorrect one, with a floor of zero. Under zero/one scoring, each correct response earns a point and incorrect ones cost nothing. Under rationale scoring, a point is earned only when both parts of a linked pair, such as a cause and its effect, are correct.

1.5 Professional, Legal and Ethical Foundations

This section is the book's main reference for nursing law and ethics. Ontario is the worked example; details differ elsewhere, and Quebec, a civil law jurisdiction, sets out consent to care in its Civil Code.

Self-Regulation and the College of Nurses of Ontario

In Ontario, nursing is a **self-regulated profession**: the government allows the profession to govern itself on condition that it puts the public interest first. CNO became an independent regulatory college in 1963 (CNO, 2023) and now regulates RNs, RPNs and NPs (see section 1.3) under the RHPA and the Nursing Act, 1991 (CNO, n.d.-a). CNO exists to protect the public, not to advocate for nurses: it sets entry requirements and practice standards, runs a quality assurance program and acts on concerns about nurses' conduct (CNO, n.d.-j).

CNO's **Code of Conduct**, the overarching practice standard, applies to every Ontario nurse in every role and setting, and CNO considers a breach of it professional misconduct (CNO, n.d.-b). Its six principles, in summary (CNO, 2026a):

- Respect patients' dignity, privacy and informed decisions.
- Give inclusive, culturally safe care through cultural humility (Chapter 2).
- Give safe, competent care within one's competence and scope.
- Collaborate respectfully with the team, including online.
- Act with integrity in patients' best interests, including privacy, boundaries and protection from abuse.
- Maintain public confidence in nursing, including by reporting errors, unsafe or unethical conduct and system problems, whether or not harm resulted.

The CNA Code of Ethics

The Canadian Nurses Association (CNA) released its *Code of Ethics for Nurses* on July 14, 2025, replacing the 2017 code. It applies to all regulated nurses: licensed and registered practical nurses, RNs, NPs and registered psychiatric nurses (CNA, 2025a). It is organized around seven values, each with guiding principles (CNA, 2025b) (Table 1.5).

Table 1.5 The seven values of the CNA Code of Ethics for Nurses (2025) in medical-surgical practice (Values from CNA, 2025b; examples are original)

Value	Example in medical-surgical practice
Honouring the dignity and autonomy of all people	A capable, informed patient declines a feeding tube after a stroke; the nurse respects the decision and keeps offering support.
Valuing relationships and humanizing care	Before a below-knee amputation, the nurse asks what worries the patient most and what matters to them in recovery.
Maintaining integrity and accountability in nursing practice	A nurse who realizes a scheduled antibiotic dose was missed reports it at once and completes an incident report.
Pursuing truth and reconciliation	A Cree patient asks for an Indigenous patient navigator and a smudging ceremony; the nurse arranges both and considers how past harms may affect trust (Chapter 2).
Promoting social justice	For a patient without stable housing being discharged after cellulitis, the nurse raises wound care needs with the team and requests a social work referral.
Providing competent professional nursing practice	Assigned an unfamiliar chest drainage system, the nurse reviews the policy and asks an experienced colleague to check the set-up.
Preserving privacy and confidentiality	The nurse discusses a new cancer diagnosis in a private room and does not open the chart of a neighbour admitted to another unit.

Consent and Capacity

Ontario's Health Care Consent Act, 1996 (HCCA) requires consent to treatment, except in an emergency as the Act allows. **Informed consent** is valid when it relates to the treatment, is informed, is voluntary and is not obtained by misrepresentation or fraud. It is informed when the person has received what a reasonable person would need to know about the treatment's nature, expected benefits, material risks and side effects, alternatives and the likely results of not having it, and has had their questions answered (CNO, 2025b; HCCA, 1996). Consent may be express or implied (such as holding out an arm for a blood pressure check) and may be withdrawn at any time.

The practitioner who proposes a treatment obtains consent: the surgeon for surgery, the nurse for nursing treatments such as a dressing change. One practitioner may obtain consent to a plan of treatment for the whole team (CNO, 2025b).

Capacity means a person can understand the information relevant to a treatment decision and appreciate the reasonably foreseeable consequences of deciding or not deciding. Capacity is presumed unless there are reasonable grounds to believe otherwise; it is treatment-specific, can change over time and has no minimum age (CNO, 2025b). A patient with delirium may be unable to decide about surgery yet able to accept help with a meal.

When a patient is incapable for a treatment, a **substitute decision-maker (SDM)** decides. The HCCA ranks who may act: a court-appointed guardian of the person; an attorney for personal care (named under the Substitute Decisions Act, 1992); a representative appointed by the Consent and Capacity Board; a spouse or partner; a child aged 16 or older, or a parent (or children's aid society); a parent with only a right of access; a brother or sister; and any other relative. The highest-ranked person who is capable, available and willing acts; the Public Guardian and Trustee decides when no one else can. The SDM follows any applicable wish the patient expressed while capable and at least 16; otherwise, the SDM decides in the patient's best interests (CNO, 2025b).

In an emergency (apparent severe suffering, or risk of serious bodily harm without prompt treatment), treatment may begin without consent if waiting for an incapable patient's SDM would prolong the suffering or risk, or if a communication barrier cannot be overcome despite reasonable efforts. It may not be given if there are reasonable grounds to believe the patient, while capable and at least 16, expressed a wish to refuse it. Efforts to reach the SDM or to communicate continue (CNO, 2025b; HCCA, 1996).

Witnessing a consent signature is not obtaining consent. CNO's position is that whoever requires the consent should obtain the signature, which has no value unless the patient was informed (CNO, n.d.-h). If a patient does not understand or has changed their mind, the nurse does not proceed, tells the practitioner who proposed the treatment, advocates for the patient and documents.

Privacy and Confidentiality

Ontario's Personal Health Information Protection Act, 2004 (PHIPA) protects personal health information. A **health information custodian** is a person or organization, such as a hospital, that has custody or control of that information while providing care. Nurses employed by a hospital are usually its **agents**, acting on its behalf (CNO, 2025a).

The **circle of care** is not a term defined in PHIPA. It is shorthand for situations in which custodians may assume a patient's implied consent to collect, use or share information among custodians for the patient's care, provided the patient has not withheld or withdrawn consent (Information and Privacy Commissioner of Ontario [IPC], 2015). Family members and friends are not custodians, so the nurse generally needs the consent of the capable patient (or the SDM) before discussing the patient's health with them.

Patients may restrict how their information is shared, informally called a **lockbox**. If locked information is reasonably necessary for care, the custodian must tell the receiving custodian that information has been withheld, without revealing it (IPC, 2005).

Snooping, looking at records without a professional reason, is a privacy breach whatever the motive. Custodians must notify affected patients and report certain breaches to the IPC, including any breach for which they must report a regulated professional to that professional's college (IPC, n.d.). Nurses access only the records of patients in their care, never share passwords and report breaches to their workplace privacy contact (CNO, 2025a). They do not post about patients on social media, because a post can identify a patient even without a name.

Documentation

CNO's revised Documentation standard took effect February 1, 2026 (CNO, 2025c). Its three principles are communication, documentation requirements and information security. The nurse documents at the time of care or soon after, never before (Figure 1.7); labels late entries with the date and time of the care; corrects errors without deleting the original; records only care the nurse gave (unless a designated recorder is used); and uses their own login. The nurse also checks technology-generated content for accuracy, obtains the patient's consent before using artificial intelligence for documentation and uses discrimination-free language.

Professional Boundaries

On March 1, 2026, CNO's Professional Boundaries and Nurse-Client Relationships standard replaced the Therapeutic Nurse-Client Relationship standard (CNO, 2025d). It asks nurses to build therapeutic relationships, keep **professional boundaries** (the line where a therapeutic relationship would become personal) and protect patients from all forms of abuse. Keeping boundaries is always the nurse's responsibility, whatever the patient does; both under-involvement (such as avoiding a demanding patient) and over-involvement (such as favouritism) can harm. Nurses do not connect with patients on personal social media, and they generally avoid gifts, accepting at most a token gift and never asking for one.

CNO describes Ontario as having a zero-tolerance standard for sexual abuse of patients by health care providers (CNO, n.d.-c). Any sexual relationship, touching or remark of a sexual nature toward a patient is sexual abuse, whether or not the patient agreed, and, for these rules, a person remains a patient for one year after the relationship ends (CNO, 2025d). Under the Health Professions Procedural Code (Schedule 2 to the RHPA), a nurse who has reasonable grounds, gained in practice, to believe that another regulated health professional (including another nurse) has sexually abused a patient must report in writing to that professional's college within 30 days, or immediately if abuse is likely to continue. The report may name the patient only with the patient's written consent (CNO, n.d.-f; RHPA, 1991).

Figure 1.7 A nurse documents in the electronic health record on a mobile workstation in the patient's room. The patient's face and the screen have been blurred to protect privacy. (credit: modification of "Princess Alexandra Hospital nurse with mobile computer work station" by Kgbo/Wikimedia Commons, CC BY-SA 4.0)

Declining or Discontinuing Care

CNO's Discontinuing or Declining to Provide Care standard requires nurses to provide care that is inclusive, culturally safe and non-discriminatory, and never to abandon or neglect a patient (CNO, 2026c). A nurse may object to specific care on grounds of conscience or religion, but not out of fear, prejudice or convenience. The nurse raises the objection early, does not leave the patient without care, helps transfer care to a provider who does not object and documents the reasons and steps taken. If no alternative can be arranged, the patient's right to care comes first. Chapter 10 discusses medical assistance in dying.

1.6 Safety and Quality in Medical-Surgical Care

Hospitals are generally safe, but harm still happens. In 2025–2026, 1 in 17 acute care hospital stays in Canada involved at least one harmful event, as measured by an indicator of unintended, potentially preventable harm (data exclude Quebec and patients with mental health and substance use diagnoses). The most common were electrolyte and fluid imbalance, urinary tract infection, delirium and pneumonia (CIHI, 2026b).

Patient Safety Incidents

Canada uses shared terms for safety events (Incident Analysis Collaborating Parties, 2012). A **patient safety incident** is an event or circumstance that led to, or could have led to, unnecessary harm to a patient. There are three types:

- **Harmful incident:** the incident reached the patient and caused harm. This term replaces "adverse event."

- **No-harm incident:** the incident reached the patient, but no harm could be detected.
- **Near miss:** the incident did not reach the patient.

Disclosure

Disclosure is the process of telling a patient (or SDM) about a patient safety incident. Canadian guidelines say harmful incidents must always be disclosed. For a no-harm incident, providers consider whether a reasonable patient in that situation would want to be told. Disclosing a near miss is a matter of judgment (Disclosure Working Group, 2011). The first conversation happens as soon as reasonably possible. It shares the facts known so far, includes an apology and explains what will happen next. The most responsible practitioner usually leads it, and the nurses involved often take part. In Ontario, an apology is not an admission of legal fault (Apology Act, 2009).

Just Culture and Systems Thinking

Most incidents arise from weaknesses in systems, not from careless individuals. Look-alike packaging, interruptions, unclear orders and short staffing set up capable nurses to fail. A systems approach asks how and why the safeguards failed. A **just culture** treats honest mistakes and system-induced errors with support and learning, while still holding people accountable for reckless choices (Incident Analysis Collaborating Parties, 2012). Reporting is how organizations learn. As section 1.5 notes, the Code of Conduct expects nurses to report errors, unsafe practice and system problems whether or not harm occurred (CNO, 2026a). Each nurse follows the employer's incident reporting process, reports promptly and records the patient's condition and care in the health record. In many organizations the incident report is a separate document that is not referred to in the chart; employer policy sets the rule.

Figure 1.8 A nurse prepares medications from a locked medication cart. Each medication is checked against the order and the patient before it is given. (credit: “Nurse during a drug administration on a UK hospital ward” by Adrian Wressell, Heart of England NHS FT/Wellcome Collection, CC BY 4.0)

Medication Safety

The Institute for Safe Medication Practices Canada (ISMP Canada) studies medication incidents and publishes ways to prevent them. **High-alert medications** are drugs whose errors are especially likely to cause serious harm. Errors with them are not necessarily more frequent, but their effects are more severe. Examples include insulin, opioids, anticoagulants, chemotherapy and parenteral nutrition. Safeguards include standardization, restricted access, warning labels and alerts, and built-in redundancies such as **independent double checks** (ISMP Canada, n.d.-b). In an independent double check, a second practitioner verifies the drug, dose, route and pump settings against the order and does any calculation separately, without seeing the first nurse's answer. The two results are then compared before the drug is given (ISMP Canada, 2016). A check done side by side is less effective, because the second person tends to confirm what they are shown. Even a true double check is not foolproof, so it is one safeguard among several (Figure 1.8).

Canada also has a federal reporting rule. Under the Protecting Canadians from Unsafe Drugs Act (2014), known as Vanessa's Law, hospitals have been required since December 16, 2019 to report serious adverse drug reactions and medical device incidents to Health Canada in writing within 30 calendar days of first documenting them. A reaction is serious if it requires or prolongs hospitalization, causes a congenital malformation, causes persistent or significant disability, is life-threatening or results in death. The duty falls on the hospital, but nurses help by recognizing and clearly documenting suspected reactions (Health Canada, 2023).

CLINICAL SAFETY

Abbreviations and Dose Designations That Cause Errors

ISMP Canada keeps a "Do Not Use" list of abbreviations, symbols and dose designations that have led to serious errors. ISMP Canada advises against them in any medication communication (ISMP Canada, 2006). Examples:

- **"U" for unit:** a handwritten U can look like 0 or 4, turning 4 units into 40. Write "unit."
- **"IU" for international unit:** it can be read as IV or 10. Write "unit."
- **Trailing zero (5.0 mg):** if the decimal point is missed, the dose reads as 50 mg. Write "5 mg."
- **Missing leading zero (.5 mg):** a missed decimal point turns the dose into 5 mg. Write "0.5 mg."
- **"µg" for microgram:** it can be mistaken for mg, a 1,000-fold error. Write "mcg."
- **"D/C":** it can mean discharge or discontinue. Write the full word.
- **Abbreviated drug names, such as "MS" or "MSO4":** these can mean morphine or magnesium sulfate. Write the full generic name.

If an order contains a dangerous abbreviation, the nurse clarifies it with the prescriber before acting.

Infection Prevention and Communication

Routine practices are the infection prevention measures used with every patient during all care. They include risk assessment before each interaction, hand hygiene, personal protective equipment, control of the environment and administrative controls (Provincial Infectious Diseases Advisory Committee [PIDAC], 2025). Hand hygiene is the single most important of these. Ontario's four moments are before first contact with the patient or the patient's surroundings, before an aseptic procedure, after a risk of body fluid exposure, and after contact with the patient or the patient's surroundings. Alcohol-based hand rub is preferred unless hands are visibly soiled (PIDAC, 2014). Chapter 4 covers infection prevention in full.

Poor communication contributes to many incidents, especially at handover, when care passes between shifts, units or settings. Structured tools give each handover a predictable shape so that important information is less likely to be missed. Chapter 6 teaches SBAR and escalation in detail.

Hospital-Acquired Harms

Many harms that start in hospital can be prevented by nursing care. Table 1.6 lists common ones and points to where this book covers them.

Table 1.6 Common hospital-acquired harms and where this book covers them (Original table)

Harm	Why adults in hospital are at risk	Chapter
Falls	Unfamiliar surroundings, sedating medications, low blood pressure on standing, urgency, delirium, and IV lines and tubes that tether the patient	Chapter 8
Pressure injuries	Immobility, long surgeries, friction and shear, moisture, poor nutrition and reduced sensation	Chapter 35
Delirium	Acute illness, older age, dementia, poor sleep, dehydration, some medications and devices such as urinary catheters	Chapter 8
Health care-associated infections	Urinary catheters, central lines, surgical wounds, ventilation and antibiotic exposure	Chapter 4
Fluid and electrolyte imbalance	IV fluids, diuretics, fasting before procedures, vomiting and changes in kidney function	Chapter 3
Venous thromboembolism	Reduced mobility, major surgery, cancer and dehydration	Chapters 7 and 19
Medication incidents	Many medications and prescribers, high-alert drugs, interruptions and changes at transfer and discharge	This chapter and the body-system chapters
Functional decline	Bed rest, restricted mobility, poor nutrition and devices that discourage walking	Chapter 8

Figure 1.9 A hospital identification band. The nurse confirms at least two person-specific identifiers, such as name and date of birth, before giving a medication or treatment (Health Standards Organization, 2024). Identifying details have been blurred. (credit: modification of “Wrist Identification Band” by Whoisjohngalt/Wikimedia Commons, CC BY-SA 4.0)

Quality Improvement Programs

Choosing Wisely Canada works with professional groups to identify tests and treatments that add little value and may cause harm. Its nursing list was developed by CNA (CNA, 2024). Two items apply to almost every surgical unit. Indwelling urinary catheters should not be inserted, or left in place, without a daily assessment of whether they are still needed, because catheters can lead to urinary tract infection, sepsis and delirium. Extra sheets and pads should not be layered under patients on a pressure-redistribution surface, because they reduce its ability to protect the skin.

Accreditation Canada, which accredits many Canadian hospitals, uses **Required Organizational Practices (ROPs)**: standardized practices that an organization must have in place to improve patient safety and reduce risk. ROPs cover areas such as patient identification, the "Do Not Use" abbreviations list, high-alert medications, information transfer at care transitions, falls and pressure injury prevention, and **medication reconciliation** at care transitions, described in section 1.7 (Health Standards Organization, 2024). Nurses meet ROPs every day through their employer's policies, such as completing a medication history on admission or checking two identifiers on the patient's identification band before giving a medication (Figure 1.9).

1.7 Partnering with Patients Across Transitions

Patients are most at risk when they move: from home to hospital, from one unit to another, and from hospital back to the community. As section 1.2 notes, information, medications and plans can be lost at each transition in care, and responsibilities can become unclear. Nurses can make these transitions safer by working with patients and their families as partners.

Health Literacy

Health literacy is a person's ability to find, understand, judge and share health information in ways that support and improve their health (Rootman & Gordon-El-Bihbety, 2008). It depends on the person's skills but also on the situation. A patient who is in pain, frightened, unwell or learning in a second language may struggle with information they would normally manage well. General literacy skills vary widely. In a 2022 international survey, 19% of Canadian adults aged 16 to 65 scored at the two lowest literacy levels (Statistics Canada, 2024). For that reason, nurses use clear communication with every patient rather than trying to guess who needs it.

Practical strategies include:

- **Plain language:** use common words ("blood thinner," then the drug name), short sentences and two or three key points per session.
- **Teach-back:** ask the patient to explain or show, in their own words, what they will do at home, such as "Tell me how you will take this pill when you get home." Teach-back checks how clearly the nurse explained, not how smart the patient is. It works better than asking "Do you understand?" (Agency for Healthcare Research and Quality [AHRQ], 2023).
- **Written and visual support:** use materials written at an easy reading level, with pictures, in the patient's preferred language.

Language Access

Patients with limited English or French need a **professional interpreter**, in person, by video or by telephone, for consent discussions, assessments and teaching. Use of professional interpreters is associated with better communication and clinical care than use of untrained (ad hoc) interpreters (Karliner et al., 2007). Family members, and children especially, should not interpret clinical information: they may leave out or soften bad news, lack medical vocabulary and compromise the patient's privacy.

French is an official language in Canada. Francophone patients may not ask for French services, for example because they expect none to be available. An **active offer** means the provider makes services in French visible and available from the first contact, so the patient does not have to ask. Ontario's French Language Services Act, modernized in 2021, makes the active offer central to French-language services. A regulation on the active offer took effect on April 1, 2023 (Ministry of Francophone Affairs, 2023). The Act applies to the provincial government and its agencies, and to designated organizations, including some hospitals (French Language Services Act, 1990). Société Santé en français, a national network of French-language health networks, offers active offer training (Société Santé en français, n.d.). Simple actions help: greet patients in both languages ("Hello, bonjour"), wear a badge that shows the languages the nurse speaks, and record the patient's preferred language.

Figure 1.10 A weekly pill organizer. A best possible medication history asks how the patient actually takes each medication at home, including what goes into an organizer like this one. (credit: “Heptagonal objects A weekly medicine box” by יוחי טייס/Wikimedia Commons, CC BY-SA 4.0)

Discharge Planning and Medication Reconciliation

As section 1.2 notes, discharge planning begins at admission. On the first day, the nurse asks where the patient lives, who helps at home, how the patient managed before admission and what might delay going home. Planning early helps avoid ALC days (see section 1.2), spent in hospital after acute care is no longer needed, while the patient waits for home care or another setting (CIHI, n.d.).

Medication reconciliation is a structured process in which health care providers, patients and families together make sure that accurate, complete medication information goes with the patient at each transition in care (ISMP Canada, n.d.-c). It starts with a **best possible medication history**: a structured interview with the patient or family plus at least one other reliable source, such as the community pharmacy or a provincial drug record (Figure 1.10). The history covers every medication taken, including non-prescription drugs, vitamins and herbal products. The team compares this history with admission orders, again at transfer between units and again at discharge, and resolves each difference. At discharge, the patient receives an updated medication list and learns what has started, stopped or changed.

Involving Families and Caregivers

Family members and other caregivers often provide much of the care after discharge. In keeping with patient- and family-centred care (see section 1.1), the nurse asks the capable patient who should take part in teaching and planning and what may be shared, and involves those people with the patient's consent. If the patient is incapable, the nurse works with the SDM.

PATIENT EDUCATION

Questions to Ask About Your Medications

ISMP Canada developed a short tool called "5 Questions to Ask About Your Medications" with the Canadian Patient Safety Institute (now part of HEC), Patients for Patient Safety Canada, the Canadian Pharmacists Association and the Canadian Society of Hospital Pharmacists. It invites patients and caregivers to ask about five topics: changes to their medications, which medications to continue, proper use, monitoring and follow-up (ISMP Canada, n.d.-a). The tool is designed for times of change, such as leaving hospital, seeing a doctor or pharmacist, or starting home care. It is available in several languages at https://www.safemedicationuse.ca.

Before discharge, the nurse can show the tool to the patient and the caregiver and encourage them to bring it to their next pharmacy or clinic visit. The nurse then uses teach-back: "Tell me which of your old pills you will stop taking, and why."

LIFESPAN CONSIDERATIONS

Older Adults in Hospital

Older adults are especially vulnerable to the harms of a hospital stay.

- **Functional decline:** many older adults lose the ability to perform a basic activity of daily living, such as bathing, dressing or getting out of bed, during an acute stay. This loss, called hospitalization-associated disability, often persists after discharge (Covinsky et al., 2011). Bed rest, catheters and waiting for help to walk all contribute. Getting the patient up early and often, as ordered, is a key nursing intervention (Figure 1.11).
- **Delirium:** it is among the most common harms in Canadian hospitals (see section 1.6). Nurses screen for it, prevent it and recognize it.
- **Polypharmacy:** older adults often take many medications from several prescribers, which raises the risk of interactions and falls. Careful medication reconciliation is essential.
- **ALC:** a long wait in hospital for home care, long-term care or another setting (see section 1.2) adds to the risks above.

Chapter 8 covers the care of older adults in acute care in depth.

Figure 1.11 An older adult walks with a walking frame and a physiotherapist. Getting up early and often during a hospital stay helps prevent hospitalization-associated disability. (credit: "Female physiotherapist with elderly female patient" by Adrian Wressell, Heart of England NHS FT/Wellcome Collection, CC BY 4.0)

1.8 Using This Book

This book serves two groups of students. RN students prepare for the NCLEX-RN. Practical nursing students prepare for the REx-PN in Ontario and British Columbia, or for the CPNRE in the other provinces and territories except Quebec (see section 1.4). The core text is written for both groups and stands on its own. Going Deeper boxes add the extra depth expected of RN students. End-of-chapter questions are tagged [Core] for all students or [RN] for RN-level content.

Boxes support the text:

- **Going Deeper:** RN-level depth; optional for PN students.
- **Scope in Practice:** applies authority, competence and context to a clinical situation.
- **Canadian Context:** Canadian laws, programs, data and health system features.
- **Clinical Judgment:** works through one patient using the six skills of the CJMM.
- **Clinical Safety:** warnings and practices that prevent harm.
- **Patient Education:** plain-language teaching for patients and families.
- **Lifespan Considerations:** differences for older adults and other age groups.
- **Medications:** key drug classes, nursing actions and monitoring.
- **Practice Story:** a composite first-person account from a nurse, with questions for reflection.

The CJMM described in section 1.4 is the reasoning framework throughout the book. The NCLEX-RN is built on it, and the REx-PN and CPNRE test the same kind of reasoning in traditional item formats. Laboratory values use units from the International System of Units (SI), such as mmol/L, which Canadian laboratories report. Reference ranges vary between laboratories, so nurses always use the range on their own laboratory's report. Drugs are named by their Canadian generic names, and brand names appear only where they help recognition.

Ontario is the worked example for law, regulation and scope of practice. Students in other provinces and territories should check the matching rules where they will practise. This book does not replace employer policy, provincial or territorial law, regulatory college standards or current product monographs. When they differ from this book, they take precedence.

The NCLEX-RN and REx-PN test nursing knowledge and judgment, not provincial law or health system structure. In Ontario, CNO tests that knowledge separately through its **Jurisprudence Examination**. This online, open-book examination covers the legislation, by-laws, practice standards and guidelines that apply to Ontario nurses (CNO, n.d.-e). The legal and professional content in this chapter is a starting point for that examination, not a substitute for studying CNO's own documents.

Chapter 1 Summary

1.1 What Medical-Surgical Nursing Is

- Medical-surgical nursing is the care of adults with acute illness, exacerbations of chronic illness, or surgery and recovery, in hospital and across other settings.
- The illness trajectory (prevention, acute illness, recovery and rehabilitation, chronic management, end of life) is not linear; people may cycle through it many times.
- Patient- and family-centred care is built on partnership; the patient defines family and chooses how others take part.
- Essential care partners provide support the patient values and differ from visitors.
- The nurse's core work includes assessment, surveillance, medication administration, teaching, coordination and advocacy.

1.2 Where Adults Receive Care in Canada

- The Canada Health Act sets five criteria (public administration, comprehensiveness, universality, portability, accessibility) for insured hospital and physician services.
- Outpatient drugs, home care, dental, vision and ambulance coverage vary by province or territory (with a federal dental plan for some uninsured residents), which affects discharge planning.
- Provinces and territories deliver most care; Health Canada, PHAC and Indigenous Services Canada (including NIHB) have federal roles.
- In Ontario, Ontario Health, its six regions, Ontario Health Teams, public hospitals, Ontario Health atHome, long-term care, primary care and public health units work together; other provinces organize care differently.
- ALC describes patients who no longer need acute care but are waiting for another setting; 6.1% of Canadian hospital stays in 2024–2025 included ALC days.

1.3 The Medical-Surgical Team and Scope of Practice

- In Ontario, CNO regulates RNs (baccalaureate entry), RPNs (practical nursing diploma entry) and NPs (graduate-level education; a single class since July 1, 2026). Outside Ontario, practical nurses are usually LPNs, and RPN can also mean registered psychiatric nurse.
- PSWs are unregulated care providers in Ontario, with voluntary registration through HSCPOA. Alberta has regulated health care aides since February 2, 2026, so rules vary by province.
- CNO's Scope of Practice standard asks every nurse to have authority, competence and context before acting. Authority comes from the RHPA and the Nursing Act, through orders, directives, delegation or initiation. Initiation and RN prescribing (in force since December 4, 2023) are not available in public hospitals.

- CNO does not divide patients into RN and RPN patients. Assigning unstable patients to RNs is a common employer practice. Every nurse who sees deterioration acts and escalates.
- Revised Scope of Practice and Medication standards, approved September 24, 2026, take effect March 1, 2027. They clarify delegation and add requirements for patient-specific orders and aesthetic services.

1.4 Clinical Judgment: The Clinical Judgment Measurement Model

- Clinical judgment is how the nurse interprets a situation and decides what to do. It is a repeating process, not a single decision.
- NCSBN built the CJMM to measure clinical judgment. It underpins the Next Generation NCLEX, launched April 1, 2023.
- The six skills are recognize cues, analyze cues, prioritize hypotheses, generate solutions, take action and evaluate outcomes. They fit within the nursing process rather than replacing it.
- This book uses the six skills to teach nursing care in every clinical chapter.
- The NCLEX-RN is built on the CJMM. The REx-PN and CPNRE test the same reasoning through traditional and case-based multiple-choice formats.

1.5 Professional, Legal and Ethical Foundations

- CNO regulates Ontario nurses to protect the public; its Code of Conduct sets six principles that apply to every nurse in every setting.
- The CNA *Code of Ethics for Nurses* (2025) is organized around seven values, from dignity and autonomy to privacy and confidentiality.
- Under the HCCA, valid consent relates to the treatment, is informed and voluntary, and is not obtained by fraud; the practitioner who proposes a treatment obtains consent, and nurses obtain consent for their own nursing care.
- Capacity is presumed and treatment-specific, with no fixed age; incapable patients have an SDM chosen from a ranked list, and emergency treatment without consent is narrowly limited.
- PHIPA allows implied consent within the circle of care among custodians only; patients may lockbox information, and snooping is a reportable breach.
- CNO's revised Documentation (February 1, 2026) and Professional Boundaries and Nurse-Client Relationships (March 1, 2026) standards, the zero-tolerance approach to sexual abuse (with mandatory reporting under the RHPA) and the duty not to abandon patients shape daily practice.

1.6 Safety and Quality in Medical-Surgical Care

- In 2025–2026, 1 in 17 acute care hospital stays in Canada (excluding Quebec) involved at least one harmful event, many of them preventable.
- Patient safety incidents are harmful, no-harm or near misses; harmful incidents are always disclosed, and Ontario's Apology Act, 2009 protects apologies.
- A just culture and systems thinking support reporting and learning from incidents.
- High-alert medications need extra safeguards such as independent double checks; dangerous abbreviations must never be used; hospitals must report serious adverse drug reactions to Health Canada within 30 days under Vanessa's Law.
- Routine practices, structured handover, Choosing Wisely recommendations and Accreditation Canada ROPs help prevent hospital-acquired harms.

1.7 Partnering with Patients Across Transitions

- Nurses use plain language and teach-back with every patient, because health literacy varies and falls with illness and stress.
- Professional interpreters, not family members, support clinical communication; the active offer makes French-language services available without the patient having to ask.
- Discharge planning starts at admission, and medication reconciliation at admission, transfer and discharge prevents medication errors.
- Older adults are at high risk of functional decline, delirium, polypharmacy harms and long ALC stays.

1.8 Using This Book

- One core text serves RN (NCLEX-RN) and PN (REx-PN or CPNRE) students; Going Deeper boxes and [RN] questions add RN-level depth, and the CJMM frames clinical reasoning for all.
- Nine box types, the CJMM, SI units, Canadian generic drug names and Ontario examples organize the book.
- Employer policy, provincial law, college standards and product monographs take precedence; Ontario law is tested on CNO's Jurisprudence Examination.

Key Terms (56)

active offer: Making services in French visible and available from the first contact so that Francophone patients do not have to ask for them.

agent: Under PHIPA, a person, such as a nurse employed by a hospital, who handles personal health information on behalf of a health information custodian.

alternate level of care (ALC): A designation for a patient who remains in a hospital bed but no longer needs acute care and is waiting for a more suitable setting.

authorizing mechanism: A legal means, such as an order, a directive or delegation, that gives a nurse authority to perform a controlled act or other activity the nurse cannot start alone.

best possible medication history: A medication history built from a structured interview with the patient or family and at least one other reliable source, covering all prescribed and non-prescribed medications.

Canada Health Act: The federal law that sets the criteria and conditions provincial and territorial health insurance plans must meet to receive full federal cash contributions for insured health services.

capacity: The ability to understand information relevant to a specific treatment decision and to appreciate the reasonably foreseeable consequences of deciding or not deciding; it is presumed and treatment-specific, and it can change over time.

circle of care: A common term, not defined in PHIPA, for situations in which custodians may assume a patient's implied consent to share personal health information with one another for the patient's health care.

clinical judgment: The reasoning a nurse uses to interpret a patient's situation and decide how to respond, observed as the result of critical thinking and decision-making.

Clinical Judgment Measurement Model (CJMM): NCSBN's layered framework for measuring clinical judgment on the NCLEX; its core is six cognitive skills from recognizing cues to evaluating outcomes.

Code of Conduct: CNO's overarching practice standard; it summarizes the behaviour and ethical conduct the public can expect from every Ontario nurse.

competence: The knowledge, skill and judgment an individual nurse needs to perform an activity safely; it changes over time and is maintained through continuing learning.

controlled act: An activity listed in the Regulated Health Professions Act, 1991 that may cause harm and that only authorized people may perform.

cue: A piece of patient information, such as a sign, symptom, test result or comment, that may signal a problem.

delegation: Passing the authority for a controlled act from a regulated professional who holds it, and can perform the act competently, to someone who does not hold it; the delegating professional stays accountable.

direct order: An order given for one specific patient, usually in writing and verbally only in limited situations.

directive: An order written in advance by an authorized provider for an activity that applies to any patient who meets specified conditions.

disclosure: The process of telling a patient or substitute decision-maker that a patient safety incident occurred, what is known and what will happen next.

essential care partner: A person the patient or substitute decision-maker identifies to give the physical, psychological and emotional support the patient considers important, whose role differs from that of a visitor.

harmful incident: A patient safety incident that reached the patient and caused harm.

health information custodian: Under PHIPA, a person or organization, such as a hospital, that has custody or control of personal health information while providing health care.

health literacy: A person's ability to find, understand, judge and share health information in ways that support and improve their health.

high-alert medication: A drug, such as insulin, an opioid or an anticoagulant, whose errors are especially likely to cause serious harm.

hypothesis: A possible explanation for a group of cues that the nurse tests against further information.

illness trajectory: The path a health condition takes over time, from prevention through acute illness, recovery, chronic management and end of life, and the care needed at each point.

independent double check: A safety check in which a second practitioner separately verifies a medication, dose, route, calculation and pump settings against the order without seeing the first practitioner's result, before the results are compared.

informed consent: Agreement to a treatment that relates to that treatment, is given voluntarily, is not obtained by misrepresentation or fraud, and is based on information about the treatment's nature, benefits, risks, side effects, alternatives and the consequences of refusing it.

initiation: The authority, set out in regulation, for RNs and RPNs to decide on their own to perform certain controlled acts without an order; not available in Ontario public hospitals.

insured health services: Under the Canada Health Act, medically necessary hospital services, medically required physician services and surgical-dental services that require a hospital.

Jurisprudence Examination: CNO's online, open-book examination on the legislation, by-laws, practice standards and guidelines that apply to Ontario nurses.

just culture: An organizational culture that responds to honest errors with learning and system improvement while holding people accountable for reckless choices.

licensed practical nurse (LPN): The title for a practical nurse in most Canadian provinces and territories outside Ontario.

lockbox: An informal term for a patient's instruction that limits how some or all of their personal health information may be used or shared.

medical-surgical nursing: The nursing care of adults who are acutely ill, living through an exacerbation of a chronic illness, or preparing for or recovering from surgery, in hospital and across other settings.

medication reconciliation: A structured process in which providers, patients and families make sure accurate, complete medication information goes with the patient at admission, transfer and discharge.

multimorbidity: Living with two or more chronic health conditions at the same time.

near miss: A patient safety incident that did not reach the patient.

Next Generation NCLEX (NGN): The version of the NCLEX, launched in April 2023, that uses case studies and new item formats to measure clinical judgment.

no-harm incident: A patient safety incident that reached the patient without detectable harm.

Non-Insured Health Benefits (NIHB): An Indigenous Services Canada program that covers specified health benefits, including medical transportation, for registered First Nations and recognized Inuit when other plans do not.

Ontario Health Team: A group of local providers, such as hospitals, primary care, home and community care and long-term care, that plans and delivers connected care for patients in a local area of Ontario.

patient safety incident: An event or circumstance that led to, or could have led to, unnecessary harm to a patient.

patient- and family-centred care: An approach to planning, giving and evaluating care built on partnership among patients, the people they define as family, and health care providers.

personal support worker (PSW): In Ontario, the most common unregulated care provider; PSWs may register voluntarily with the Health and Supportive Care Providers Oversight Authority, which sets no scope of practice.

professional boundaries: The limits that keep a nurse-patient relationship therapeutic rather than personal; keeping them is always the nurse's responsibility.

professional interpreter: A trained interpreter who conveys health information accurately and confidentially between languages; preferred over family members.

registered psychiatric nurse: A separately regulated nursing profession, found in the western provinces, Yukon and several other jurisdictions, that also uses the letters RPN.

Required Organizational Practices (ROPs): Standardized patient safety practices that organizations accredited by Accreditation Canada must have in place.

routine practices: The infection prevention and control practices used with every patient during all care, including risk assessment, hand hygiene, personal protective equipment, environmental controls and administrative controls.

scope of practice: The range of activities a nurse is permitted and able to perform safely, shaped by authority, competence and context.

self-regulated profession: A profession that the government allows to govern its own members, on condition that it acts in the public interest; in Ontario, nursing is regulated through the College of Nurses of Ontario.

snooping: Accessing a person's health information without a professional reason; a privacy breach whatever the motive.

substitute decision-maker (SDM): The person who makes a treatment decision for a patient who is incapable for that decision, chosen according to the ranked list in Ontario's Health Care Consent Act, 1996.

teach-back: A technique in which the patient or caregiver explains or shows, in their own words, what they have been taught; it checks how clearly the nurse taught.

transition in care: Any move of a patient between settings or care teams, including admission, transfer and discharge.

unregulated care provider (UCP): A care provider who is not regulated under the Regulated Health Professions Act, 1991 and has no legally defined scope of practice; in Ontario, most often a personal support worker.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

1. [CORE] A 58-year-old patient in Ontario with no private drug plan is being discharged after treatment for a heart attack. The patient says, "My pills were free in here. Will the new prescriptions be free at home too?" Which response by the nurse is most accurate?

a. "Yes. The Canada Health Act requires every province to pay for all prescribed medications you need."

b. "Hospital drugs are covered; home drug coverage depends on provincial programs. Let's check."

c. "No. Once you leave hospital, no prescription drugs are ever publicly covered in Canada."

d. "Yes. Under portability, your hospital coverage continues for three months after discharge."

Answer: b — Drugs given in hospital are part of insured hospital services under the Canada Health Act, but coverage of drugs taken at home is decided by each province or territory and often depends on age, income or other criteria (section 1.2). Option a is wrong because the Act does not require coverage of outpatient prescriptions. Option c is wrong because provinces do run public drug programs, such as the Ontario Drug Benefit program for people 65 and older and some younger groups. Option d misstates portability, which concerns coverage when residents move or travel, not coverage after discharge.

2. [CORE] A resident of Nova Scotia develops appendicitis while visiting family in Ontario and has an emergency appendectomy in an Ontario hospital. The patient is not billed, and the hospital is paid through the patient's home provincial plan. Which Canada Health Act criterion does this situation best illustrate?

a. Universality

b. Comprehensiveness

c. Portability

d. Public administration

Answer: c — Portability requires provinces to keep paying for insured services when residents are temporarily away from home (section 1.2, Table 1.1). Universality (a) means all insured residents are covered on the same terms, not coverage while travelling. Comprehensiveness (b) concerns which services are covered. Public administration (d) concerns how the plan is run, by a public, non-profit authority.

3. [CORE] An 84-year-old patient is medically stable after surgery for a hip fracture and is waiting for a bed in a long-term care home. The patient's son asks what it means that his mother has been "designated ALC." Which explanation by the nurse is accurate?

a. "It means she will be discharged home later today without services."

b. "It means she no longer needs any nursing care or monitoring while she waits."

c. "It means she has been formally admitted to a rehabilitation program."

d. "It means she no longer needs acute care and is waiting for another setting."

Answer: d — Alternate level of care (ALC) describes a patient who remains in a hospital bed but no longer needs the intensity of acute care and is waiting for a more suitable setting, such as long-term care (section 1.2). Option a is wrong because ALC patients are waiting for a place to go, not being sent home without support. Option b is wrong because ALC patients still need nursing care and are often at risk while they wait. Option c is wrong because rehabilitation is one possible destination, not what the ALC designation itself means.

4. [CORE] A capable 72-year-old patient with heart failure has named her neighbour as her essential care partner. Which actions by the nurse reflect patient- and family-centred care? Select all that apply.

a. Asking the patient how she would like her neighbour involved in her care

b. Planning the discharge destination with the neighbour while the patient is asleep

c. Inviting the neighbour, with the patient's agreement, to join the discharge teaching

d. Explaining the plan of care in clear, complete terms the patient can use

e. Asking the neighbour to leave during care because she is not a relative

f. Asking the patient what matters most to her about going home

Answer: a, c, d, f — Patient- and family-centred care rests on partnership, respect, information sharing and participation at the level the patient chooses (section 1.1). The patient decides who counts as family and how they take part (a), essential care partners can join teaching with the patient's agreement (c), complete and usable information supports participation (d), and asking what matters most respects the patient's goals (f). Option b leaves a capable patient out of her own decision. Option e is wrong because the patient, not the nurse, defines family, and an essential care partner's role differs from that of a visitor.

5. [CORE] A nurse on a surgical unit in Ontario is preparing a patient for discharge. The patient will need dressing changes at home for several weeks. Which organization coordinates publicly funded home and community care for this patient?

a. Ontario Health atHome

b. The local public health unit

c. The Public Health Agency of Canada

d. Health Canada

Answer: a — Since June 28, 2024, Ontario Health atHome has coordinated home and community care across Ontario, including care coordination and placement services (section 1.2). Public health units (b) deliver population programs such as immunization and infectious disease control, not individual home care. The Public Health Agency of Canada (c) is a federal agency focused on health promotion, disease prevention and public health emergencies. Health Canada (d) administers the Canada Health Act and regulates health products; it does not arrange home care.

6. [CORE] A registered First Nations patient from a remote community in northwestern Ontario is ready for discharge after surgery at a regional hospital and needs to fly home. Which program is most likely to cover the cost of this travel?

a. The portability criterion of the Canada Health Act

b. Ontario Health atHome

c. The Non-Insured Health Benefits program

d. The Public Health Agency of Canada's emergency fund

Answer: c — The Non-Insured Health Benefits (NIHB) program, run by Indigenous Services Canada, covers medical transportation for registered First Nations and recognized Inuit to reach medically necessary care not available in their community, and prior approval may be needed (section 1.2, Canadian Context box). Portability (a) concerns provincial insurance coverage while residents are away from their home province, not travel costs. Ontario Health atHome (b) coordinates home and community care, not medical travel. The Public Health Agency of Canada (d) works on population health and emergencies and does not fund individual patient travel.

Case: Mr. Arthur Lindqvist (Questions 7–12): Mr. Arthur Lindqvist, 79, is on a surgical unit on postoperative day 2 after a hip hemiarthroplasty for a fractured hip. Yesterday he was alert and oriented and walked with a walker and physiotherapy. At 0800 today the RPN finds him restless and oriented to person only. Vital signs: temperature 38.2 °C, heart rate 116, respiratory rate 28, blood pressure 118/70 (his baseline is 134/78), SpO2 88% on room air. He has a moist cough with yellow sputum and crackles at the right lung base. His hip dressing is dry. He rates his hip pain 3/10 at rest. Laboratory results: white blood cell count 14.6 × 10^9/L (yesterday 9.1 × 10^9/L), hemoglobin 112 g/L (yesterday 114 g/L), sodium 138 mmol/L.

7. [CORE] Which findings require immediate follow-up? Select all that apply.

a. Respiratory rate 28
b. SpO2 88% on room air
c. New confusion and restlessness
d. Hemoglobin 112 g/L
e. Hip pain 3/10 at rest
f. Temperature 38.2 °C

Answer: a, b, c, f — Recognize cues (section 1.4). A rapid respiratory rate, low oxygen saturation, a new change in mental status and fever are abnormal and new, and together they point to a patient who is deteriorating. The hemoglobin is close to yesterday's value, so it does not suggest new bleeding. Pain of 3/10 at rest is well controlled and expected after hip surgery.

8. [CORE] Which group of cues best supports a respiratory infection as the cause of Mr. Lindqvist's change?

a. Stable hemoglobin, a dry hip dressing, controlled pain at rest and a normal sodium level
b. Normal sodium, a blood pressure below his usual baseline, restlessness and his advanced age
c. Fever, moist cough, right basal crackles and rising white cell count
d. His age, his recent hip surgery, his reduced mobility and his use of a walker

Answer: c — Analyze cues (section 1.4). Fever, a productive cough, localized crackles and a rising white cell count belong together and fit a lung infection, such as a pneumonia after surgery. Option a groups cues that argue against bleeding but say nothing about infection. Option b mixes unrelated findings, and a normal sodium does not support any hypothesis here. Option d lists risk factors, not cues of a current problem.

9. [CORE] Which hypothesis should the RPN treat as the priority?

a. Acute pain related to the surgical incision
b. Impaired gas exchange from a likely lung infection
c. Risk for falls related to new confusion
d. Constipation related to reduced mobility

Answer: b — Prioritize hypotheses (section 1.4). Low oxygen saturation, a fast respiratory rate and new confusion show that breathing and oxygen delivery are affected now, so this is both likely and dangerous. Pain is controlled. Falls are a real risk, but they follow from the confusion, which is itself likely caused by low oxygen and infection. Constipation is not urgent and is not supported by the cues.

10. [CORE] Which actions should the RPN plan at this point? Select all that apply.

a. Raise the head of the bed and help him sit upright
b. Report to the RN and the most responsible provider and use the rapid response process if criteria are met
c. Give the next scheduled opioid dose early to settle his restlessness
d. Reassess vital signs and level of consciousness often
e. Restrict his oral fluids to protect his lungs
f. Coach him to take deep breaths and cough
g. Apply wrist restraints so he does not pull at his tubing

Answer: a, b, d, f — Generate solutions (section 1.4). Sitting upright and deep breathing help ventilation. Escalation is required because he is deteriorating (section 1.3), and frequent reassessment will show whether he is getting better or worse. Giving an opioid early could slow his breathing and worsen confusion. Fluids should not be restricted without an order, and he may need more fluid with fever. Restraints are not a first response to restlessness and can increase harm and agitation.

11. [CORE] The physician sees Mr. Lindqvist and orders oxygen titrated to a target saturation, a chest X-ray, a sputum specimen and an IV antibiotic. Which action should the nurse take first?

a. Arrange transport to the imaging department
b. Collect a sputum specimen
c. Call his daughter to update her
d. Apply oxygen and titrate to the target

Answer: d — Take action (section 1.4). His most urgent problem is low oxygen, so oxygen comes first. The X-ray and sputum specimen are needed but can follow within minutes; the order in which cultures and the antibiotic are done follows the orders and hospital policy (Chapter 4). Updating his family matters but does not come before treating hypoxemia.

12. [CORE] Two hours later, which finding best shows that the plan is working?

a. Respiratory rate 20, SpO2 94% on ordered oxygen, oriented to person and place
b. Heart rate 124, temperature 38.6 °C and a moist cough that is now producing more sputum
c. Urine output of 15 mL/h for each of the past two hours, with darker, concentrated urine
d. Now drowsy, wakes only when spoken to loudly, and no longer pulls at his oxygen tubing

Answer: a — Evaluate outcomes (section 1.4). A slower respiratory rate, better oxygen saturation and improving orientation show that the actions are working, though monitoring continues. A rising heart rate and fever, low urine output and a falling level of consciousness all show worsening and call for further escalation.

13. [CORE] An RPN in an Ontario public hospital finds that a patient's only peripheral IV has infiltrated. There is no order to restart it. The RPN is competent to insert IVs and knows the regulation allows nurses to initiate peripheral venipuncture with 0.9% sodium chloride in some situations. What should the RPN do?

a. Insert a new IV now, because the regulation allows nurses to initiate this controlled act

b. Get an order or use a directive, since initiation is not allowed in public hospitals

c. Ask the RN to insert it, because only RNs may start peripheral IVs

d. Insert the IV once the charge nurse gives verbal permission for it to be done on this shift

Answer: b — Authority (section 1.3). Initiation is not available in public hospitals under the Public Hospitals Act, 1990, so the RPN needs an order or a directive. Option a ignores the setting. Option c is wrong because RPNs are authorized to perform this controlled act with an order. A charge nurse's permission is not an authorizing mechanism.

14. [CORE] An RPN is assigned a patient who returns from surgery with a chest tube. The RPN has never cared for a chest tube drainage system and has had no teaching on it. What is the best action?

a. Read the manufacturer's leaflet on the drainage system carefully and then carry on with the assignment as given

b. Refuse to care for the patient and leave the unit's other nurses to decide among themselves who will take over

c. Ask the PSW to watch the drainage system closely during the shift and report any bubbling or change in the drainage

d. Tell the charge nurse, ask for teaching and support, and consult or transfer care until competent

Answer: d — Competence (section 1.3). A nurse who lacks the knowledge, skill and judgment for an activity does not perform it alone. The nurse seeks help and learning and makes sure the patient is safe in the meantime. A leaflet does not give competence. Walking away without a safe handover leaves the patient at risk. Monitoring a chest tube needs nursing assessment and cannot simply be handed to a UCP.

15. [CORE] Which statement about scope and assignment for Ontario nurses is accurate?

a. An employer can limit a nurse's scope through policy but cannot expand it beyond what law and CNO allow

b. CNO's standards require that RPNs be assigned only patients whose condition is stable and predictable

c. CNO's three-factor framework of client, nurse and environment decides which nurse cares for each patient

d. When an employer policy conflicts with a CNO practice standard, the nurse's first duty is to follow the policy

Answer: a — Context (section 1.3). Employers may narrow, but never widen, a nurse's scope. Assigning stable patients to RPNs is a common employer practice, not a CNO rule. The three-factor framework was retired in 2023. When a policy conflicts with a CNO standard, the nurse's first accountability is to the standard.

16. [CORE] A nurse notes that a patient has a temperature of 38.5 °C, a heart rate of 110 and a new productive cough, and links them as signs of a possible pneumonia. Which CJMM skill is the nurse using?

a. Recognize cues

b. Prioritize hypotheses

c. Analyze cues

d. Generate solutions

Answer: c — Analyze cues (section 1.4). Grouping cues and linking them to a possible explanation is analyzing cues. Recognizing cues is noticing that the findings matter. Prioritizing hypotheses ranks several explanations. Generating solutions plans actions.

17. [RN] In which layer of the CJMM do the six cognitive skills sit?

a. Layer 0

b. Layer 1

c. Layer 3

d. Layer 4

Answer: c — Going Deeper box (section 1.4). Layer 3 holds the six cognitive skills and is the level at which NCLEX items are written. Layer 0 is the context of the patient's needs, Layer 1 is clinical judgment as a whole, and Layer 4 holds environmental and individual factors.

18. [RN] An NGN item has four correct options and is scored by the plus/minus rule. A candidate selects three correct options and one incorrect option. How many points does the candidate earn?

a. 2 points

b. 3 points

c. 0 points

d. 1 point

Answer: a — Going Deeper box (section 1.4). Under plus/minus scoring, the candidate gains a point for each correct choice and loses one for each incorrect choice, so 3 − 1 = 2. Three points ignores the deduction. Zero would apply only if deductions equalled or exceeded correct choices. One point miscounts the deduction.

19. [RN] Which statement about Next Generation NCLEX items is accurate?

a. Bow-tie items appear only inside the six-item case studies, never on their own as stand-alone items

b. Case studies have now replaced all stand-alone items, so every item belongs to a case

c. Every item, including select-all items, is scored only as fully right or fully wrong

d. Each case study has six items on one patient, one for each cognitive skill in order

Answer: d — Going Deeper box (section 1.4). An NGN case study follows one patient through six items from recognizing cues to evaluating outcomes. Bow-tie and trend are stand-alone formats. Stand-alone items still appear alongside case studies. Items with more than one correct answer can earn partial credit.

Case: Mr. Paul Lavoie (Questions 20–23): Mr. Paul Lavoie, 72, is admitted to a surgical unit in an Ontario hospital for an elective right total hip replacement. He lives with his wife. He has a valid power of attorney for personal care that names his daughter, Monique. Kiran Dhillon, RPN, is assigned to his care.

20. [CORE] On the morning of surgery, the surgeon asks the RPN to "get Mr. Lavoie's consent form signed." When the RPN brings the form, Mr. Lavoie says, "The surgeon never told me what could go wrong." What is the RPN's best action?

a. Explain the usual risks of hip replacement surgery to him and then witness his signature.

b. Hold the form and tell the surgeon that Mr. Lavoie needs more information.

c. Ask him to sign now, because the signature only confirms that he is the right patient.

d. Ask his wife, who is at the bedside, to sign the consent form for him instead.

Answer: b — The practitioner who proposes a treatment is responsible for obtaining informed consent, including explaining material risks (section 1.5). A signature means little if the patient is not informed, so the nurse holds the form and advocates for the patient to get the information. Option a takes on the surgeon's responsibility and the nurse may not know the specific risks of this surgery. Option c ignores the patient's statement and misstates what the signature represents. Option d is wrong because Mr. Lavoie is presumed capable, so no substitute decision-maker is involved.

21. [CORE] On the second night after surgery, Mr. Lavoie becomes acutely confused and cannot understand information about a proposed blood transfusion. The physician proposing the transfusion finds him incapable with respect to this decision. Monique is available and willing to act. Who should give or refuse consent?

a. His wife, because a spouse ranks first among family members.

b. The surgeon, because the transfusion is medically needed.

c. His daughter, Monique, as his attorney for personal care.

d. The RPN, because the nurse knows his wishes and condition best.

Answer: c — Under the HCCA hierarchy, an attorney for personal care ranks above a spouse, so Monique is his substitute decision-maker (section 1.5). Option a would apply only if no higher-ranked person were available and willing. Option b is wrong because the situation is not described as an emergency, and the surgeon proposes treatment but does not consent on the patient's behalf. Option d is wrong because nurses do not act as SDMs for their patients.

22. [CORE] Monique consents, and the transfusion begins. Two days later, Mr. Lavoie's confusion has cleared and he is assessed as capable. During a second ordered unit of red blood cells, he says, "I don't want any more blood. Please stop it." What should the RPN do first?

a. Stop the transfusion and notify the prescriber.

b. Continue, because his daughter already consented.

c. Slow the infusion rate until his daughter can be reached.

d. Remind him that the hemoglobin result shows he needs the blood.

Answer: a — A capable person may withdraw consent at any time, and once Mr. Lavoie is capable, he makes his own decisions (section 1.5). The RPN stops the transfusion, keeps the IV access as policy directs, tells the prescriber and documents. Option b is wrong because the SDM's authority ends when the patient regains capacity for the decision. Option c continues treatment without consent. Option d may be part of a later conversation but pressures him and delays respecting his decision.

23. [CORE] The next morning, Mr. Lavoie agrees to have his vital signs checked but refuses his scheduled wound dressing change. What is the RPN's most appropriate response?

a. Ask the surgeon to speak with him and obtain consent for the dressing change.

b. Change the dressing anyway, because he consented to all care on admission.

c. Record that he is non-compliant and try again at the end of the shift.

d. Explore his reasons, explain the risks of refusing and respect his decision.

Answer: d — The nurse is responsible for obtaining consent for nursing care the nurse proposes, and consent is specific to each treatment (section 1.5). Exploring his reasons may reveal a concern, such as pain, that the nurse can address, and informing him of the consequences makes his decision informed. Option a passes the nurse's responsibility to another practitioner. Option b relies on general consent that does not cover a specific procedure he is refusing now. Option c uses a judgmental label and does not explore or inform.

24. [CORE] A capable patient on a medical unit is admitted with pneumonia. Her adult son telephones the nurse and asks for her latest chest X-ray results. The patient has not said who may receive information. What should the nurse do?

a. Share the results, because family members are part of the circle of care.

b. Tell the son that privacy law forbids sharing any information with family.

c. Ask the physician to call the son with the results.

d. Ask the patient whether she agrees to sharing the results with her son.

Answer: d — The circle of care allows custodians to assume implied consent only when sharing information with other health information custodians for the patient's care (section 1.5). A son is not a custodian, so the capable patient's consent is needed. Option a misstates the circle of care. Option b is wrong because sharing is allowed with consent. Option c still discloses information without the patient's consent.

25. [CORE] At 1600, a nurse realizes she did not document a dressing change she completed at 1000. What is the correct way to record it?

a. Write a late entry that states the time the dressing was actually changed.

b. Insert the note between the 0900 and 1100 entries so the record stays in time order.

c. Ask the nurse on the next shift to document it.

d. Leave it undocumented, because the care plan shows the dressing was due.

Answer: a — CNO's Documentation standard requires late entries to be clearly labelled and to state when the care happened (section 1.5). Option b makes the entry look as if it was written at the time of care, which misrepresents the record. Option c breaks the rule that nurses document only care they personally provided. Option d leaves the record incomplete, and a care plan shows what was planned, not what was done.

26. [CORE] A patient whom the nurse cared for after a bowel resection was discharged last week. He sends the nurse a friend request on her personal social media account with the message "Thanks for everything!" What is the nurse's best action?

a. Accept the request, because the therapeutic relationship ended at discharge.

b. Accept the request but avoid discussing his health or his care online.

c. Decline the request and, if needed, kindly explain why she cannot accept.

d. Report the patient's message to the hospital's security department.

Answer: c — CNO's Professional Boundaries and Nurse-Client Relationships standard expects nurses not to connect with patients on personal social media, and keeping boundaries is always the nurse's responsibility (section 1.5). Options a and b turn a recent therapeutic relationship into a personal one; discharge a week earlier does not make that appropriate, and avoiding health topics online does not remove the boundary problem. Option d overreacts to a friendly gesture that is not a threat.

27. [CORE] A nurse gives a patient a dose of metoprolol that was ordered for the patient in the next bed. The nurse discovers the error within minutes. The patient's vital signs stay within normal limits, and no harm is detected. How is this event classified?

a. Near miss

b. No-harm incident

c. Harmful incident

d. Adverse drug reaction

Answer: b — A no-harm incident reached the patient but caused no detectable harm (section 1.6). Option a is wrong because a near miss is caught before it reaches the patient. Option c is wrong because no harm occurred. Option d is wrong because an adverse drug reaction is a harmful, unintended response to a drug, and no harmful response occurred; the event is classified by whether it reached the patient and caused harm.

28. [CORE] A nurse has programmed an IV insulin infusion and asks a colleague for an independent double check. Which action by the colleague shows a true independent double check?

a. Watching the first nurse program the pump and agreeing that all the settings look correct

b. Reading the first nurse's written calculation and confirming that the math is right

c. Signing the medication record after the first nurse reads the order and settings aloud

d. Working out the rate alone from the order, then comparing it with the pump settings

Answer: d — In an independent double check, the second practitioner verifies the order, drug, dose and pump settings and does the calculation separately, without seeing the first result. Only then are the two results compared (section 1.6). Options a, b and c expose the checker to the first nurse's work, so the checker tends to confirm what is shown rather than catch an error.

29. [CORE] A nurse is preparing discharge teaching about a new anticoagulant for a patient who speaks Punjabi and has limited English. The patient's 15-year-old granddaughter offers to interpret. What is the nurse's best action?

a. Accept the granddaughter's offer, because the patient trusts her.

b. Book a professional interpreter and include the granddaughter if the patient wishes.

c. Give the patient a written English handout and ask the granddaughter to translate it at home.

d. Teach slowly in English and ask the patient whether she understands.

Answer: b — Professional interpreters improve communication and quality of care, and family members, especially children, should not interpret clinical information (section 1.7). The granddaughter can still take part as a caregiver if the patient agrees. Options a and c rely on a young family member who may lack medical vocabulary and may leave out information. Option d relies on asking "Do you understand?", which does not confirm understanding, and does not overcome the language barrier.

30. [RN] A patient on an Ontario medical unit develops a severe skin reaction to a newly started antibiotic. The reaction extends his hospital stay by six days. The nurse documents the reaction in the health record on Monday. Which statement about reporting under Vanessa's Law is accurate?

a. The prescribing physician must personally report the reaction to Health Canada within 15 days.

b. Reporting is voluntary, because the antibiotic was prescribed and given correctly.

c. The hospital must report it to Health Canada within 30 days of Monday's documentation.

d. It must be reported only if the patient dies or is left with a permanent disability.

Answer: c — Since December 16, 2019, hospitals must report serious adverse drug reactions in writing to Health Canada within 30 calendar days of first documentation in the hospital (section 1.6). The reaction is serious because it prolonged hospitalization. Nurses contribute by recognizing and documenting it. Option a names the wrong reporter and the wrong time limit. Option b is wrong because the rule covers serious adverse drug reactions regardless of whether the drug was prescribed and given correctly. Option d omits other criteria for a serious reaction, including prolonged hospitalization.

02 Equity, Cultural Safety and Indigenous Health in Adult Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how the social and structural determinants of health shape adults' illness, access to care and outcomes in Canada.
2. Distinguish cultural awareness, competence, humility and safety, and apply trauma- and violence-informed care on a medical-surgical unit.
3. Describe First Nations, Inuit and Métis health using a distinctions-based, strengths-based approach that names colonial structures and Indigenous-specific racism.
4. Apply the Truth and Reconciliation Commission's Calls to Action 18 to 24, the United Nations Declaration on the Rights of Indigenous Peoples, Joyce's Principle and the First Nations principles of OCAP® to nursing practice.
5. Adapt care for racialized, 2SLGBTQI+ and disabled adults, newcomers and refugees, and adults experiencing homelessness or poverty.
6. Recognize bias, including race-based clinical tools, and respond to discrimination through advocacy and reporting.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 3	Advocate; Clinician; Scholar	Foundations of Practice; Collaborative Practice

Introduction

Two patients with the same diagnosis can leave the same unit with very different chances of recovering. One goes home to a stocked kitchen, a drug plan and a partner who drives. The other cannot afford the new prescriptions, lives two bus transfers from the clinic and has no one to check the wound. The treatment was the same, but the conditions the patient goes home to are not. This chapter treats those conditions as clinical facts, because they shape adherence, readmission, complications and trust as surely as a laboratory value does.

Equity is also a patient-safety issue inside the hospital. Anti-Black racism in clinical interactions and institutional policies, for example, is linked to health disparities, poorer quality of care and patient mistrust (Registered Nurses' Association of Ontario [RNAO], 2026). A patient who has been dismissed before may delay reporting new pain or leave before treatment is finished. The College of Nurses of Ontario (CNO) expects every nurse in Ontario to assess each patient's risk of health inequities and act to secure the best possible outcomes (CNO, 2026).

This chapter begins with health equity and the determinants of health, then explains cultural safety, cultural humility and trauma- and violence-informed care. It then turns to First Nations, Inuit and Métis health (section 2.3); the rights, policies and data principles that guide nurses (section 2.4); care of other equity-deserving adults (section 2.5); and equity in everyday medical-surgical practice (section 2.6). Every later chapter applies this lens. Risk factors use Canadian data and name structural causes, findings are described on a range of skin tones, and Canadian Context boxes show how care differs by place and community.

2.1 Health Equity and the Determinants of Health

Most of what makes people healthy or unwell happens outside hospitals. Medical-surgical nurses see the results in who is admitted, how sick they are on arrival and what waits for them at discharge.

Equity and Equality

Equality means giving everyone the same thing. **Equity** means giving people what they need so that each person has a fair chance at good outcomes. A unit that hands every patient the same printed discharge sheet treats patients equally. A unit that offers the sheet in the patient's language, checks that the patient can afford the medications and arranges a ride to the follow-up clinic is working toward equity.

The Public Health Agency of Canada (PHAC) describes **health equity** as a fair opportunity for every person to reach their best possible health, regardless of the social and structural conditions of their lives (PHAC, 2026a). Differences in health between groups are **health inequalities**; they become **health inequities** when they are systematic and could plausibly be prevented or reduced by collective action; such differences may be judged unjust (PHAC, 2018). The National Collaborating Centre for Determinants of Health (NCCDH) adds that inequities are unfair, avoidable and modifiable, because they stem from choices about how resources and opportunities are allocated (NCCDH, 2023). Inequities are not accidents of biology or personal failings; they come from conditions that people, including health care providers, can change.

Determinants of Health

The **determinants of health** are the conditions that shape the health of individuals and populations; PHAC now groups them into two levels (PHAC, 2026a).

Social determinants of health are the everyday conditions of people's lives. PHAC's examples include income and education; decent, safe and secure work that pays a living wage; community and social support, including access to health care; adequate, affordable housing; accessible public spaces; and freedom from discrimination and violence where people live (PHAC, 2026a). PHAC's longstanding list names 12 interrelated key determinants: income and social status, social support networks, education and literacy, employment and working conditions, social environments, physical environments, personal health practices and coping skills, healthy child development, biology and genetic endowment, health services, gender, and culture (PHAC, 2022). Even personal health practices are shaped by social and economic conditions (PHAC, 2022).

PHAC also recognizes perspectives on the determinants from First Nations, Inuit and Métis Peoples, and from Critical Race Theory and Two-Spirit, lesbian, gay, bisexual, transgender, queer and intersex (2SLGBTQI+) scholarship (see section 2.5), which help explain how racism, colonialism and discrimination can lead to different health outcomes (PHAC, 2026a). Section 2.3 returns to First Nations, Inuit and Métis perspectives.

Structural Determinants and Intersectionality

Structural determinants of health are the large systems that shape society, including how resources and opportunities are distributed. They include governments at every level; the systems that run education, health care, immigration and finance; labour markets; and international agreements. Their laws, policies and institutional practices shape the everyday conditions described above (PHAC, 2026a). Colonial policies, institutional racism and the rules that set income supports or drug coverage are all structural determinants. They explain why social determinants are not shared evenly: low income, for example, follows patterns these systems set.

Intersectionality is a way of understanding how a person's social positions, such as race, gender, disability, age, sexual orientation, immigration status and income, combine to shape their experiences of advantage and disadvantage. The legal scholar Kimberlé Crenshaw introduced the term in 1989, showing that treating race and sex as separate categories hid the discrimination Black women faced (Crenshaw, 1989). An older racialized woman (see section 2.5) with a disability who speaks limited English may meet barriers that no single label explains, so the nurse looks at the whole person.

Determinants in Canadian Data

A few national figures show the size of these issues:

- **Food insecurity: Food insecurity** means a household cannot count on enough food because money is short. In 2024, 24.0% of Canadians (about 9.8 million people) lived in a household with marginal, moderate or severe food insecurity in the 12 months before the interview. Almost half (44.4%) of people in one-parent families were affected. Rates were higher for racialized people (30.4%; provinces only) than for non-racialized people (21.0%), and for Indigenous people aged 15 and older (34.7%) than for non-Indigenous people (22.4%); the survey does not cover reserves or other Indigenous settlements in the provinces (Statistics Canada, 2026a). PHAC points to systemic inequities such as racism, colonialism and discrimination as causes of differences like these (PHAC, 2026a).
- **Poverty:** About 4.5 million people (11.0% of the population) had incomes below Canada's Official Poverty Line in 2024. The line is set using the Market Basket Measure (Statistics Canada, 2026a).
- **Homelessness:** Coordinated point-in-time counts in 74 communities, held mostly in October and November 2024, identified nearly 60,000 people experiencing homelessness (defined in section 2.5). A one-night count understates homelessness over a year, and Quebec did not take part (Housing, Infrastructure and Communities Canada [HICC], 2025a). In the counts' survey (preliminary results), 28% of respondents had spent one or more nights in a hospital or other health facility during the previous year (HICC, 2025b).
- **The income gradient:** In 2023, health-adjusted life expectancy (the years a person can expect to live in good health) at birth was 61.9 years in the lowest neighbourhood income quintile and 70.0 years in the highest, a gap of 8.1 years; income was measured by neighbourhood, not household (Statistics Canada, 2026b).
- **Medication cost:** In a 2021 survey of adults in the provinces, 9% of those who had taken or been prescribed a medication in the previous 12 months did not take it as prescribed because of cost. The rate was 17% among people without prescription insurance and 7% among those with coverage (Cortes & Smith, 2022).

Determinants on the Medical-Surgical Unit

Determinants show up at the bedside. A patient discharged on a new anticoagulant with no drug plan may stretch doses to make the supply last. A patient with no car may miss the wound check that would catch an infection early. A person experiencing homelessness may be discharged after surgery to a shelter that closes by day, with nowhere to rest or keep dressings clean. A patient with diabetes and an empty fridge is at risk of hypoglycemia once a new insulin dose starts. Caregivers who work shifts may not be able to learn tube feeding or ostomy care before discharge, and virtual follow-up assumes a device, data, privacy and the skill to use them.

Starting at admission, the nurse asks every patient about these conditions rather than guessing who needs to be asked; asking everyone in the same respectful way avoids stereotyping and normalizes the questions (Table 2.1). With the patient's consent, answers go to the team so that social work, pharmacy and discharge planners can act: checking public drug programs, arranging transport or choosing a dressing the patient can manage. Chapter 1 covers discharge planning, medication reconciliation, health literacy and language access (section 1.7) and alternate level of care and medical travel (section 1.2); this chapter adds the equity questions that make those plans work.

Table 2.1 Determinants of health and questions the nurse can ask on admission and before discharge (Original table; determinants from PHAC, 2022, 2026a)

Determinant	Why it matters in medical-surgical care	Questions the nurse can ask
Income and drug coverage	New prescriptions, dressings and devices may cost more than the patient can pay, leading to skipped doses or unfilled prescriptions.	"Some people find it hard to pay for medications. Is cost a worry for you?" "Do you have a drug plan through work, the province or another program?"
Food security	Healing, blood glucose control and medications taken with food all depend on regular, adequate meals.	"In the past year, have you worried about food running out before there was money to buy more?" "Will you be able to get the foods we talked about?"
Housing	A safe, stable place to recover affects wound care, mobility, rest and infection risk.	"Where will you stay after you leave hospital?" "Are there stairs, and can you get to a bathroom and a bed?" "Is your housing safe and secure for you right now?"

Determinant	Why it matters in medical-surgical care	Questions the nurse can ask
Employment and working conditions	Lost wages, unsafe or physical work and lack of paid sick leave can push patients to return to work too soon.	"What kind of work do you do?" "Will taking time off affect your income or your job?"
Social support and caregiving	Recovery often depends on help at home, and patients may themselves be caregivers for others.	"Who can help you at home in the first few weeks?" "Is anyone counting on you for care, such as a child, partner or parent?"
Transportation and distance	Follow-up visits, laboratory tests and pharmacy trips require a way to get there, especially in rural and remote areas.	"How will you get to your follow-up appointments?" "How far is the nearest pharmacy or clinic?"
Digital access	Virtual visits, patient portals and remote monitoring need a device, data, privacy and the skills to use them.	"Do you have a phone or computer you can use for a video visit?" "Would a phone call or in-person visit work better for you?"
Literacy and language	Understanding instructions and asking questions depend on clear communication in the patient's preferred language (see Chapter 1, section 1.7).	"What language do you prefer for health information?" "How do you like to learn new things: reading, watching or doing?"
Safety, discrimination and past care experiences	Violence at home, or past experiences of discrimination in health care, affect trust, disclosure and willingness to return for care.	"Is there anything about your past experiences with health care that would help us care for you?" "Do you feel safe where you live?"

2.2 Cultural Safety, Humility and Trauma- and Violence-Informed Care

How the nurse behaves in each encounter shapes whether a patient feels able to speak up, trust the plan and come back.

Where Cultural Safety Came From

Cultural safety emerged in Aotearoa New Zealand in the late 1980s, when Māori nursing students and teachers saw that nursing education had to confront racism and the unequal health outcomes Māori faced (Nursing Council of New Zealand [NCNZ], n.d.). The Māori nurse and educator Irihapeti Ramsden led the work. The Nursing Council resolved in 1991 to bring cultural safety into nursing curricula, and from 1992 nursing and midwifery programs had to include it (NCNZ, 2013). Ramsden chose "safety" deliberately to give power to the person receiving care, who judges whether a service is safe to use; cultural safety is about the nurse, not the patient's culture (Ramsden, 2002).

In Canada, the Aboriginal Nurses Association of Canada (now the Canadian Indigenous Nurses Association) published a 2009 framework for cultural competence and cultural safety in nursing education, guided by a steering committee that included the Canadian Association of Schools of Nursing (CASN) and the Canadian Nurses Association (CNA); it asks nurses to accept that the people they care for decide whether care is culturally safe (Hart-Wasekeesikaw, 2009). In July 2015, the chief executive officers of all British Columbia health authorities signed a commitment to cultural safety and humility (First Nations Health Authority [FNHA], n.d.-b).

Cultural Safety and Cultural Humility

The FNHA describes cultural safety as an outcome of respectful engagement that works to correct the power imbalances in health care, so that patients receive care free of racism and discrimination and feel safe. **Cultural humility** is the process that leads there: ongoing reflection on personal and systemic biases, with the provider as a learner about the patient's experience (FNHA, n.d.-a). Humility builds the trust and respect that make safety possible (FNHA, n.d.-b).

Power is central to both. A patient in a gown, in pain, with staff controlling information, medications and discharge, has little power; humility asks the nurse to notice and reduce that imbalance. Tervalon and Murray-García (1998) proposed humility, a lifelong commitment to self-evaluation, correcting power imbalances and partnering with communities, as a better goal than **cultural competence** seen as mastery of a fixed body of knowledge.

Only the patient can say whether care felt culturally safe; good intentions are not enough. Cultural awareness and sensitivity focus on the "other" culture, whereas cultural safety turns the focus to the provider and the system (Chief Public Health Officer Health Professional Forum, 2023) (Table 2.2).

Table 2.2 From cultural awareness to cultural safety (Chief Public Health Officer Health Professional Forum, 2023; FNHA, n.d.-a; Tervalon & Murray-García, 1998; original wording and examples)

Concept	What it means	What it looks like in practice
Cultural awareness	Noticing that cultures differ; an early step that asks nothing of the provider's own self-reflection.	The nurse knows that patients on the unit may hold beliefs about illness that differ from the nurse's own.
Cultural sensitivity	Accepting that differences deserve respect and adjusting one's manners to what the other person finds courteous.	The nurse asks how a patient prefers to be addressed and avoids assumptions about family roles.
Cultural competence	Examining how one's own cultural values shape care, and building knowledge and skills to plan care that fits a person's beliefs; limited if culture is treated as a checklist of traits.	The nurse learns about fasting practices and works with the team to adjust medication times for a patient who is fasting.
Cultural humility	A lifelong process of self-reflection on personal and systemic biases and privilege, approaching each person as the expert on their own life.	After a patient declines a treatment, the nurse asks what matters to the patient and reflects on whether the nurse's own assumptions shaped the conversation.
Cultural safety	An outcome, judged by the patient, in which care is free of racism and discrimination and power imbalances are addressed.	A patient says she felt heard and respected and would come back to this hospital; the team changed its routines when patients said what felt unsafe.

Professional Expectations

In Ontario, the second principle of the CNO Code of Conduct states that nurses provide inclusive, culturally safe care by practising cultural humility. Nurses reflect on how their privileges, biases, values and power affect the nurse–patient relationship, do not act on stereotypes, and seek feedback on their practice. They meet language, cultural and communication needs, use preferred names, titles and pronouns, assess risk for health inequities, build on strengths, act against discrimination, and keep learning about Indigenous health, determinants of health, cultural safety, humility and anti-racism (CNO, 2026).

Two values in the CNA *Code of Ethics for Nurses* (2025) apply directly (see Chapter 1, section 1.5, for all seven). Under "pursuing truth and reconciliation," nurses commit to truth and reconciliation and value bringing First Nations, Inuit and Métis knowledge into their practice. Under "promoting social justice," they consider the social determinants of health and advocate for everyone's freedom from oppression, racism and discrimination (CNA, 2025).

Anti-Racist Practice

Anti-racism is any approach that reduces power differences in ways that benefit racialized groups (Chief Public Health Officer Health Professional Forum, 2023). Being "not racist" is passive; anti-racist practice names racism, including systemic racism, and works to change it. In 2021, CNA and other nursing organizations released a joint declaration that nurses would no longer be silent about anti-Black racism, with principles and actions for which the profession would be accountable (CNA, 2021). RNAO's 2026 best practice guideline, focused on Black nurses and nursing students, recommends interactive, dialogue-based education and formal mentorship, calls for zero-tolerance policies and notes that intersecting factors such as gender identity, class and disability compound racism (RNAO, 2026).

On a medical-surgical unit, anti-racist practice includes:

- questioning assumptions, such as judging reported pain by appearance or labelling a patient "drug-seeking" without assessment;
- never treating race as a biological explanation for a finding, but asking what exposure, condition or barrier explains it;
- speaking up, and reporting through proper channels (see section 2.6), when a colleague's words or actions are discriminatory;
- giving every patient the same thorough assessment, explanation and pain management.

Trauma- and Violence-Informed Care

Many adults in hospital have lived through violence, such as childhood abuse, intimate partner violence, war or the harms of residential schools and other colonial policies; for some it is ongoing. **Trauma- and violence-informed care (TVIC)** recognizes the links between violence, trauma and health, and aims to increase safety, control and resilience for the people receiving care (PHAC, 2025). Adding "violence" to the older term trauma-informed care highlights ongoing violence and systemic or structural violence, such as racism and colonization, not only past events (PHAC, 2025; Wathen & Varcoe, 2021). TVIC does not require disclosure; the nurse does not need to know a patient's history to provide it (PHAC, 2025).

PHAC and EQUIP Health Care name four principles (EQUIP Health Care, n.d.; PHAC, 2025):

- **Understand trauma and violence** and their effects on people's lives and behaviour.
- **Make care settings safe** physically, emotionally and culturally, for patients and staff.
- **Offer choice, collaboration and connection.**
- **Build on strengths and capacity** to support coping and resilience.

On a medical-surgical unit, the principles become everyday actions:

- **Explain before touching.** Say what will happen and why, ask permission and check in throughout, especially for intimate or invasive care such as urinary catheters, nasogastric tubes, perineal care and breast or chest examination.
- **Offer real choices.** Where possible, let the patient choose the timing of a bath, who is present, a position or a pause.
- **Protect privacy.** Knock, close curtains, drape well and limit who is in the room.
- **Recognize possible triggers.** A raised voice, being held still, a dark room, a closed door or someone entering at night may cause fear; agitation may be a trauma response, not "non-compliance."
- **Avoid restraint wherever possible.** Restraint removes control and can be deeply distressing; try alternatives and follow the employer's least-restraint policy (see Chapter 8 for delirium).
- **Respond well to disclosure.** If a patient shares an experience of violence, believe and affirm them, express concern for their safety and offer supports according to employer policy.

2.3 First Nations, Inuit and Métis Health

First Nations, Inuit and Métis patients are on every medical-surgical unit. Their health is shaped by the determinants in section 2.1 and by laws and institutions, hospitals among them, that the Canadian state built to control, assimilate and segregate them. This section covers the three Peoples, colonial history, racism and Indigenous-led care.

Distinctions-Based Language

A **distinctions-based approach** recognizes First Nations, Inuit and Métis as distinct Peoples with their own histories, languages, governments, rights and priorities. Section 35 of the Constitution Act, 1982 affirms existing Aboriginal and treaty rights and defines Aboriginal peoples as including the "Indian, Inuit and Métis peoples" (Constitution Act, 1982, s. 35). "Indian" survives in law; nurses use the terms people use for themselves.

In the 2021 Census, 1,807,250 people (5.0% of the population) identified as Indigenous: 1,048,405 as First Nations, 624,220 as Métis and 70,545 as Inuit (single identities). The average age was 33.6 years, against 41.8 for non-Indigenous people (Statistics Canada, 2022b).

First Nations are many distinct Nations, each with its own language, laws and protocols; the Assembly of First Nations refers to more than 600 First Nations communities (Assembly of First Nations [AFN], n.d.).

Inuit are the Indigenous People of **Inuit Nunangat**, a homeland of land, water and ice spanning 72% of Canada's coastline and about 40% of its land area, in four regions: the Inuvialuit Settlement Region (Northwest Territories), Nunavut, Nunavik (northern Quebec) and Nunatsiavut (northern Labrador) (Inuit Tapiriit Kanatami [ITK], n.d.-a). One person is an Inuk; two or more are Inuit.

In 2021, Inuit Nunangat was home to 69.0% of Inuit, a share that is falling as more live in cities such as Ottawa, Edmonton and Montréal (Statistics Canada, 2022b).

The **Métis** are a distinct Indigenous People who emerged from the 18th-century fur trade, with their own culture, language (Michif) and nationhood. Their Homeland includes the Prairie provinces and parts of Ontario, British Columbia, the Northwest Territories and the northern United States (Métis National Council [MNC], n.d.-a). Being Métis is not the same as mixed ancestry; Métis governments keep citizenship registries, which can differ from self-identified census counts (MNC, n.d.-b).

"Status" is a legal category, not an identity. **Indian status** means being registered under the **Indian Act**, the federal law that has governed First Nations since 1876. There is no federal register for Inuit or Métis (Indigenous Services Canada [ISC], n.d.-a). In 2021, 71.8% of First Nations people had Registered or Treaty Indian status, and 40.6% of them lived on reserve (Statistics Canada, 2022b). A First Nations person without status is no less First Nations. Status matters clinically: the **Non-Insured Health Benefits (NIHB)** program, which pays for medically necessary drugs, dental and vision care, counselling, supplies and medical transportation not covered by other plans, serves registered First Nations people and recognized Inuit (ISC, n.d.-c; Table 2.3).

Table 2.3 First Nations, Inuit and Métis Peoples: key distinctions for nurses (original table; AFN, n.d.; FNHA, 2022; Government of the Northwest Territories, 2021; ISC, n.d.-a, n.d.-c, 2026b, 2026c; ITK, n.d.-a, n.d.-b; Manitoba Métis Federation, 2021; Métis Nation British Columbia, 2024; Métis Nation–Saskatchewan, 2024; MNC, n.d.-a, n.d.-b, n.d.-c; Statistics Canada, 2022b)

Peoples	Who they are	National organization	Federal health programs that may apply	Notes for nurses
First Nations	Many distinct Nations across Canada, each with its own language, laws and protocols; may live on reserve, in rural areas or in cities; may or may not have status under the Indian Act	Assembly of First Nations, which takes direction from First Nations in Assembly through resolutions; many regional and treaty organizations also represent First Nations	Non-Insured Health Benefits (NIHB) for people registered under the Indian Act; Jordan's Principle for First Nations children; nursing stations and health centres in many remote communities; in British Columbia, the First Nations Health Authority runs many programs, including health benefits transferred from NIHB for First Nations residents	Ask which Nation or community the patient belongs to; ask about protocols for ceremony, family and Elders rather than assuming; patients without status are not eligible for NIHB
Inuit	The Indigenous People of Inuit Nunangat (Inuvialuit Settlement Region, Nunavut, Nunavik, Nunatsiavut); many now live in southern cities; Inuktut is widely spoken	Inuit Tapiriit Kanatami, whose voting board members are the four regional Inuit land claims organizations	NIHB for Inuit whom a land claim organization recognizes; Inuit Child First Initiative for Inuit children	Use "Inuk" for one person and "Inuit" for more than one; offer an Inuktut interpreter (see Chapter 1, section 1.7); patients may be far from home for care (see Chapter 1, section 1.2)
Métis	A distinct People with roots in the fur trade, its own culture and the Michif language; Homeland centred on the Prairie provinces	Métis National Council, whose Governing Members are the Otipemisiwak Métis Government (Alberta) and the Métis Nation of Ontario; the Manitoba Métis Federation (2021), Métis Nation–Saskatchewan (2024) and Métis Nation British Columbia (2024) announced their withdrawal from the Council	Not eligible for NIHB; provincial or territorial health coverage applies; the Northwest Territories runs a Métis Health Benefits program	Do not assume a Métis patient has federal benefits; check drug and equipment coverage early in discharge planning; ask about supports offered by the patient's Métis government

Colonial History and Health

The 1876 Indian Act combined earlier laws and gave the federal government sweeping power over First Nations status, reserve lands, governance and education (Canadian Museum of History, n.d.). Canada imposed band councils and banned ceremonies, among them the Potlatch and the Sun Dance (Truth and Reconciliation Commission of Canada [TRC], 2015a).

Residential schools were church-run, government-funded schools that removed Indigenous children from their families to assimilate them. The federal government estimates that at least 150,000 First Nations, Métis and Inuit children attended; the last federally supported schools closed in the late 1990s. The TRC called this cultural genocide and documented poor diets, poorly heated and ventilated buildings, abuse, and deaths no other school system would have tolerated (TRC, 2015a). A scoping review of 61 studies linked attendance with poorer health, chronic and infectious disease, mental distress, substance use and suicidal behaviour in Survivors and their descendants (Wilk et al., 2017). These **intergenerational effects** pass through disrupted families, lost languages and unresolved trauma.

Hospitals were part of this system. From 1936 to 1981, Canada operated 33 **Indian hospitals**. They began as racially segregated facilities to isolate Indigenous people with tuberculosis (TB) and limit its spread to non-Indigenous people, then became segregated general hospitals, with admission based on Indigenous status. Approving a class action settlement in 2025, the Federal Court noted that patients experienced physical and sexual abuse; the representative plaintiffs also said patients were restrained to their beds without medical reason (*Hardy v. Canada (Attorney General)*, 2025). Canada has said it "profoundly regret[s] the abuse and the destruction of culture" in these hospitals (Crown-Indigenous Relations and Northern Affairs Canada [CIRNAC], 2025a).

From the 1940s to the 1960s, Inuit were screened for TB without consent and sent south for months or years in sanatoria. Children were separated from parents, families often were not told where relatives were, and some who died were buried in the South, not always in marked graves. Canada apologized in 2019 and, with Inuit organizations, created the Nanilavut ("let's find them") Initiative to help families find information about relatives (Prime Minister of Canada, 2019).

In the **Sixties Scoop**, between the 1960s and the 1980s, child welfare authorities removed Indigenous children from their homes and placed many in non-Indigenous foster and adoptive homes; in 2017, Canada reached an agreement in principle to settle claims that it failed to protect their Indigenous identity (Indigenous and Northern Affairs Canada, 2017). Communities were also moved: in the 1950s, Inuit families from Inukjuak and Pond Inlet were relocated more than 1,000 km to the High Arctic without adequate shelter and supplies, for which Canada apologized in 2010 (CIRNAC, 2010).

These policies are within living memory: an older patient may have attended a residential school, been treated in an Indian hospital or sent south for TB, or have a parent who never came home; for that patient, hospital can mean separation, restraint and not returning. Fear, reluctance to stay overnight or distrust of consent forms are reasonable responses, not "non-compliance." The nurse explains each step, keeps family close and respects the patient's decisions (see section 2.2).

Indigenous-Specific Racism in Health Care

Indigenous-specific racism is the particular stereotyping, bias and prejudice directed at Indigenous Peoples, rooted in settler colonialism, that keeps power imbalances and unequal outcomes in place (Turpel-Lafond, 2020). It works through individual behaviour and seemingly neutral routines.

In 2020, British Columbia (BC) appointed a reviewer after allegations that emergency staff were guessing Indigenous patients' blood alcohol levels as a "game." The review, *In Plain Sight*, heard from almost 9,000 people; it found no organized game but widespread Indigenous-specific racism and discrimination across BC health care. Only 16% of Indigenous survey respondents reported no discrimination on eight measures, and 35% of responding health workers had personally witnessed discrimination against Indigenous patients or families. Stereotypes cast Indigenous patients as drinkers, drug-seeking, less worthy of care or "frequent flyers." The review linked racism to avoided care, harm and death, and made 24 recommendations (Government of British Columbia, 2020; Turpel-Lafond, 2020).

In September 2008, Brian Sinclair, a 45-year-old Indigenous man and double amputee who used a wheelchair, was sent to the Health Sciences Centre emergency department in Winnipeg about a blocked urinary catheter. After speaking to a triage aide, he waited 34 hours without assessment or treatment and died in the waiting room of peritonitis from a bladder infection. The inquest found the death avoidable, found no evidence that he was intoxicated, and noted that staff wrongly assumed he was homeless; it made 63 recommendations (Manitoba Ombudsman, 2019; Provincial Court of Manitoba, 2014). A *CMAJ* news report noted that some staff had assumed he was drunk or homeless, and Indigenous health conference speakers objected that the inquest would address patient flow, not profiling and stereotyping (Vogel, 2015).

In September 2020, Joyce Echaquan, a 37-year-old Atikamekw woman, died at the hospital in Joliette, Quebec, after livestreaming a video in which staff made degrading remarks to her. The coroner found that she was quickly labelled as dependent on narcotics without any explained clinical basis, and did not receive the close monitoring ordered while she was restrained. The coroner concluded that racism and prejudice contributed to her death, that it could have been avoided, and that the Quebec government should recognize systemic racism in its institutions (Kamel, 2021).

CLINICAL SAFETY

Racism Is a Patient Safety Issue

Racism causes harm through ordinary clinical shortcuts. When a team assumes that an Indigenous patient is intoxicated, drug-seeking or "just waiting for a ride," it stops looking for other causes. Hypoglycemia, stroke, sepsis, head injury and hypoxia can all look like intoxication. Brian Sinclair's death, described earlier in this section, shows where these shortcuts lead.

Every nurse:

- **Assesses fully:** vital signs, level of consciousness, blood glucose and the presenting complaint, for every patient, every time.
- **Documents objectively:** records what was seen, heard and measured ("speech slurred; capillary glucose 2.4 mmol/L"), not labels ("drunk," "drug-seeking").
- **Escalates:** reports abnormal or worsening findings at once and uses rapid response criteria when they are met (see Chapter 6).
- **Speaks up:** challenges stereotyping comments, supports the patient, and acts on discrimination, including reporting it through the employer's process, as the CNO Code of Conduct requires (see sections 2.2 and 2.6).

Health Outcomes in Context

Health gaps are real, and they result from policy, not individual choices or biology.

- **Life expectancy:** Among people living in private households, life expectancy at age 1 in 2011 was 8.9 years shorter for First Nations men and 9.6 years shorter for First Nations women than for non-Indigenous men and women; the gaps were 4.5 and 5.0 years for Métis and 11.4 and 11.2 years for Inuit. The authors cite colonization, racism, intergenerational trauma and other determinants (Tjepkema et al., 2019). Estimates for 2016 to 2021, released since, show trends that varied by region and group (Statistics Canada, 2025).
- **Tuberculosis:** In 2024, TB incidence was 186.9 per 100,000 among Inuit and 0.4 per 100,000 among non-Indigenous people born in Canada (PHAC, 2026b). TB spreads in crowded homes; in 2021, 52.9% of Inuit in Inuit Nunangat lived in crowded housing, compared with 9.4% of non-Indigenous people (Statistics Canada, 2022a). The Inuit Tuberculosis Elimination Framework names inadequate housing, food insecurity, poverty, stigma and the legacy of past TB policy as drivers, and sets an Inuit-led goal of eliminating TB in Inuit Nunangat by 2030 (ITK, 2018b, 2026).
- **Diabetes:** In the First Nations Regional Health Survey (2015–2016), age-standardized diabetes prevalence among First Nations adults on reserve and in northern communities was 19.2% (First Nations Information Governance Centre [FNIGC], 2018). Diabetes Canada's guideline, citing the World Health Organization, ranks colonization first among the social determinants of Indigenous health, acting through forced relocation, residential schools and discriminatory child welfare laws, with poverty and accumulated stress adding to the burden (Crowshoe et al., 2018; see Chapter 22). The survey itself is a strength: a national health survey that First Nations themselves govern and carry out (FNIGC, 2018).

Strengths and Indigenous-Led Care

Culture, language and land protect health. First Nations adults in land-based activities report greater physical or spiritual balance, and daily language users greater spiritual balance; culture and language are sources of healing and resilience (National Collaborating Centre for Aboriginal Health, 2016). Many Inuit continue to speak Inuktut and harvest country foods (ITK, n.d.-a).

In 2013, the FNHA, the first province-wide health authority of its kind, took over federal First Nations health programs in BC; its services include traditional healing (Government of British Columbia, n.d.). In Ontario, Indigenous Primary Health Care Organizations (formerly Aboriginal Health Access Centres) are Indigenous-governed, community-led teams that blend traditional healing with clinical care (Ontario Ministry of Health & Ontario Health, 2026).

London Health Sciences Centre's policy affirms Indigenous patients' right to ceremony, citing TRC Call to Action 22, and offers a liquid smudge to patients on oxygen (London Health Sciences Centre, 2025); Quinte Health designates smudging spaces and states that no one should be pressured to smudge (Quinte Health, 2022). **Indigenous patient navigators** support patients and families; at Hamilton's Juravinski Cancer Centre, the navigator joins patients at visits, helps arrange interpretation and transport, and links patients to traditional, spiritual and cultural services (Hamilton Health Sciences, n.d.).

At the bedside, the nurse:

- **Asks, does not assume:** asks how the patient identifies, their Nation or community, their preferred language, and whether they would like ceremony, traditional medicines, an Elder or a healer; not everyone does.

Figure 2.1 Braided sweetgrass (Hierochloe odorata), one of the sacred medicines used in First Nations, Inuit and Métis smudging and healing ceremonies. (credit: “Braided Sweet Grass” by Jamfam1000/Wikimedia Commons, CC BY-SA 4.0)

Figure 2.2 The health centre in Cambridge Bay, Nunavut. When a patient from a northern or remote community is discharged, the nurse connects with the community's health centre so that care continues at home. (credit: “38 Health centre” by CambridgeBayWeather/Wikimedia Commons, CC BY-SA 4.0)

- **Includes family:** asks who should be involved in decisions; family may include extended kin and community (see Chapter 1, section 1.5).
- **Respects protocols:** handles medicine bundles, eagle feathers and other sacred items only with permission, and follows the patient's or Elder's direction (Figure 2.1).
- **Uses supports:** involves the Indigenous patient navigator, spiritual care and the ceremony policy, including fire and oxygen safety.
- **Plans transitions with community:** connects with the patient's health centre, nursing station or Indigenous primary care team before discharge (Figure 2.2).

CANADIAN CONTEXT

Joyce's Principle

After Joyce Echaquan's death, the Council of the Atikamekw of Manawan and the Atikamekw Nation Council published a brief in November 2020. **Joyce's Principle** aims to guarantee every Indigenous person equitable access, free of discrimination, to all health and social services, and the right to the highest possible level of physical, mental, emotional and spiritual health. It also calls for Indigenous traditional and living knowledge to be recognized and respected in every aspect of health (Council of the Atikamekw of Manawan & Atikamekw Nation Council, 2020).

The brief asks governments to recognize the systemic racism Indigenous people face in health and social services. It asks health organizations to adopt the principle, ensure cultural safety, train staff in programs developed with Indigenous people and actively oppose racism. Professional regulators and schools are asked to build the principle into training and continuing education. The principle is inspired by Article 24 of the United Nations Declaration on the Rights of Indigenous Peoples (see section 2.4).

> For the nurse, Joyce's Principle means treating every Indigenous patient's account of symptoms as credible, involving family and traditional knowledge when the patient wishes, and refusing to stay silent when a colleague demeans a patient.

2.4 Rights, Policy and Data

Several national documents set out what Indigenous Peoples are owed in health care and what health professionals must do. Nurses meet them in hospital policies, accreditation standards and their own professional codes (see section 2.2).

The TRC's Health Calls to Action

In 2015, the TRC issued 94 **Calls to Action**, specific steps to redress the legacy of residential schools and advance reconciliation. Calls 18 to 24 address health (TRC, 2015b). Table 2.4 summarizes them in plain language, with examples of what a nurse can do. Call 24 speaks directly to nursing: every nursing and medical student should take a course on Indigenous health that covers the history and legacy of residential schools, the United Nations Declaration on the Rights of Indigenous Peoples, Treaties and Aboriginal rights, and Indigenous teachings and practices, with skills-based training in anti-racism, human rights, conflict resolution and intercultural competency. CASN and the Canadian Indigenous Nurses Association have set out strategies for schools to respond to Calls 23 and 24, including community partnerships, resident Elders and cultural safety training (CASN, 2020).

Table 2.4 The TRC's health Calls to Action and what nurses can do (original summary and examples; TRC, 2015b)

Call to Action	What it asks (summary)	What a nurse can do
18	Federal, provincial, territorial and Indigenous governments acknowledge that the current state of Indigenous health is a direct result of past Canadian government policies, including residential schools, and recognize Indigenous health rights under international law, the Constitution and Treaties	Learn the colonial history behind health gaps; explain gaps by their causes, not by individual blame
19	The federal government sets measurable goals to close health gaps and reports progress every year on indicators such as life expectancy, chronic disease, mental health and access to services	Read gap data critically (see the Going Deeper box); support community-led monitoring
20	The federal government recognizes and addresses the distinct health needs of Métis, Inuit and off-reserve Indigenous people, to address jurisdictional disputes	Check coverage early for Métis, non-status and urban patients; advocate when jurisdiction delays care
21	The federal government gives lasting funding to Indigenous healing centres that address residential school harms, with priority for Nunavut and the Northwest Territories	Know local Indigenous healing and wellness services and refer patients who want them
22	Those who can effect change in the health system recognize the value of Indigenous healing practices and use them with Indigenous healers and Elders when patients ask	Offer ceremony, traditional medicines and Elder visits; follow the facility policy; involve the navigator
23	Governments increase the number of Indigenous health professionals, help them stay in Indigenous communities and give every health professional cultural competency training	Mentor and support Indigenous students and colleagues; complete cultural safety training
24	Medical and nursing schools require every student to take a course on Indigenous health, history, rights and teachings, with anti-racism and related skills training	Take courses seriously; bring what is learned into practice; speak up about racism

UNDRIP and the Federal Act

The **United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP)**, adopted by the United Nations General Assembly in 2007, sets minimum standards for the rights of Indigenous Peoples. Article 24 affirms Indigenous Peoples' right to their traditional medicines and health practices, Indigenous individuals' right to all social and health services without discrimination, and their equal right to "the highest attainable standard of physical and mental health." Under Article 23, Indigenous Peoples have the

right to take an active part in shaping the health programs that affect them and, where possible, to run those programs through their own institutions (United Nations, 2007).

Canada's United Nations Declaration on the Rights of Indigenous Peoples Act received Royal Assent on June 21, 2021. It affirms the Declaration as an international human rights instrument that applies in Canadian law. It requires the federal government, working "in consultation and cooperation with Indigenous peoples," to make federal laws consistent with the Declaration, to prepare an action plan within two years, and to report on progress every year (United Nations Declaration on the Rights of Indigenous Peoples Act, 2021). The action plan, released on June 21, 2023, contains 181 measures (Department of Justice Canada, 2023).

Missing and Murdered Indigenous Women and Girls

The National Inquiry into Missing and Murdered Indigenous Women and Girls released its final report, *Reclaiming Power and Place*, on June 3, 2019, with 231 Calls for Justice (CIRNAC, 2025b). Calls for Justice 7.1 to 7.9 are addressed to health and wellness service providers. Among other things, they call for treating Indigenous Peoples as the experts on their own healing; supporting healing from intergenerational, multigenerational and complex trauma; backing Indigenous-led prevention; revitalizing Indigenous health, child-care and Elder-care practices; paying for healing programs and for services offered in Indigenous languages; ongoing training for health workers on Indigenous realities; and helping more Indigenous people enter health and wellness careers (CIRNAC, 2025b; National Inquiry into Missing and Murdered Indigenous Women and Girls, 2019). Nurses also apply these calls when they respond safely to disclosures of violence (see section 2.2).

Jordan's Principle and the Inuit Child First Initiative

Jordan's Principle aims to ensure that First Nations children can get essential government services without gaps or delays because of their identity or where they live; in February 2026, Canada committed funding to renew it to March 31, 2027 (ISC, 2026c). The **Inuit Child First Initiative** helps Inuit children get the health, social and educational services and supports they need; its funding was also renewed to March 31, 2027, while Canada and Inuit partners develop a long-term, Inuit-led approach (ISC, 2026b). Adult patients may be parents or caregivers of children with complex needs, so the nurse may mention these programs when a parent's admission threatens a child's care.

Data Sovereignty

Data sovereignty is the right of a People to govern data about themselves. **The First Nations Principles of OCAP®** state that First Nations have Ownership of, Control over, Access to and Possession of data about their communities. Ownership means a community owns its information collectively. Control means First Nations have the right to control research and information management that affects them. Access means First Nations can reach data about themselves wherever they are held and decide who else may. Possession means the physical stewardship of the data (FNIGC, n.d.). OCAP® applies specifically to First Nations. Inuit set out their own approach in the National Inuit Strategy on Research, one of whose priorities is to "ensure Inuit access, ownership, and control over data and information" (ITK, 2018a). The Métis National Council's 2025 Métis Nation Data Strategy affirms Métis governments' sovereignty over Métis data (MNC, 2025).

For nurses, data sovereignty matters when they read and cite First Nations, Inuit or Métis statistics, join quality improvement projects or research that includes Indigenous patients, or collect identity data on admission. The nurse asks whether the community approved the use of its data, uses data from Indigenous-governed sources where they exist, explains to patients why identity questions are asked and how answers are protected, and never shares community-level data without the agreement of the Nation or organization that governs it. OCAP® is a registered trademark of the First Nations Information Governance Centre (FNIGC).

GOING DEEPER

Reading Indigenous Health Data Critically

Required for registered nurse (RN) students; optional for practical nurse (PN) students.

RNs use statistics in care plans, unit education and quality projects, so they need to read Indigenous health data with care.

- **Distinctions:** an "Indigenous" average can hide large differences. In 2024, TB incidence per 100,000 was 186.9 among Inuit, 13.5 among First Nations and 1.3 among Métis (PHAC, 2026b). For Inuit living in Inuit Nunangat, ITK reports 246.4 per 100,000 (ITK, 2026). Geography and source change the number.

- **Who is counted:** the regional health survey covers First Nations people on reserve or in northern communities (FNIGC, 2018). Life expectancy studies cover only people in private households, leaving out people in collective dwellings such as institutions and shelters (Statistics Canada, 2025; Tjepkema et al., 2019). In 2021, 63 reserves and settlements were not fully counted in the census (Statistics Canada, n.d.).
- **Denominators:** census identity is self-reported and can change between censuses, so trends may reflect who identifies, not only who becomes ill (Statistics Canada, 2025).
- **Framing:** deficit-only lists invite blame. Pair each gap with its structural cause and with community strengths.
- **Governance:** check whether the data were used with community approval and under OCAP® or other Indigenous data principles.

Before using a statistic, the RN asks: Which People and place does it describe? Who was left out? What does it compare against? What causes does it name? Who owns these data, and did they agree to this use?

2.5 Caring for Other Equity-Deserving Adults

Sections 2.3 and 2.4 address First Nations, Inuit and Métis Peoples separately because of their distinct history and rights. Many other adults meet barriers to safe care that come from systems and from how people are treated, not from who they are. The groups overlap (see intersectionality, section 2.1), and Table 2.5 summarizes barriers and nursing actions.

Racialized Patients and Anti-Black Racism

Race is a social category, not a biological one: societies sort people by features such as skin colour, name, accent or origin and treat the groups unequally, a process called **racialization**. The Ontario Human Rights Commission uses **racialized** for a person treated this way and calls terms such as "visible minority" outdated (Ontario Human Rights Commission [OHRC], n.d.-b). A gap between racial groups points to exposure to racism, not to biology (RNAO, 2026).

Anti-Black racism is the discrimination, stereotyping and prejudice that people of African descent face. It is built into Canadian institutions and is often so normal that it goes unseen (RNAO, 2026). Section 2.2 summarizes RNAO's 2026 guideline *Addressing Anti-Black Racism in Nursing*.

Inequities also show up in outcomes. A Statistics Canada study linked 2016 census responses to hospital records for people aged 10 to 74, excluding Quebec residents and First Nations, Inuit and Métis respondents. In every year from 2016–2017 to 2021–2022, after adjusting for age, sex, income, education and immigrant status, the Black population had higher odds than the non-racialized population of hospitalization for conditions that good primary care can usually prevent; the authors suggest barriers to quality primary care as a reason (Brobbey et al., 2025).

On the unit, in addition to the anti-racist practices in section 2.2, the nurse:

- assesses skin by touch as well as sight, because redness and cyanosis are harder to see on darker skin (see Chapter 35);
- questions tools built on racial categories (see the Going Deeper box in section 2.6);
- documents behaviour objectively, avoiding labels such as "aggressive" or "non-compliant" that follow the patient (see the Clinical Safety box in section 2.3).

2SLGBTQI+ Patients

2SLGBTQI+ stands for Two-Spirit, lesbian, gay, bisexual, transgender, queer and intersex, with the plus sign for people who use other terms. "2S" is placed first in recognition that **Two-Spirit** people, an Indigenous identity, formed the first of these communities (Women and Gender Equality Canada [WAGE], 2024). **Gender identity** is a person's inner sense of being a man, a woman, both or neither. A **transgender** person's gender identity differs from the sex assigned at birth; a **cisgender** person's matches it (WAGE, 2024). In the 2021 Census, about 1 in 300 people aged 15 or older were transgender or non-binary (Statistics Canada, 2022c). Since 2012, Ontario's Human Rights Code has protected gender identity and gender expression (OHRC, n.d.-a).

Inclusive care starts at intake:

- **Chosen name and pronouns.** A **chosen name** is the name a person uses, which may differ from their legal name. As CNO's Code of Conduct expects, the nurse asks every patient for their name and pronouns, uses them and records them where possible (CNO, 2026); a mistake calls for a brief apology.
- **Sex assigned at birth only when it matters.** Custodians may collect only the personal health information that is reasonably needed (Information and Privacy Commissioner of Ontario, n.d.). The nurse asks about sex assigned at birth, anatomy or surgeries only when the answer changes care, and explains why.
- **Privacy.** Sexual orientation and gender history are personal health information, shared only with team members who need them for care.
- **Partners and chosen family.** The patient names their support people, such as partners, friends or **chosen family** (people a person treats as family), and a capable patient decides what they are told. The substitute decision-maker ranking includes a spouse or partner of any gender (see Chapter 1, section 1.5).

In a 2026 federal research summary on 2SLGBTQI+ adults aged 55 and older, about 80% of those surveyed had experienced discrimination; many feared mistreatment in care, separation from partners and having to hide their identity again (Employment and Social Development Canada, 2026). Rainbow Health Ontario offers provider training and clinical resources (Rainbow Health Ontario, n.d.); Chapter 29 covers gender-affirming surgery aftercare.

People with Disabilities

Under the Accessible Canada Act (2019), a **disability** is any impairment, such as a physical, mental, sensory or communication impairment, that, when it meets a barrier, prevents a person from taking part fully and equally in society. Barriers can be physical, attitudinal, informational or built into policies. This book uses person-first language, but many Deaf and autistic people prefer identity-first terms; the nurse follows the patient's preference.

- The Act aims for a barrier-free Canada in federal jurisdiction by 2040 and recognizes American, Quebec and Indigenous sign languages as the primary languages of deaf people (Accessible Canada Act, 2019).
- Ontario's Accessibility for Ontarians with Disabilities Act, 2005 (AODA) sets standards for organizations such as hospitals; its 2023 review called missing the 2025 goal of an accessible Ontario a near certainty and found poorer experiences for people with disabilities in health care (Accessibility for Ontarians with Disabilities Act, 2005; Donovan, 2023).
- Ontario's Human Rights Code adds a **duty to accommodate**: health care and other services are adjusted to the person, with dignity, short of undue hardship (OHRC, 2016).

Accommodation on the unit includes:

- **Communication supports:** a sign language interpreter booked early (see Chapter 1, section 1.7), facing a patient who lipreads, written or pictorial materials and extra time.
- **Service animals:** welcomed, following hospital policy, when easily identified (such as by a vest) or confirmed in a note from a regulated health professional; where another law bars animals from an area, staff offer another way to meet the need (Government of Ontario, 2026c).
- **Equipment:** mobility aids, hearing aids and communication devices kept within reach and never moved without asking, and an adapted call bell, such as a soft-touch pad, in place before the nurse leaves.

In **supported decision-making**, trusted people help a person understand choices and express a decision that stays the person's own; in **substitute decision-making**, someone else decides for a person who is incapable (see Chapter 1, section 1.5). Ontario law does not formally recognize supported decision-making (Law Commission of Ontario, 2017), but nurses can apply it: speak directly to the patient, use the patient's own ways of communicating, slow down and involve familiar supporters without letting them take over (Sullivan et al., 2018).

Diagnostic overshadowing is blaming new symptoms on a known diagnosis, such as a disability or mental illness, so that the real cause is missed (Hallyburton, 2022; Sullivan et al., 2018). New agitation in a man with an intellectual disability may be pain from urinary retention, so the nurse compares findings with his baseline, asks supporters what has changed and looks for physical causes first.

Newcomers and Refugees

Coverage for newcomers depends on immigration status and province. Ontario has no waiting period: people eligible for the Ontario Health Insurance Plan (OHIP) are covered right away (Government of Ontario, 2025).

The **Interim Federal Health Program (IFHP)** gives refugees, refugee claimants and certain others limited, temporary coverage until they qualify for provincial or territorial insurance, including hospital and physician care, tests, most drugs on the provincial formulary and some supplemental services (Immigration, Refugees and Citizenship Canada [IRCC], 2026b). Since May 1, 2026, beneficiaries pay $4 per prescription and 30% of the cost of other eligible supplemental services, such as dental care; basic hospital and physician care remains fully covered (IRCC, 2026a).

Many refugees have survived violence or dangerous journeys; most recover once they are safe, and pressing for disclosure may do more harm than good (Pottie et al., 2011). The nurse uses the trauma- and violence-informed approach in section 2.2 and a professional interpreter (see Chapter 1, section 1.7).

People Experiencing Homelessness or Living in Poverty

The *Canadian Definition of Homelessness* describes **homelessness** as lacking stable, permanent and suitable housing, with no immediate prospect, means or ability to obtain it. It arises from systemic barriers, too little affordable housing, personal challenges, and racism and discrimination, and it includes people in shelters or couch surfing as well as those sleeping outside (Gaetz et al., 2012). Section 2.1 gives the latest national count.

Without housing, conditions such as cellulitis, foot wounds and frostbite are harder to prevent and treat. In a Toronto study, hospital and shelter workers said discharges to shelters were undermined by poor follow-up care, hard-to-get shelter beds and little communication between the two (Jenkinson et al., 2022). Discharge planning starts on admission (see Chapter 1, section 1.7) and covers:

- **Shelter by night and day:** many shelters close in the daytime, so the social worker contacts the shelter, a respite program or a housing worker early; the team avoids late-evening discharges.
- **A plan that fits:** leg elevation and dressing changes are hard without a bed or bathroom, so the team simplifies care and arranges community follow-up.
- **Belongings:** listed and stored on admission, because losing identification or a phone cuts people off from care.
- **Medications and food:** coverage checked early (see the Patient Education box), a simple regimen in blister packs and a plan for meals.
- **Contact:** a phone number, shelter or drop-in centre where the team can reach the patient.

Figure 2.3 A mobile community health and wellness clinic van, one model used to bring primary care, wound care and harm reduction directly to underserved neighbourhoods. (credit: “Mobile health van - 2021-08-27 - Sarah Stierch” by Sarah Stierch [Missvain]/Wikimedia Commons, CC BY 4.0)

Partners include shelter and outreach workers, community health centres and peer workers; harm reduction is part of care for patients who use substances (see Chapter 11) (Figure 2.3).

Weight-Inclusive Care

Canada's adult obesity guideline describes obesity as a chronic disease in which excess body fat impairs health, and warns that weight bias in health care can worsen the care that people living with obesity receive. **Weight stigma** is the devaluing of people because of their body size. Providers should examine their own attitudes, avoid judgmental words and practices, not assume that a complaint is caused by weight, and ask permission before discussing weight or taking measurements (Wharton et al., 2020): "Is it all

right with you if we talk about your weight today?" When weight is needed for safe care, such as a weight-based dose, the nurse explains why and weighs the patient in private.

Equipment matters for safety and dignity. A cuff that is too small gives falsely high blood pressure readings: in one US trial, a regular cuff on an arm that needed an extra-large cuff raised systolic readings by about 20 mm Hg on average (Ishigami et al., 2023). The nurse uses a correctly sized cuff and arranges right-sized beds, chairs, commodes, gowns and lifts before the patient arrives.

Table 2.5 Adapting medical-surgical care for equity-deserving adults (Original table)

Group	Common barriers	What the nurse can do
Racialized patients	Racism in interactions and systems; symptoms dismissed or undertreated; assessment tools validated mainly on lighter skin; mistrust after past experiences	Assess pain and other symptoms in the same way for every patient; assess skin by touch as well as sight; question race-based assumptions and tools; document behaviour objectively; act on discrimination
2SLGBTQI+ patients	Wrong name or pronouns; intrusive questions; disclosure of identity without consent; partners or chosen family excluded	Ask every patient for name and pronouns and use them; ask about sex assigned at birth only when it changes care; share identity information only as needed; involve the people the patient names
People with disabilities	Inaccessible equipment, call bells and information; communication needs unmet; assumptions about capacity; diagnostic overshadowing	Arrange interpreters and communication supports early; keep mobility and communication devices within reach; welcome service animals per policy; presume capacity and support the patient's decisions; look for physical causes of change
Newcomers and refugees	Limited or temporary health coverage; co-payments; language barriers; past trauma; unfamiliar systems	Use professional interpreters and teach-back; explain each step and offer choices; refer to social work about IFHP or OHIP; avoid pressing for trauma histories
People experiencing homelessness or poverty	No safe place to recover; lost belongings and identification; cost of medications and supplies; poor access to food; no reliable phone	Start discharge planning on admission; store belongings safely; simplify the regimen and check coverage; link with shelters, outreach and community health centres; offer harm reduction
People living with obesity	Weight stigma; symptoms blamed on weight; equipment that does not fit; inaccurate measurements	Ask permission before discussing weight; weigh in private; use a correctly sized cuff; prepare right-sized beds, gowns, chairs and lifts in advance

PATIENT EDUCATION

Paying for Medications After Discharge

A prescription that is never filled cannot work. Before discharge, the nurse asks, "Is cost a worry for you?" and shares this plain-language guide for patients and families in Ontario.

- **Ontario Drug Benefit (ODB):** You are enrolled automatically on the first day of the month after you turn 65. You may also be covered at a younger age if you get Ontario Works or the Ontario Disability Support Program, live in a long-term care home, receive professional services through home and community care, are 24 or younger with no private plan, or are enrolled in the Trillium Drug Program (Government of Ontario, 2026a).
- **Trillium Drug Program:** If you do not qualify for the ODB, no plan pays all of your drug costs, and your prescriptions cost about 4% or more of your household's after-tax income, you can apply. You pay a yearly deductible based on income, then up to $2 for each prescription filled (Government of Ontario, 2026b).
- **Non-Insured Health Benefits:** Registered First Nations people and recognized Inuit are covered for many medications not covered by other plans (ISC, n.d.-b).
- **Interim Federal Health Program:** Refugees and refugee claimants who are covered pay $4 per prescription (IRCC, 2026a).
- **National pharmacare:** Under the federal Pharmacare Act (2024), Canada pays for no-cost coverage of some contraception and diabetes medications, but only in provinces and territories that sign an agreement. As of October 24, 2026, Health Canada listed agreements with four (British Columbia, Manitoba, Prince Edward Island and Yukon); Ontario was not one of them (Health Canada, 2024, 2026).
- **Ask for help:** Your pharmacist can check your coverage and suggest lower-cost options. The hospital social worker can help you apply for programs.

2.6 Equity in Everyday Medical-Surgical Practice

Equity is not a separate task added to a busy shift. It shows up in how the nurse assesses, documents, plans discharge and speaks up. This section brings the chapter's ideas to the bedside.

Implicit Bias and Diagnostic Overshadowing

Implicit bias is an attitude or stereotype that works outside a person's awareness and shapes judgments without the person intending it. A systematic review found evidence of implicit bias among physicians and nurses in almost all included studies, at levels similar to the general public. In several studies, higher implicit bias was linked to poorer interactions with Black patients or to treatment decisions that favoured White patients (FitzGerald & Hurst, 2017). Having implicit bias does not make a nurse a bad person; acting on it without checking does harm.

Pain care is where bias is easiest to see. A meta-analysis of US emergency department studies published between 1990 and 2018 found that Black patients with acute pain were less often given analgesia than White patients; the result for Hispanic patients leaned the same way but was not statistically significant (Lee et al., 2019). Canadian evidence is consistent. In the Indigenous Peoples' Survey of BC's *In Plain Sight* review (section 2.3), 35% of Indigenous respondents said they always received medication when they needed or asked for it, compared with 58% of non-Indigenous respondents (Turpel-Lafond, 2020). Diagnostic overshadowing (section 2.5) is a related trap: a new symptom is blamed on a known label, such as a disability, a mental illness, substance use or weight.

The nurse can slow down these quick judgments:

- Believe the patient's report of pain, assess it fully and treat it according to the plan (see Chapter 5).
- Ask, "Would I respond the same way if this patient were someone else?"
- Compare findings with the patient's own baseline, not with a stereotype.
- Use structured tools, such as early warning scores, consistently for every patient (see Chapter 6).

Screening for Social Needs

Social needs affect whether a plan of care can work. On admission and again before discharge, the nurse asks about income and drug coverage, food, housing, support, transportation, digital access, language and safety, using the kinds of questions in Table 2.1 (section 2.1). The nurse explains why the questions are asked, accepts "I'd rather not say," documents needs in neutral language and refers to the social worker or community partners. Screening without a plan to respond can feel intrusive, so the nurse knows the referral pathways before asking.

Speaking Up and Reporting Discrimination

CNO's Code of Conduct expects nurses to act to prevent discrimination and to respond when they see discrimination against a patient. Nurses also report errors and unsafe or unethical conduct to the appropriate authority, such as the employer or CNO (CNO, 2026). In practice, the nurse:

- addresses a disrespectful comment directly when it is safe to do so, often privately and calmly ("That comment isn't how we talk about patients here");
- puts the patient's safety and dignity first, which may mean changing an assignment;
- reports through the employer's process, such as a safety report, the manager or a human rights or equity office;
- documents the facts of care objectively in the health record, without opinions about colleagues.

Some situations carry legal reporting duties, such as the mandatory report of sexual abuse of a patient by a regulated health professional (see Chapter 1, section 1.5). Patients have their own routes. In Ontario, a patient or caregiver first raises a concern with the hospital's patient relations office. If the concern is not resolved, Patient Ombudsman, a provincial office, can help resolve complaints about care in public hospitals, home care, long-term care homes and community surgical and diagnostic centres (Patient Ombudsman, n.d.). Concerns about an individual nurse's practice can go to CNO.

GOING DEEPER

Race in Clinical Algorithms

Required for RN students; optional for PN students.

Some clinical formulas and devices carry racial assumptions that can harm patients.

Estimated glomerular filtration rate (eGFR). The 2009 Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) creatinine equation added a correction that raised eGFR for patients recorded as Black. In practice, that could make kidney disease look milder and delay referral. In 2021, new CKD-EPI equations were developed without race (Inker et al., 2021). The 2024 Kidney Disease: Improving Global Outcomes (KDIGO) guideline advises, in Practice Point 1.2.4.2, that the use of race in calculating eGFR should be avoided (KDIGO CKD Work Group, 2024). Canadian authors have called for **race-free equations** nationally, noting that Black people in Canada are referred later for kidney care (Parekh et al., 2022). Some Canadian laboratories have moved to the 2021 equation; Alberta Precision Laboratories, for example, began reporting it on January 20, 2026 (Alberta Precision Laboratories, 2026). Chapter 27 discusses eGFR in detail.

Pulse oximetry. In two large US cohorts, **occult hypoxemia**, an arterial oxygen saturation (SaO_2) below 88% despite a pulse oximeter reading (SpO_2) of 92% to 96%, occurred nearly three times as often in Black patients as in White patients (Sjoding et al., 2020). Health Canada warns that oximeter readings may be less accurate for people with dark skin (Health Canada, 2022).

What the nurse does:

- Assess the whole patient: respiratory rate, work of breathing, level of consciousness and trend, not the SpO_2 number alone.
- When signs and the reading disagree, report it; an arterial blood gas may be ordered to measure oxygenation directly (Health Canada, 2022).
- Report device problems through the hospital, which must report serious medical device incidents to Health Canada (Health Canada, 2023).

LIFESPAN CONSIDERATIONS

Older Residential School Survivors in Hospital

Many First Nations, Inuit and Métis older adults are Survivors of residential schools (see section 2.3), and many more were raised by Survivors. In the schools, children were separated from their families and from brothers and sisters, their hair was cut, their own clothes were replaced with school clothing, some were given numbers, their languages were suppressed and daily life was strictly controlled (TRC, 2015a). A hospital can echo that experience: uniforms, rules, locked doors, restraints, being told when to eat and sleep, separation from family, and staff who do not speak the patient's language.

Trauma- and violence-informed actions (section 2.2) include asking how the patient wants to be addressed and who they want with them; explaining each step; offering a professional interpreter (see Chapter 1, section 1.7); flexible visiting; avoiding restraint; welcoming Elders, ceremony and traditional foods according to the patient's wishes and hospital policy; and involving the Indigenous patient navigator where there is one.

Supports include the Indian Residential Schools Resolution Health Support Program, which offers cultural, emotional and counselling support to Survivors and their families; the 24-hour National Indian Residential School Crisis Line (1-866-925-4419); and the Hope for Wellness Help Line (1-855-242-3310), which serves all Indigenous people by phone or online chat (ISC, 2026a).

PRACTICE STORY

Hearing What Mr. Peters Wasn't Saying

Names and details are fictional; this is a composite story.

Nurse: Megan Kowalchuk, RN. Years in practice: 9. Setting: surgical unit, regional hospital, northwestern Ontario.

Mr. Peters was 74 and had flown in from a fly-in First Nation in northwestern Ontario for a bowel resection. On the first day after surgery, every time I asked about his pain, he said "two" and looked away. He wasn't using his incentive spirometer, and he refused to walk. His heart rate was 104, his blood pressure 152/90 and his respiratory rate 22, and he held his abdomen whenever he shifted in bed.

His nephew, travelling with him as his escort, stopped me in the hall. "He says 'okay' to be polite," he told me. "He uses English for everyday things. For something this important, he thinks in Oji-Cree." He added that his uncle hadn't wanted to bother the nurses, because the last time he was in a hospital, years ago, he was told to stop complaining.

I called our Indigenous patient navigator and booked an interpreter. With the interpreter beside us, Mr. Peters described pain that felt like a knife when he coughed or moved. I gave the hydromorphone that was ordered as needed and called the surgeon, who

added regular acetaminophen. An hour later he rated his pain as 4, did his breathing exercises and walked to the door with me. His heart rate was 88.

After that, I changed how I assessed him. I asked about his pain through the interpreter, with his nephew there when he wanted him; watched what he could do, not only the number he gave; and told him that reporting pain helps him heal.

The navigator and I also planned his trip home. We confirmed his medical travel and his nephew's escort travel, sent a discharge summary to the nursing station, and checked that the nursing station had the dressing supplies and could remove his staples. We made sure his pain medications could be filled before his flight.

On his last day, he shook my hand and spoke to his nephew, who translated: "You listened."

Reflect: What made the care Mr. Peters received early on unsafe for him, and who should judge whether his care was culturally safe? Within the RN's scope, what could I have done on the first day, before the escort spoke up?

Chapter 2 Summary

2.1 Health Equity and the Determinants of Health

- Equality gives everyone the same; equity gives people what they need for a fair chance at good outcomes.
- Health inequities are systematic, avoidable and unjust differences in health produced by how resources and power are distributed, not by biology or personal choice.
- PHAC describes social determinants (everyday conditions such as income, work, housing and freedom from discrimination) and structural determinants (the systems, laws and policies that shape those conditions); intersectionality explains how social positions combine.
- Canadian data show large inequities: 24.0% of Canadians lived in food-insecure households in 2024, and health-adjusted life expectancy differed by 8.1 years between the lowest and highest neighbourhood income groups in 2023.
- On medical-surgical units, determinants affect medication affordability, food, housing, caregiving, transport and digital access after discharge; the nurse asks every patient about them, from admission onward.

2.2 Cultural Safety, Humility and Trauma- and Violence-Informed Care

- Cultural safety came from Māori nursing students and teachers in Aotearoa New Zealand, led by Irihapeti Ramsden; it is defined by the person receiving care, not by the provider.
- Cultural humility is the ongoing self-reflective process; cultural safety is the outcome; both centre on power.
- The CNO Code of Conduct (principle 2) requires culturally safe, inclusive care through cultural humility, and the CNA Code (2025) includes pursuing truth and reconciliation and promoting social justice.
- Anti-racist practice is active: questioning assumptions, never treating race as biology, speaking up about and reporting discrimination.
- Trauma- and violence-informed care creates safety, choice and control without requiring disclosure, for example by explaining before touching, protecting privacy and avoiding restraint.

2.3 First Nations, Inuit and Métis Health

- First Nations, Inuit and Métis are distinct Peoples; nurses use a distinctions-based approach and the terms people use for themselves. Indian status is a legal category, not an identity, and it affects eligibility for federal health benefits.
- The Indian Act, residential schools, Indian hospitals, TB evacuations of Inuit, the Sixties Scoop and forced relocations harmed health across generations and explain why some patients, especially older adults, fear or distrust hospitals.
- Indigenous-specific racism is well documented in Canadian health care, as *In Plain Sight* (BC) and the deaths of Brian Sinclair and Joyce Echaquan show; assumptions such as intoxication delay diagnosis and cause harm.
- Health gaps, such as shorter life expectancy, high TB incidence among Inuit and high diabetes prevalence in First Nations communities, come from structural causes such as crowded housing, poverty, loss of land and racism, not from individual choices or biology.

- Culture, language, land and Indigenous-led services support health. The nurse asks about ceremony, family and Elders, respects protocols, involves the navigator and never assumes.

2.4 Rights, Policy and Data

- TRC Calls to Action 18 to 24 address health; Call 22 supports Indigenous healing practices when patients ask, and Call 24 asks nursing and medical schools to require a course on Indigenous health for every student.
- UNDRIP Article 24 affirms the right to traditional medicines and to health services without discrimination; the federal UNDRIP Act (2021) requires laws to align with the Declaration, and its 2023 action plan has 181 measures.
- The National Inquiry into Missing and Murdered Indigenous Women and Girls, in Calls for Justice 7.1 to 7.9, asks health providers to treat Indigenous Peoples as the experts on their own healing and to support trauma-informed, Indigenous-led care.
- Jordan's Principle and the Inuit Child First Initiative, both funded to March 31, 2027, support First Nations and Inuit children; adult patients may be their parents or caregivers.
- OCAP®, the National Inuit Strategy on Research and the Métis Nation data strategy affirm that Indigenous Peoples govern their own data; nurses read and use these data critically and with community agreement.

2.5 Caring for Other Equity-Deserving Adults

- Race is a social category, not a biological one; anti-Black racism is built into institutions and shows up in outcomes such as higher odds of avoidable hospitalization for Black people.
- Inclusive care for 2SLGBTQI+ patients means asking every patient's name and pronouns, asking about sex assigned at birth only when it changes care, protecting privacy and involving the support people the patient names.
- Disability arises when an impairment meets a barrier; nurses accommodate communication, mobility and service animal needs, support patients' own decisions and guard against diagnostic overshadowing.
- The Interim Federal Health Program gives temporary coverage to refugees and refugee claimants, with co-payments for prescriptions and supplemental services since May 1, 2026; eligible Ontario residents have OHIP coverage with no waiting period.
- Safe discharge for people experiencing homelessness starts on admission and plans for shelter, belongings, medications, food and follow-up with community partners.
- Weight-inclusive care asks permission before discussing weight and provides correctly sized equipment, including blood pressure cuffs.

2.6 Equity in Everyday Medical-Surgical Practice

- Implicit bias is common among health professionals and can affect assessment and treatment, including pain care; nurses check their judgments and assess every patient the same way.
- Nurses screen for social needs on admission and before discharge, using questions like those in Table 2.1, and have a referral plan before they ask.
- CNO expects nurses to act when they see discrimination; nurses address it, report it through employer processes and know patients' complaint routes, including Patient Ombudsman.
- Race-free eGFR equations and awareness of occult hypoxemia with pulse oximetry show why nurses question tools and assess the whole patient.

Key Terms (58)

2SLGBTQI+: An umbrella term for Two-Spirit, lesbian, gay, bisexual, transgender, queer and intersex people and others who are sexually and gender diverse; "2S" is placed first in recognition that Two-Spirit people formed the first of these communities.

anti-Black racism: The discrimination, stereotyping and prejudice that people of African descent face, built into the policies, practices and institutions of Canadian society and often unseen because it is so normal.

anti-racism: Active practice that names racism, including racism built into systems, and works to reduce the power differences that disadvantage racialized people.

Calls to Action: The 94 specific steps issued by the Truth and Reconciliation Commission of Canada in 2015 to redress the legacy of residential schools and advance reconciliation; Calls 18 to 24 address health.

chosen family: People a person chooses as family, such as close friends or partners, who may provide support in place of or alongside relatives by birth.

chosen name: The name a person uses, which may differ from the name on a health card or other legal record.

cisgender: Describes a person whose gender identity matches the sex they were assigned at birth.

cultural competence: The ability to reflect on one's own cultural values and to build the knowledge and skills to plan care that respects other people's values and beliefs.

cultural humility: A lifelong process of self-reflection on one's own biases, privilege and power, in which the provider approaches each person as a learner.

cultural safety: An outcome, judged by the person receiving care, in which care is respectful, free of racism and discrimination, and attentive to power imbalances in the health system.

data sovereignty: The right of a People to govern the collection, ownership and use of data about themselves.

determinants of health: The conditions and factors, social, economic, physical, biological and structural, that shape the health of individuals and populations.

diagnostic overshadowing: Attributing a new symptom to an existing diagnosis, such as a disability or mental illness, so that the real cause is missed.

disability: An impairment of any kind, such as a physical, mental, cognitive, sensory, learning or communication impairment, that, when it meets a barrier, prevents a person from taking part fully and equally in society.

distinctions-based approach: An approach that recognizes First Nations, Inuit and Métis as distinct Peoples with their own histories, rights, governments and priorities, instead of treating them as one group.

duty to accommodate: The obligation under human rights law to adjust services to an individual's disability-related needs in ways that respect dignity and support full participation, short of undue hardship.

equality: Giving every person the same resources or treatment, whatever their needs.

equity: Giving people what they need so that each person has a fair chance at good outcomes.

First Nations: The many distinct Indigenous Nations across Canada, each with its own language, laws and protocols; a First Nations person may or may not have Indian status.

food insecurity: Not being able to count on enough food, in quantity or quality, because money is short.

gender identity: A person's internal sense of their own gender, such as being a man, a woman, both or neither.

health equity: A state in which every person has a fair opportunity to reach their best possible health, regardless of the social and structural conditions of their lives.

health inequality: A measurable difference in health between groups of people.

health inequity: A systematic difference in health between groups that is avoidable and unjust because it results from how resources, power and opportunities are distributed.

homelessness: The situation of a person, family or community that lacks stable, permanent and suitable housing and has no immediate prospect, means or ability to obtain it.

implicit bias: An attitude or stereotype that operates outside a person's awareness and shapes judgments and actions without the person intending it.

Indian Act: The federal law, first passed in 1876, that defines who is registered as an "Indian" and has governed many aspects of First Nations life, including reserves and band governance.

Indian hospitals: Racially segregated federal hospitals for Indigenous patients, operated from 1936 to 1981 and first set up to isolate people with tuberculosis; patients experienced abuse in them.

Indian status: The legal standing of a First Nations person registered under the Indian Act; a legal category, not an identity.

Indigenous patient navigator: A hospital or health-system staff member who supports Indigenous patients and families, improves communication with the care team and connects patients with cultural, spiritual and community services.

Indigenous-specific racism: The particular stereotyping, bias and prejudice directed at Indigenous Peoples, rooted in settler colonialism, that sustains power imbalances and unequal outcomes.

intergenerational effects: Harms of colonial policies that pass from one generation to the next, for example through disrupted families, lost languages and unresolved trauma.

Interim Federal Health Program (IFHP): A federal program, run by Immigration, Refugees and Citizenship Canada, that provides limited, temporary health coverage to eligible refugees, refugee claimants and certain others until they qualify for provincial or territorial insurance.

intersectionality: A way of understanding how a person's social positions, such as race, gender, disability, age, income and immigration status, combine to shape experiences of advantage and disadvantage.

Inuit: The Indigenous People of Inuit Nunangat, many of whom now also live in southern cities; one person is an Inuk.

Inuit Child First Initiative: A federal initiative that helps Inuit children get the health, social and educational services and supports they need.

Inuit Nunangat: The Inuit homeland of land, water and ice, made up of the Inuvialuit Settlement Region, Nunavut, Nunavik and Nunatsiavut.

Jordan's Principle: A principle that aims to ensure First Nations children can get essential government services without gaps or delays caused by their identity or where they live.

Joyce's Principle: A principle set out in 2020 by the Council of the Atikamekw of Manawan and the Atikamekw Nation Council, after the death of Joyce Echaquan, that aims to guarantee Indigenous people equitable access to health and social services without discrimination, and respect for Indigenous knowledge in health.

Métis: A distinct Indigenous People who emerged from the 18th-century fur trade, with their own culture, language (Michif) and nationhood; being Métis is not the same as having mixed ancestry.

Non-Insured Health Benefits (NIHB): A federal program that pays for medically necessary benefits not covered by other plans, such as prescription drugs, dental and vision care, counselling, supplies and equipment, and medical transportation, for registered First Nations people and recognized Inuit.

OCAP®: The First Nations principles of Ownership, Control, Access and Possession, which state that First Nations govern data about their communities; a registered trademark of the First Nations Information Governance Centre.

occult hypoxemia: Low arterial oxygen saturation (below 88%) that is hidden by a pulse oximeter reading in the normal-looking range (92% to 96%).

race: A social category that sorts people by features such as skin colour, name or origin and ranks them unequally; it is not a biological measure.

race-free equations: Equations for estimated glomerular filtration rate (eGFR) that do not use race, such as the 2021 CKD-EPI equations.

racialization: The process by which a society treats races as real and distinct and ranks them unequally, with effects on people's economic, political and social lives.

racialized: Describes a person or group that society treats as belonging to a race and treats unequally because of it; preferred over older terms such as "visible minority."

residential schools: Church-run, government-funded schools that removed at least 150,000 First Nations, Inuit and Métis children from their families to assimilate them; the last federally supported schools closed in the late 1990s.

Sixties Scoop: The removal of many Indigenous children from their families by child welfare authorities, from about the 1960s to the 1980s, and their placement in non-Indigenous foster and adoptive homes.

social determinants of health: The everyday conditions in which people live and work, such as income, education, work, housing, social support and freedom from discrimination and violence.

structural determinants of health: The large systems, laws, policies and institutional practices, such as governments, labour markets and health, education, immigration and financial systems, that shape how resources and opportunities are distributed and so shape the social determinants.

substitute decision-making: An approach in which another person makes a decision on behalf of a person who is incapable of making it.

supported decision-making: An approach in which trusted people help a person understand choices and express a decision, while the decision remains the person's own.

transgender: Describes a person whose gender identity differs from the sex they were assigned at birth.

trauma- and violence-informed care (TVIC): An approach to care that recognizes the links between violence, trauma and health, including ongoing and structural violence, and focuses on creating safety, choice and control without requiring disclosure.

Two-Spirit: An English umbrella term used by some Indigenous people for an identity rooted in their own cultures, which may include gender, spiritual and sexual identity.

United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP): A declaration adopted by the United Nations General Assembly in 2007, which sets minimum standards for Indigenous rights, including the right to traditional medicines and to health services without discrimination (Article 24).

weight stigma: The social devaluing of people because of their body size, which can show up as stereotypes, judgmental language and equipment or practices that do not fit them.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

1. [CORE] A 61-year-old patient is ready for discharge after treatment for a new diagnosis of type 2 diabetes. During teaching, the patient says, "Some weeks I skip meals so the rent gets paid." Which action by the nurse is the priority before discharge?

a. Give the patient a printed meal plan from Diabetes Canada and review it with teach-back.

b. Document that the patient is likely to be non-adherent to the diet.

c. Report the food insecurity to the team and request social work and pharmacy input.

d. Advise the patient to take the new glucose-lowering medication only on days when meals are eaten.

Answer: c — The patient has described food insecurity, a determinant that can raise the risk of hypoglycemia with some glucose-lowering drugs and of poor glucose control; with the patient's agreement, the nurse shares it so the team can address income supports, food programs and medication choice before discharge (section 2.1, Table 2.1). A meal plan (a) assumes the patient can buy the food. Labelling the patient non-adherent (b) blames the patient for a structural problem and does not change the plan. Advising the patient to change the dose schedule (d) is outside the nurse's authority without an order and could be unsafe.

2. [CORE] A nurse is admitting a 47-year-old patient for an elective hip replacement. Which actions reflect an equity-oriented approach to admission? Select all that apply.

a. Ask the patient how they will get to follow-up appointments after discharge.

b. Ask about drug coverage only if the patient appears to have a low income.

c. Ask whether the patient cares for anyone at home who will need help while they recover.

d. Ask who will be at home to help in the first weeks after surgery.

e. Ask the same questions about housing and food of every patient, in a respectful way.

f. Wait until the day of discharge to ask about stairs and bathroom access at home.

Answer: a, c, d, e — Transport (a), caregiving responsibilities (c), help at home (d) and asking every patient the same questions (e) identify determinants early so the team can plan (section 2.1, Table 2.1). Asking about drug coverage only when a patient "appears" to have low income (b) relies on stereotypes and misses people whose needs are not visible. Discharge planning begins at admission (see Chapter 1, section 1.7), so waiting until the day of discharge (f) leaves no time to arrange equipment or services.

3. [CORE] A medical unit is updating its discharge process. Which change best reflects equity rather than equality?

a. Every patient receives the same printed discharge booklet in English, with a copy for the family.

b. Each patient is asked about language, drug costs and transport, and teaching is adjusted to fit.

c. Every patient receives a 10-minute discharge teaching session from a nurse at the same time of day.

d. Follow-up appointments are booked for all patients at the hospital's main clinic in the same time slot.

Answer: b — Equity means giving people what they need to have a fair chance at good outcomes; asking each patient about language, drug costs and transport and adjusting teaching to fit does this (section 2.1). Options a, c and d give everyone the same thing, which is equality. Identical resources can leave some patients, such as those with limited English, no drug plan or no transport, without what they need.

4. [CORE] Which statement by a nurse best shows cultural humility rather than cultural competence?

a. "I took a course on the beliefs of different cultural groups, so I know what this patient will want."

b. "I keep a list of the main cultural practices of groups on our unit, so I can apply the right ones to each patient I care for."

c. "I treat every patient exactly the same, so culture does not affect my care."

d. "I asked the patient what matters to her, and I am thinking about how my own assumptions shaped our talk."

Answer: d — Cultural humility is ongoing self-reflection on one's own biases, with the patient treated as the expert on their own life (section 2.2, Table 2.2). Options a and b describe a knowledge-based view of competence that can reduce culture to a checklist and lead to stereotyping. Option c ignores how differences in power and experience affect care, and treating everyone the same is equality, not safety.

5. [CORE] A nurse is about to insert an indwelling urinary catheter in a 34-year-old patient after surgery. As the nurse begins, the patient tenses, pulls the sheet up and says, "Wait." What should the nurse do first?

a. Stop, acknowledge the request, explain each step and ask what would help the patient feel in control.

b. Continue quickly so the procedure is over sooner and causes less distress.

c. Ask the patient directly whether they have a history of sexual abuse, so the nurse can plan the rest of their care.

d. Call another staff member to help hold the patient's legs in position so the catheter can be inserted safely.

Answer: a — Trauma- and violence-informed care builds safety and control: the nurse stops, respects the request, explains, and offers choices such as a pause or a different position (section 2.2). Continuing (b) overrides the patient's request and could retraumatize them; consent can be withdrawn at any time (see Chapter 1, section 1.5). Asking about abuse history (c) is not needed, because TVIC does not require disclosure. Holding the patient still (d) is a possible trigger and would proceed without consent.

6. [CORE] A First Nations patient tells the nurse, "The way the night staff talked to me last night didn't feel safe. They acted like I was just here for the pills." What is the best initial response by the nurse?

a. "I'm sure they didn't mean it that way. Night shift is very busy."

b. "If you're unhappy with your care, you should make a formal complaint to the patient relations office downstairs."

c. "Thank you for telling me. Can you tell me more about what happened and what would help you feel safer here?"

d. "I'll speak to the night nurse about this and ask her to come and apologize to you when she is back on shift tonight."

Answer: c — Only the patient can say whether care felt culturally safe; the nurse listens, believes the patient, thanks them for the feedback and asks what would help, and then acts and reports according to policy (section 2.2). Option a defends staff and dismisses the patient's experience. Option b passes responsibility on before the nurse has heard the concern, although the patient may be told about this option later. Option d decides on a solution without asking the patient what they want.

7. [CORE] A nurse is caring for a 72-year-old woman who is racialized, uses a wheelchair, lives alone on a fixed income and speaks limited English. She has been readmitted with heart failure. A colleague says, "She's just not following her plan." Which understanding should guide the nurse's response?

a. Her readmission is best explained by her age, so the plan should focus on her heart failure.

b. Her social positions and circumstances combine to create barriers to following the plan, and those barriers need to be assessed.

c. Her limited English is the only barrier, so a professional interpreter will solve the problem.

d. Her readmission shows a lack of motivation, so the discharge teaching should stress the serious risks of not following her heart failure plan.

Answer: b — Intersectionality describes how several social positions, such as race, disability, age, income and language, combine to shape barriers; the nurse assesses each barrier, such as cost, access to the pharmacy, mobility and understanding, rather than blaming the patient (section 2.1). Age (a) and language (c) each explain only part of her situation, although an interpreter is still needed (see Chapter 1, section 1.7). Option d attributes the readmission to personal choice and ignores the conditions shaping it.

8. [CORE] A 72-year-old First Nations patient is recovering from a bowel resection on a surgical unit. He receives oxygen at 2 L/min by nasal cannula. His daughter asks whether an Elder can come to smudge with him tomorrow. What is the best response by the nurse?

a. "Smudging isn't possible on this unit while your father is on oxygen, so the Elder could visit after he goes home instead."

b. "Thank you. I'll ask the Indigenous patient navigator and spiritual care to arrange it under our ceremony policy, including oxygen safety."

c. "You can go ahead tomorrow. I'll turn his oxygen off for a few minutes while the Elder smudges at the bedside."

d. "I'll need a physician's order before any ceremony can take place in his room, so I'll ask at rounds."

Answer: b — TRC Call to Action 22 and hospital policies support ceremony when patients ask, and the safe route is through the navigator, spiritual care and the facility's policy, which covers fire and oxygen safety, for example a liquid smudge or another space (section 2.3). Refusing outright (a) denies a right the facility can usually accommodate. Turning oxygen off without an order or a plan (c) is unsafe and bypasses policy. Ceremony is arranged through the facility's policy, not by a physician's order (d), although the team plans it together.

9. [CORE] A nurse is admitting several Indigenous patients during a shift. Which actions reflect respectful, distinctions-based practice? Select all that apply.

a. Asking each patient how they identify and which Nation or community they are from

b. Recording "Aboriginal" for every Indigenous patient so the chart is consistent

c. Referring to one Inuit patient as "an Inuk woman"

d. Assuming an Inuk patient from Nunavik prefers to speak Inuktut and booking an interpreter without asking

e. Asking a Métis patient about drug coverage early in discharge planning

f. Telling a colleague that "our Indigenous patients" usually want to smudge

Answer: a, c, e — Asking how a person identifies (a) and using the People's own terms, such as Inuk for one person (c), are distinctions-based. Métis patients are not eligible for NIHB, so checking coverage early (e) prevents a gap at discharge (section 2.3, Table 2.3). A single blanket term (b) erases distinctions, and "Aboriginal" is now kept mostly for legal and historical names. Language preference must be asked, not assumed (d); the nurse offers an interpreter (Chapter 1, section 1.7). Possessive phrasing ("our Indigenous patients") and generalizing about ceremony (f) are disrespectful and assume practices that differ between Nations and people.

10. [CORE] Which patient qualifies for Non-Insured Health Benefits (NIHB)?

a. A Métis citizen registered with her Métis government who lives in Toronto

b. A First Nations man who is not registered under the Indian Act

c. An Inuk woman recognized by Nunavut Tunngavik Incorporated who now lives in Ottawa

d. A woman who identified as Indigenous on the 2021 Census

Answer: c — NIHB covers residents of Canada who are First Nations people registered under the Indian Act, Inuit whom an Inuit land claim organization recognizes, and children under 2 whose parent is eligible; living outside Inuit Nunangat does not change eligibility (section 2.3, Table 2.3). Métis people are not eligible (a). A First Nations person without registration is not eligible, though no less First Nations (b). Census self-identification does not establish eligibility (d).

11. [CORE] A 54-year-old First Nations man is brought to the emergency department after he was found sitting outside a shopping centre. His speech is slurred and he is drowsy. A colleague says, "He's probably drunk again. Let him sleep it off in the hallway." What should the nurse do first?

a. Ask the man's family whether he has a history of alcohol use.

b. Let him rest on a hallway stretcher and recheck his condition in 2 hours.

c. Ask security to stay with him in case he becomes aggressive.

d. Assess him fully, including vital signs, level of consciousness and capillary blood glucose.

Answer: d — Slurred speech and drowsiness can come from hypoglycemia, stroke, head injury, sepsis or hypoxia, so a full assessment comes first, and abnormal findings are escalated (section 2.3, Clinical Safety box; Chapter 6). Asking about alcohol (a) follows the stereotype instead of the cues. Leaving him unassessed (b) repeats the error that led to Brian Sinclair's death. Calling security (c) treats him as a threat without evidence. The nurse should also challenge the colleague's comment.

12. [CORE] During care, a nurse hears a colleague tell a First Nations patient, "You people always exaggerate your pain to get drugs." The patient turns away and says nothing. What should the nurse do?

a. Stay with the patient, reassess her pain, and report the comment through the unit's process for reporting racism.

b. Wait until the end of the shift, then talk with the colleague privately and decide together whether the comment needs to be reported.

c. Ask the patient whether she wants to make a complaint before taking any action.

d. Write in the chart that the patient appears to be seeking drugs, so the next shift is aware.

Answer: a — The nurse's first duty is the patient's safety and dignity: support her, reassess the pain as credible, and report racism as the CNO Code of Conduct and Joyce's Principle expect (sections 2.2 and 2.3). Delaying (b) leaves the patient exposed and lets the behaviour go unaddressed. The patient may choose to complain, but the nurse's duty to report does not depend on her deciding to (c). Charting a label (d) repeats the kind of unfounded label that harmed Joyce Echaquan and is not objective documentation.

13. [CORE] A medical unit wants to respond to TRC Call to Action 22. Which action fits this call best?

a. Collect Indigenous identity on every admission so the unit can report its numbers.

b. Set up a clear process for patients to request Elders, healers and traditional medicines.

c. Send every Indigenous patient to the patient navigator at admission, whether or not they ask.

d. Require all staff to complete a course on Treaties and Aboriginal rights.

Answer: b — Call 22 asks the health system to recognize Indigenous healing practices and use them with healers and Elders when patients request it (section 2.4, Table 2.4). Collecting identity data (a) does not address healing practices and must follow data principles. Mandatory referral (c) removes the patient's choice. Staff training (d) relates more closely to Calls 23 and 24.

14. [CORE] A nurse on a hospital quality committee wants to present wound-healing outcomes for patients from a nearby First Nation at a conference. Which action follows the First Nations Principles of OCAP®?

a. Seek approval and involvement from the First Nation's leadership or health centre before using the data.

b. Remove patient names and other identifiers; once the data are de-identified, community approval is not needed.

c. Use the data freely because they were collected in the hospital's own records under its privacy policies.

d. Ask the First Nations Information Governance Centre for permission on the community's behalf.

Answer: a — Under OCAP®, the First Nation collectively owns and controls data about its community and decides how they are used, so the nurse seeks the community's approval and involvement (section 2.4). De-identifying individuals (b) does not remove the community's collective interest. Where the data are stored (c) does not decide who governs them. FNIGC holds the OCAP® trademark but cannot consent on behalf of a particular community (d).

15. [CORE] A 78-year-old Inuk woman from Nunavut is admitted to a southern hospital with pneumonia. She is restless, keeps asking to go home and refuses to stay overnight. Through an interpreter, she says her mother was sent south for tuberculosis and never came back. What is the best response by the nurse?

a. Reassure her that patients are no longer sent away for long periods the way her mother was, so she has nothing to worry about.

b. Ask for a psychiatry consultation to assess her anxiety before treatment continues.

c. Acknowledge her experience, explain the plan and when she may go home, and ask who she would like with her.

d. Explain that refusing to stay overnight will be documented as non-compliance with her treatment plan.

Answer: c — Her fear is a reasonable response to a real history of TB evacuations, so the nurse acknowledges it, keeps her informed, brings family and supports such as the Indigenous patient navigator close, and respects her choices (section 2.3; section 2.2 on trauma- and violence-informed care). Brushing the history aside (a) dismisses her experience. Treating the response as a psychiatric problem (b) pathologizes a reasonable fear. Threatening a label (d) is coercive and damages trust.

16. [RN] An RN preparing a unit education session finds the statement "Indigenous people in Canada have a TB rate many times higher than other Canadians." Which questions should the RN ask before using it? Select all that apply.

a. Does the figure separate First Nations, Inuit and Métis?

b. Which people and places were included, such as on reserve, in Inuit Nunangat or only private households?

c. Does the source name the structural causes, such as crowded housing?

d. Were the data used with the agreement of the communities that govern them?

e. Is the number large enough to persuade staff that the issue matters?

f. Does the statistic show that the group has a genetic risk for TB?

Answer: a, b, c, d — Aggregated "Indigenous" figures hide differences: 2024 TB incidence ranged from 1.3 per 100,000 among Métis to 186.9 among Inuit (a). Coverage and geography change the number (b). Naming causes avoids blame (c), and data governance respects OCAP® and Inuit and Métis data principles (d) (section 2.4, Going Deeper box). Choosing a figure for its impact (e) is not a test of its quality. Health gaps are not explained by race as biology (f); they reflect housing, poverty and history.

Case: Mr. Leonard Fraser (Questions 17–26): Mr. Leonard Fraser, 58, has been on a medical unit in an Ontario city for 4 days with cellulitis of the right lower leg. He was treated with intravenous antibiotics and will be switched to oral cephalexin capsules, four times a day, for 7 more days. Today: temperature 37.2 °C, heart rate 84, blood pressure 132/78, respiratory rate 16, SpO_2 97% on room air. White blood cell count 9.1 × 10^9/L (15.6 × 10^9/L on admission); random glucose 6.4 mmol/L; creatinine 92 µmol/L. The redness, warmth and swelling have shrunk well inside the border marked on admission. Mr. Fraser has slept at an overnight shelter for 8 months. The shelter opens at 2000 and closes at 0800. He says, "My boots leak, and I have nowhere to put my feet up." He has an Ontario health card but no drug plan, and he has lost his medications twice this year when his backpack was stolen. His phone has no data plan.

17. [CORE] The nurse reviews Mr. Fraser's information on the planned day of discharge. Which findings threaten a safe discharge? Select all that apply.

a. He must leave the shelter at 0800 each day.

b. His temperature is 37.2 °C.

c. He has no drug plan for the cephalexin.

d. His medications have been stolen before.

e. His white blood cell count has fallen to 9.1 × 10^9/L.

f. He cannot keep his legs elevated or his feet dry.

Answer: a, c, d, f — Recognizing cues means picking out the findings that matter for the decision at hand (see section 2.5 and Chapter 1, section 1.4). Having nowhere to rest in the day (a), no drug coverage (c), a history of stolen medications (d) and no way to elevate his leg or keep his feet dry (f) all threaten his recovery after he leaves. A temperature of 37.2 °C (b) is within normal limits, and a falling white blood cell count (e) shows the infection is responding; neither threatens the discharge.

18. [CORE] Which statement best explains how Mr. Fraser's housing situation relates to his cellulitis?

a. Wet feet and having nowhere to rest or elevate his leg raise his risk of the infection coming back.

b. His housing has no bearing on his leg once he has finished the full antibiotic course.

c. His cellulitis was caused mainly by poor hygiene choices that discharge teaching can correct.

d. His risk of cellulitis is high mainly because of his age, which cannot be changed.

Answer: a — Analyzing cues links findings to their likely causes. Homelessness exposes his skin to moisture, swelling and injury, and makes leg elevation and wound care hard, which raises the risk of recurrence (section 2.5). Option b ignores the conditions he returns to. Option c blames the individual rather than naming the structural cause; the Canadian Definition of Homelessness stresses that systemic barriers drive homelessness. Option d names a fixed factor and misses the main, changeable one.

19. [CORE] Which concern should the team address first in Mr. Fraser's discharge plan?

a. Teaching him to recognize the signs of a fungal infection between the toes.

b. Arranging a follow-up visit with a dermatologist within 3 months.

c. Making sure he can get, keep and take the full course of cephalexin.

d. Helping him join a smoking cessation program.

Answer: c — Prioritizing hypotheses means choosing the most important and urgent problem. An incomplete antibiotic course risks treatment failure and readmission, and three of his cues (no drug plan, stolen medications, nowhere to stay in the day) threaten it (section 2.5). Option a is useful, because foot care can prevent recurrence, but less urgent. Option d addresses a problem the case does not mention. Option b is a long-term step that does not address the immediate risk.

20. [CORE] Which actions should the nurse include when planning Mr. Fraser's discharge with the team? Select all that apply.

a. Ask the social worker to check his eligibility for drug coverage and help pay for the first fill.

b. Arrange for the shelter or a respite program to offer a daytime place to rest and elevate his leg.

c. Discharge him at 1930 so that he arrives just as the shelter opens.

d. Ask the prescriber and pharmacist whether a simpler regimen or blister packaging is possible.

e. Arrange new, dry socks and footwear through a hospital or community program.

f. Tell him to come back to the emergency department if he has any questions at all.

Answer: a, b, d, e — Generating solutions means planning actions that fit the patient's real situation (section 2.5). Securing coverage and the first fill (a), a daytime place to rest (b), a regimen he can manage (d) and dry footwear (e) all address his barriers. Option c creates a late-evening discharge, which the team should avoid; it leaves him exposed if the shelter has no bed. Option f sends routine questions to the emergency department instead of arranging follow-up, such as a community clinic or outreach nurse.

21. [CORE] On the morning of discharge, Mr. Fraser says, "I'll just go. I've never been able to get pills paid for, and the shelter doesn't want sick people." What should the nurse do first?

a. Document that he is non-compliant with the discharge plan.

b. Acknowledge his worry and tell him what has been arranged for his medications and shelter.

c. Remind him that he will need to be readmitted if he does not take his antibiotics.

d. Ask a family member to persuade him to stay.

Answer: b — Taking action starts with a respectful, trauma- and violence-informed response that builds trust (sections 2.2 and 2.5). Acknowledging his past experience and explaining the concrete plan gives him real information and choice. Option a uses a stigmatizing label and does nothing to solve the problem. Option c uses fear rather than support. Option d brings in another person without his consent, and he has not named anyone.

22. [CORE] Mr. Fraser returns for a follow-up visit 5 days later at a community health centre. Which finding best shows that the discharge plan is working?

a. He says the hospital staff treated him with respect during his stay.

b. He reports that his leg feels "about the same" as it did at discharge.

c. He has been placed on a waiting list for a unit in social housing.

d. He takes his doses from his blister pack, and the redness has shrunk since discharge.

Answer: d — Evaluating outcomes compares results with the goals of care: completing the antibiotic and continued healing (section 2.5). Option d shows both. Option a is welcome but does not show that he is taking the antibiotic or that the infection is healing. Option b suggests no improvement and needs further assessment. Option c is valuable for his long-term health but does not show that the infection is resolving.

23. [CORE] The admission record shows a first name that Sam does not use. Which action should the RPN take first?

a. Call him by the name on his health card, because it is his legal name.

b. Ask him what name and pronouns he uses, and use them.

c. Avoid using any name until the record is changed.

d. Ask his partner what he would like to be called.

Answer: b — CNO's Code of Conduct expects nurses to use the name, title and pronouns a patient prefers (section 2.5). The nurse asks the patient directly and records the chosen name where the record allows, while still using the legal name and two identifiers for patient identification. Option a ignores his identity and the CNO expectation. Option c is awkward and impersonal. Option d asks someone else when Sam is capable of answering for himself.

24. [CORE] During the admission interview, the RPN is completing the nursing assessment. When is it appropriate to ask about Sam's sex assigned at birth or his past surgeries?

a. Only when the answer would change his care, explaining why the question is asked.

b. At every admission, because curiosity helps nurses learn about transgender patients.

c. Never, because such questions are always discriminatory.

d. Only after his partner leaves the room, without explaining the reason.

Answer: a — Custodians may collect only the personal health information that is reasonably necessary, so the nurse asks about anatomy or past surgeries only when it affects care, such as an anatomy-specific assessment, and explains why (section 2.5). Option b collects information for the nurse's interest, not the patient's care. Option c could miss information that is clinically needed. Option d may be appropriate for privacy if Sam wants it, but leaving out the explanation makes the question feel intrusive.

25. [CORE] After surgery, Sam is drowsy but capable. Daniel asks the RPN how the surgery went. What should the RPN do?

a. Refuse, because only relatives by birth or marriage can receive information.

b. Share the information, because partners are part of the circle of care.

c. Ask Sam whether he agrees to the RPN sharing information with Daniel.

d. Tell Daniel to ask the surgeon.

Answer: c — A capable patient decides who receives his health information, and partners and family members are not health information custodians (Chapter 1, section 1.5; section 2.5). Option a is wrong and discriminatory; the patient, not the type of relationship, decides who his support people are. Option b misstates the circle of care. Option d delays the answer and still requires Sam's consent.

26. [CORE] At handover, a colleague jokes about Sam's identity in a voice that can be heard in the hallway. What is the RPN's best response?

a. Ignore the comment so that handover finishes on time.

b. Tell Sam what the colleague said so that he can complain.

c. Write an account of the colleague's comment in Sam's health record.

d. Address the comment calmly with the colleague and report it through the employer's process.

Answer: d — The Code of Conduct expects nurses to take action when they see discrimination against a patient (section 2.6). Speaking to the colleague and using the employer's reporting process protects Sam and future patients. Option a lets discrimination continue. Option b may cause Sam distress and shifts the burden onto him; he can still be supported if he raises a concern himself. Option c misuses the health record, which documents care, not opinions about colleagues.

27. [CORE] A patient on a surgical unit tells the nurse that she felt dismissed and judged by staff during her stay and wants to make a complaint. What should the nurse tell her about the usual first step in Ontario?

a. File a complaint directly with Patient Ombudsman before speaking to anyone at the hospital.

b. Wait until after discharge, because complaints cannot be made during a hospital stay.

c. Contact the hospital's patient relations office, and go to Patient Ombudsman if the concern is not resolved.

d. Write a letter to the College of Nurses of Ontario, which handles all hospital complaints.

Answer: c — Patient Ombudsman asks people to try to resolve the concern with the organization first and becomes involved if it is not resolved (section 2.6). The nurse also reports her own concerns about discrimination through the employer's process. Option a skips the hospital's process. Option b is false and delays the response. Option d is wrong because CNO handles concerns about individual nurses, not hospital complaints in general.

28. [RN] A laboratory changes from the 2009 race-adjusted CKD-EPI creatinine equation to the 2021 race-free equation. What is the likely effect for a Black patient with chronic kidney disease whose results were previously reported with the race adjustment?

a. The reported eGFR will be lower, which may lead to earlier referral for kidney care.

b. The reported eGFR will be higher, so the kidney disease will appear milder than before.

c. The measured serum creatinine value will fall because the calculation has changed.

d. The patient's actual kidney function will improve as a result of the change.

Answer: a — The race correction in the 2009 equation raised eGFR for patients recorded as Black, which could make kidney disease look milder and delay referral; removing it gives a lower reported eGFR in that situation (Going Deeper box, section 2.6). Option b describes the effect of the old correction, not of the change. Option c is wrong because the equation changes only the calculation, not the measured creatinine. Option d confuses a change in reporting with a change in the patient's kidney function.

29. [RN] A patient with darker skin has pneumonia and is receiving oxygen at 2 L/min by nasal prongs. The pulse oximeter reads 94%, but the patient is newly confused, has a respiratory rate of 28 and is using accessory muscles. What should the RN do first?

a. Document the SpO_2 and reassess in 4 hours, because 94% is acceptable.

b. Escalate to the prescriber now and anticipate an arterial blood gas.

c. Move the probe to another finger and record whichever reading is higher.

d. Remove the oxygen to see whether the saturation stays the same.

Answer: b — Pulse oximeters can overestimate oxygen saturation in people with darker skin, and occult hypoxemia can hide behind readings of 92% to 96% (Going Deeper box, section 2.6). The RN treats the reading as possibly inaccurate: new confusion, tachypnea and accessory muscle use are signs of deterioration that need urgent escalation, and an arterial blood gas measures oxygenation directly. Option a ignores the clinical signs. Option c picks the most reassuring number rather than assessing the patient. Option d is unsafe in a patient who is deteriorating.

30. [RN] An RN notices that one model of pulse oximeter on the unit often gives readings that do not match patients' arterial blood gas results. What should the RN do?

a. Stop using every pulse oximeter on the unit until the manufacturer has inspected them.

b. Subtract 4% from each reading from this model before documenting it.

c. Tell patients that readings from this model are unreliable and they should ignore them.

d. Report the problem through the hospital's incident reporting process.

Answer: d — Hospitals must report serious medical device incidents to Health Canada, and the nurse's report through the hospital's process starts that review (Going Deeper box, section 2.6). Option a removes a useful monitoring tool without a plan. Option b invents a correction that has not been validated. Option c alarms patients without fixing the problem.

03 Fluids, Electrolytes and Acid–Base Balance

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how the body regulates water, electrolytes and acid–base balance, including osmosis, antidiuretic hormone, the renin–angiotensin–aldosterone system, the kidneys and the lungs.
2. Recognize, analyze and prioritize cues of fluid volume deficit and excess in adults, especially older adults.
3. Compare common intravenous solutions and apply safe practices for giving intravenous fluids and electrolytes, including concentrated potassium.
4. Explain the causes, manifestations and nursing care of sodium and potassium imbalances, including electrocardiogram changes.
5. Describe calcium, magnesium and phosphate imbalances, including refeeding syndrome.
6. Identify the four primary acid–base disorders from a blood gas and link each to its common causes.
7. Teach patients and families to prevent and recognize fluid and electrolyte problems at home.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 4, 5, 6	Clinician; Scholar	Foundations of Practice
2	Clinician; Coordinator	Foundations of Practice; Collaborative Practice
3	Clinician; Leader	Foundations of Practice; Professional Practice
7	Educator; Communicator	Foundations of Practice; Collaborative Practice

Introduction

Every patient on a medical-surgical unit depends on a stable internal environment. Water, electrolytes and acids must stay within narrow limits for cells, nerves and the heart to work. Illness, surgery, medications and treatments disturb that balance every day. A patient who vomits for two days, an older adult who stops drinking during a heat wave, a patient with heart failure who gains weight, and a patient after bowel surgery receiving intravenous (IV) fluids all need a nurse who can recognize early cues and act before harm occurs.

Nurses play a central part in this work. They measure intake and output, weigh patients, give and monitor IV fluids and electrolytes, interpret laboratory results, and notice early changes in vital signs or mental status. Errors with IV fluids and concentrated electrolytes can cause serious harm, so safe practice also matters.

This chapter begins with how the body regulates fluid (section 3.1), then covers fluid volume deficit and excess (section 3.2) and IV fluids and fluid management (section 3.3). Later sections address sodium, potassium, calcium, magnesium and phosphate imbalances and acid–base balance. Shock is covered in Chapter 6, fluids in sepsis in Chapter 4, heart failure in Chapter 18, diabetic emergencies in Chapter 22 and kidney disease in Chapter 27.

3.1 Body Fluids and How They Are Regulated

Total Body Water and Fluid Compartments

Water makes up about 50% to 60% of an adult's body weight (Danziger & Zeidel, 2015). It is held in two main compartments. **Intracellular fluid (ICF)** is the water inside cells, and it accounts for about two-thirds of body water. **Extracellular fluid (ECF)** is

all the water outside cells, about one-third of the total. The ECF has two main parts. **Interstitial fluid** bathes the cells in the tissues and makes up most of the ECF. **Intravascular fluid** is the plasma, the liquid part of blood. Plasma is the smallest compartment, but it maintains blood pressure, so even small losses from it matter.

Water moves freely between compartments. When the body gains or loses pure water (water without sodium), most of the change ends up inside cells, and only a small share stays in the blood vessels (Danziger & Zeidel, 2015).

Osmosis, Osmolality and Tonicity

Osmosis is the movement of water across a membrane from an area of lower solute concentration to one of higher solute concentration. **Osmolality** is the concentration of dissolved particles per kilogram of water, reported in mOsm/kg. A typical adult serum osmolality is about 275 to 295 mOsm/kg, although reference ranges vary by laboratory (University of Ottawa, 2022). Product labels for IV fluids usually report **osmolarity**, the concentration per litre of solution (mOsmol/L).

Tonicity is the effect a fluid has on cell volume. It depends only on solutes that cannot cross cell membranes freely, mainly sodium in the ECF. Urea and, when insulin is present, glucose cross into cells easily, so they add to osmolality but not to tonicity (Danziger & Zeidel, 2015). An **isotonic** fluid has about the same tonicity as plasma, so cells keep their size. A **hypotonic** fluid has a lower tonicity, so water moves into cells and they swell. A **hypertonic** fluid has a higher tonicity, so water moves out of cells and they shrink. Brain cells are especially affected by these shifts, so a change in tonicity can show as headache, nausea, lethargy or seizures (Baxter Corporation, 2018c).

Starling Forces

Fluid exchange between plasma and the interstitial space depends on **Starling forces**. Capillary hydrostatic pressure, the pressure of blood against the vessel wall, pushes fluid out of the capillary. Plasma oncotic pressure, created mainly by albumin and other plasma proteins, holds fluid in the vessel (Woodcock & Michel, 2021). Current research shows that in most tissues, capillaries filter a small amount of fluid out continuously but do not draw much back in. Instead, the lymphatic system returns that fluid to the circulation. **Edema**, excess fluid in the interstitial space, forms when filtration rises, for example from high venous pressure, inflammation or fluid overload, or when lymphatic drainage cannot keep up (Woodcock & Michel, 2021).

Thirst and Antidiuretic Hormone

Special nerve cells in and near the hypothalamus called osmoreceptors sense the tonicity of the blood. When plasma osmolality rises, these cells shrink and send signals that trigger thirst and the release of **antidiuretic hormone (ADH)**, also called vasopressin (Danziger & Zeidel, 2015). ADH is made in the hypothalamus and stored in the posterior pituitary gland. In the kidney's collecting ducts, it causes water channels called aquaporins to move to the cell surface, so more water returns to the blood and the urine becomes more concentrated. When osmolality falls, ADH release stops and the kidneys excrete dilute urine.

Rising osmolality is the most sensitive trigger for ADH. A fall in the blood volume or pressure that the body senses, detected by stretch receptors in the heart, large arteries and kidneys, also increases ADH release. This happens in dehydration and bleeding, and in conditions such as heart failure and cirrhosis, in which the body senses low effective volume even though total body water is high (Danziger & Zeidel, 2015). In those patients, ADH can lower serum sodium by holding on to water.

The Renin–Angiotensin–Aldosterone System

The **renin–angiotensin–aldosterone system (RAAS)** protects blood pressure and sodium balance. Cells in the kidney's afferent arterioles release the enzyme renin when renal blood flow falls, when sympathetic nerves are activated, or when less sodium chloride reaches a sensing area of the nephron (Klabunde, 2022). Renin starts a chain of reactions that produces angiotensin II. Angiotensin II constricts blood vessels, increases sodium reabsorption in the kidney, stimulates thirst and ADH release, and signals the adrenal cortex to release **aldosterone**. Aldosterone causes the kidneys to keep more sodium, and water follows sodium (Klabunde, 2022). Common medications such as angiotensin-converting enzyme (ACE) inhibitors and spironolactone act on this system.

Natriuretic Peptides

The heart has its own counterweight to the RAAS. When the atria or ventricles are stretched by extra volume, heart muscle cells release **natriuretic peptides**: atrial natriuretic peptide (ANP) from the atria and B-type natriuretic peptide (BNP) mainly from the

ventricles. These peptides increase sodium and water excretion, reduce renin release (and therefore angiotensin II and aldosterone), and widen blood vessels (Klabunde, 2023). Their blood levels rise in states of volume excess, so BNP and N-terminal pro-BNP are used as markers of heart failure (Chapter 18).

The Kidneys' Role

The kidneys carry out the instructions of all these systems, adjusting how much water and sodium they return to the blood. A healthy kidney can make small amounts of concentrated urine to save water or large amounts of dilute urine to remove it. Urine output is therefore a key bedside measure, and a falling hourly output can be an early warning of hypovolemia or acute kidney injury (Chapter 27).

Age-Related Changes

With aging, the kidneys become less able to concentrate urine, and thirst weakens, so the signal to drink comes late or not at all (Parkinson et al., 2023). Older adults are also at higher risk of hyponatremia from glucose-containing IV fluids (Baxter Corporation, 2021). Section 3.2 describes how these changes appear in practice.

3.2 Fluid Volume Deficit and Excess

Fluid Volume Deficit

Fluid volume deficit (hypovolemia) is a loss of ECF volume. It may occur alone or with changes in serum sodium. The term **dehydration** is often used loosely, but strictly it means loss of water more than sodium, which raises serum osmolality. Research in older adults uses a directly measured serum osmolality above 300 mOsm/kg as the reference standard for low-intake dehydration (Parkinson et al., 2023).

Causes fall into three groups:

- **Losses:** vomiting, diarrhea, nasogastric suction, drains, fistulas, bleeding, burns, fever and heavy sweating, and excess urine from diuretics or high blood glucose.
- **Poor intake:** nausea, nil-by-mouth orders, swallowing difficulty, cognitive impairment, reduced mobility or lack of help to drink.
- **Third spacing:** a shift of fluid out of the circulation into spaces where it cannot support blood pressure, such as the bowel wall and lumen in bowel obstruction, the abdomen in ascites, or inflamed tissue after burns, pancreatitis or major surgery. Inflammation increases capillary filtration (Woodcock & Michel, 2021), so the patient can be edematous and hypovolemic at the same time.

Fluid Volume Excess

Fluid volume excess (hypervolemia) is too much sodium and water in the ECF. It usually occurs when the body cannot excrete what it takes in. Common causes are heart failure (Chapter 18), acute kidney injury or chronic kidney disease (Chapter 27) and liver cirrhosis (Chapter 26), in which the RAAS and ADH are activated and the kidneys hold on to sodium and water. Excess IV fluid can also cause it in hospital, especially in older or frail patients and those with heart or kidney disease (National Institute for Health and Care Excellence [NICE], 2017a). High sodium intake and some medications, such as corticosteroids, can add to the load.

Recognizing the Cues

No single finding confirms a fluid imbalance. The nurse looks for a pattern across vital signs, physical findings, intake and output, weight and laboratory results (Table 3.1).

In hypovolemia, the heart rate rises to maintain cardiac output, and blood pressure falls later. **Orthostatic hypotension** is a fall in systolic blood pressure of at least 20 mm Hg, or diastolic pressure of at least 10 mm Hg, within 3 minutes of standing (Fedorowski et al., 2017). A rise in pulse of 30 beats/min or more on standing, or dizziness so severe that the patient cannot stand, suggests a large blood loss (McGee et al., 1999). The nurse measures orthostatic vital signs only when it is safe to do so, with help nearby, because

the patient may faint. Moist mucous membranes argue against hypovolemia, while a dry axilla supports it (McGee et al., 1999). Urine becomes scant and concentrated, and weight falls.

Some popular signs are weak. Capillary refill time and skin turgor have not been shown to detect hypovolemia in adults (McGee et al., 1999), and skin turgor is not accurate in older adults, whose skin loses elasticity with age (Parkinson et al., 2023). A systematic review of 67 bedside tests in older adults found that no single test was reliable, so the nurse combines findings (Hooper et al., 2015). Mental status matters: dehydration is a risk factor for delirium, so new confusion, drowsiness or agitation in an older adult calls for a check of fluid status (Registered Nurses' Association of Ontario [RNAO], 2016).

Figure 3.1 Pitting edema of the lower leg: pressing with a finger leaves dents that fill slowly. (credit: “Oedema, finger marks” by John Campbell/Flickr, public domain)

In hypervolemia, weight rises, often before edema is visible. **Edema** may be pitting, leaving an indentation after pressure (Figure 3.1), and collects in dependent areas: the ankles and lower legs in a patient who sits or stands, and the sacrum and back in a patient in bed. Swelling can be harder to see on darker skin, so the nurse also looks for taut, shiny skin and deep marks along the sock line, and presses to check for pitting (Mukwende et al., 2020). Fluid in the lungs causes shortness of breath, a faster respiratory rate, crackles on auscultation and falling oxygen saturation. **Jugular venous distension**, visible filling of the neck veins with the head of the bed at 30 to 45 degrees, reflects high venous pressure. Blood pressure may rise, and the pulse may feel full.

Colour changes need care on all skin tones. Pallor and cyanosis are harder to see on darker skin. The nurse checks the conjunctivae and palms for pallor and the oral mucous membranes for cyanosis, and compares findings with the patient's usual colour (Mukwende et al., 2020).

Laboratory Findings

Laboratory results support the clinical picture:

- **Urine specific gravity** reflects urine concentration. A typical range is 1.005 to 1.030 (University Health Network, n.d.). It rises in hypovolemia as the kidneys conserve water, unless kidney disease or diuretics interfere.
- **Urea** (reported as blood urea nitrogen, BUN, in the United States) is about 2.5 to 8.0 mmol/L in adults, and **creatinine** about 35 to 88 µmol/L in females and 62 to 106 µmol/L in males (University of Ottawa, 2022). In hypovolemia, urea often rises more than creatinine because the kidneys reabsorb more urea when blood flow is low (Malugari et al., 2024). A rising creatinine signals reduced kidney function.
- **Hematocrit**, the proportion of blood made up of red cells, is about 0.38 to 0.50 L/L (University of Ottawa, 2022). It rises when plasma volume falls (hemoconcentration) and falls when plasma is diluted.
- **Serum osmolality** rises with water loss and falls with water excess.

All reference ranges vary by laboratory; the nurse uses the range on the patient's report.

Table 3.1 Fluid volume deficit and excess compared (McGee et al., 1999; Mukwende et al., 2020; NICE, 2017a; Parkinson et al., 2023)

Feature	Fluid volume deficit	Fluid volume excess
Common causes	Vomiting, diarrhea, bleeding, diuretics, poor intake, third spacing	Heart failure, kidney failure, cirrhosis, excess IV fluid
Weight	Falls over hours to days	Rises over hours to days, often before edema appears

Feature	Fluid volume deficit	Fluid volume excess
Heart rate and blood pressure	Heart rate rises; blood pressure falls, with orthostatic changes	Blood pressure may rise; pulse may feel full
Breathing and lungs	Lungs clear; breathing may be fast if shock develops	Shortness of breath, crackles, falling oxygen saturation
Neck veins	Flat when lying down	Distended with head raised 30 to 45 degrees
Skin and mucous membranes	Dry mouth and axilla; skin turgor unreliable in older adults	Pitting edema in dependent areas; taut, shiny skin and deep sock marks, which help on darker skin where swelling is harder to see
Urine	Low volume, concentrated, high specific gravity	Volume varies with cause; may be low in kidney or heart failure
Laboratory results	Hematocrit and urea may rise; serum osmolality high if water loss	Hematocrit and serum sodium may fall from dilution
Mental status	Confusion, drowsiness or agitation, especially in older adults	Confusion if sodium falls or oxygenation worsens

Nursing Care Using Clinical Judgment

The six skills of the Clinical Judgment Measurement Model (see Chapter 1, section 1.4) guide care for both imbalances.

Recognize and analyze cues. Accurate measurement comes first. The nurse records all intake (oral fluids, tube feeds, IV fluids, IV medications and flushes) and all output (urine, vomit, drainage, stool if liquid) and totals them each shift. **Daily weights** are a key bedside measure of change in body fluid over a short period. Because 1 L of water weighs about 1 kg, a change of 1 kg in a day mostly reflects fluid gained or lost. To be useful, weights must be taken at the same time each day (usually early morning before breakfast), on the same scale, with similar clothing and bedding. The nurse compares the weight with the previous day's, not just with the admission weight, and reports a change that meets the prescriber's parameters.

Prioritize hypotheses and generate solutions. The nurse asks which problem is most urgent: is circulation threatened, or are the lungs filling with fluid? Expected outcomes might be a heart rate under 100, stable blood pressure without orthostatic symptoms, urine output at or above the ordered minimum, clear lungs and a stable weight.

Take action for a deficit. Mild deficits are treated by mouth when possible. The nurse offers drinks the patient likes, at regular times, within reach, and helps patients who cannot drink without assistance. If oral intake is not enough, the prescriber orders IV fluids (section 3.3) and the nurse gives them as ordered. The nurse also treats the cause, as ordered, for example with antiemetics, and plans safety measures, because orthostatic hypotension and confusion raise the risk of falls.

Take action for an excess. The prescriber may order a fluid restriction, sodium restriction and a diuretic. The nurse spreads restricted fluid across the day, offers ice chips and mouth care for thirst, and counts all fluids, including those with medications. Raising the head of the bed eases breathing. Edematous skin breaks down easily, so the nurse repositions the patient regularly, supports swollen limbs and inspects pressure points (Chapter 35).

Diuretics are the main drugs for fluid excess. Loop diuretics such as furosemide act quickly and strongly. They can cause low potassium, sodium, magnesium and calcium, and an overly brisk diuresis can lower blood pressure, on standing or suddenly (JAMP Pharma Corporation, 2022). The nurse checks blood pressure and electrolyte results before giving a dose, watches urine output and weight afterward, and reports ringing in the ears, which has been reported with furosemide (JAMP Pharma Corporation, 2022). Electrolyte effects of diuretics are discussed in later sections of this chapter.

Evaluate outcomes and escalate. The nurse checks whether the plan is working: vital signs, urine output, lung sounds, weight and mental status. Every nurse who notices deterioration acts at once. Warning signs include a rising heart rate with falling blood pressure, urine output below the ordered minimum, new or worsening confusion, increasing shortness of breath, falling oxygen saturation or new crackles. The nurse stays with the patient, gets help, and reports using SBAR (Situation, Background, Assessment, Recommendation), calling the rapid response team when criteria are met (Chapter 6). A practical nurse (PN), called a registered practical nurse (RPN) in Ontario, consults the registered nurse (RN) as the patient's needs change.

CLINICAL JUDGMENT

An Older Adult With Dehydration

Mrs. Hélène Bouchard, 86, is admitted to a medical unit from home after a week of hot weather. She lives alone and takes hydrochlorothiazide for hypertension.

- **Recognize cues:** Her heart rate is 108 and blood pressure 104/62 lying. On standing with help, her blood pressure falls to 84/52 and she feels faint. Temperature is 37.4 °C. Her mouth and axillae are dry. Her daughter says she is "not herself" and has been mixing up the days. She has passed 120 mL of dark urine in 4 hours. Her weight is 54.2 kg. Results: sodium 147 mmol/L, urea 14.8 mmol/L, creatinine 128 µmol/L (82 µmol/L three months ago), hematocrit 0.47 L/L, serum osmolality 312 mOsm/kg.
- **Analyze cues:** Tachycardia, orthostatic hypotension, low urine output, a high osmolality and a urea raised out of proportion to the creatinine point to fluid volume deficit with water loss. New confusion suggests delirium.
- **Prioritize hypotheses:** Hypovolemia with possible acute kidney injury (her creatinine is about 1.5 times her last known value) is the priority. Delirium and falls are linked risks. Infection is less likely but stays on the list.
- **Generate solutions:** Goals are a heart rate under 100, no orthostatic symptoms, urine output at or above the ordered minimum and a return to her usual thinking.
- **Take action:** The nurse reports to the prescriber using SBAR. The prescriber orders an IV crystalloid bolus, then a maintenance infusion, holds the hydrochlorothiazide and orders repeat blood work. The nurse starts strict intake and output, daily weights, delirium screening and falls precautions, and offers drinks every hour while awake.
- **Evaluate outcomes:** Four hours later, her heart rate is 92, blood pressure 118/66 lying, and urine output 45 mL/h. She is calmer but still unsure of the date. The nurse continues monitoring and follows up the repeat results.

LIFESPAN CONSIDERATIONS

Older Adults and Fluid Balance

Older adults are the group most at risk of fluid volume deficit. Thirst weakens with age, and the kidneys cannot concentrate urine as well, so water is lost even when intake is low (Parkinson et al., 2023). Diuretics, limited mobility, cognitive impairment, fear of incontinence and needing help to drink add to the risk (Parkinson et al., 2023).

Extreme heat is a particular danger. Health Canada (2024) lists older adults among the groups most affected and names drug classes that reduce the body's ability to cope with heat, including diuretics, ACE inhibitors, beta blockers and antipsychotics. In British Columbia's 2021 extreme heat event, 619 deaths were identified as heat-related; 67% of those who died were 70 or older, 56% lived alone, and 98% died indoors (Government of British Columbia, 2022).

Dehydration is a recognized risk factor for delirium (RNAO, 2016). New confusion in an older adult calls for assessment of fluid status, not an assumption of dementia (Chapter 8).

PATIENT EDUCATION

Daily Weights and Fluid Limits at Home

Patients with heart failure, kidney disease or liver disease may be asked to weigh themselves at home. The nurse teaches:

- Weigh yourself every morning before breakfast, on the same scale, wearing similar clothing. Write the number down.
- Compare today's weight with yesterday's. A quick gain usually means your body is holding fluid, before you see swelling.
- Call your care team if your weight goes above the limit they gave you. British Columbia's heart failure zones guide tells patients to call their health care provider if they gain more than 2 kg (4 lb) over 2 consecutive days or more than 2.5 kg (5 lb) in 1 week (Guidelines and Protocols Advisory Committee, 2023). Follow the numbers your own team gives you.
- If you have a fluid limit, measure your cups so you know how much they hold. Count soup, ice and other foods that melt.
- Call 9-1-1 if you have severe trouble breathing.

The nurse uses teach-back to check understanding (see Chapter 1, section 1.7). Chapter 18 describes heart failure self-care in detail.

3.3 IV Fluids and Fluid Management

Why IV Fluids Are Given

IV fluids are prescribed like medications. They have benefits and risks, and each needs an order that states the type of fluid, the rate and the volume (NICE, 2017a). They are given only when a patient's needs cannot be met by mouth or by feeding tube, and stopped as soon as possible (NICE, 2017a). This chapter draws on NICE's guideline from the United Kingdom because it gives a clear framework for IV fluid therapy in adults in hospital. The guideline organizes IV fluid therapy around five purposes, called the 5 Rs (NICE, 2017a):

- **Resuscitation:** rapid restoration of circulating volume in a patient with signs of hypovolemia, such as a systolic blood pressure below 100 mm Hg, heart rate above 90 beats/min, or capillary refill longer than 2 seconds or cold extremities.
- **Routine maintenance:** meeting daily needs for water, electrolytes and some glucose in a patient who cannot eat or drink.
- **Replacement:** making up existing deficits or ongoing losses, such as from vomiting, drains or a stoma.
- **Redistribution:** managing fluid in patients whose fluid has shifted, such as those with edema, sepsis or kidney, liver or heart disease. These patients often need expert input.
- **Reassessment:** regular review of the patient's fluid status and of the plan.

The nurse uses these purposes to understand an order and to judge whether the patient's response is what the prescriber intended.

Crystalloids

Crystalloids are solutions of water with electrolytes, glucose or both. They are grouped by tonicity (Table 3.2).

Isotonic crystalloids stay in the ECF and expand both the interstitial and intravascular spaces. They are used for resuscitation and replacement. **0.9% sodium chloride** (normal saline) contains 154 mmol/L of sodium and 154 mmol/L of chloride (Omega Laboratories, 2020). Its chloride content is higher than plasma's, and hyperchloremic metabolic acidosis has been reported with similar products (Omega Laboratories, 2020). **Ringer's lactate** provides, per litre, 130 mmol of sodium, 109 mmol of chloride, 4 mmol of potassium, 1.4 mmol of calcium and 28 mmol of lactate, which the body converts to bicarbonate (Baxter Corporation, 2018d). **Balanced solutions** such as Plasma-Lyte A have an electrolyte content closer to plasma; Plasma-Lyte A contains sodium 140 mmol/L, potassium 5 mmol/L, magnesium 1.5 mmol/L, chloride 98 mmol/L, and acetate and gluconate as buffers (Baxter Corporation, 2019a). NICE (2017a) recommends a crystalloid with 130 to 154 mmol/L of sodium for resuscitation, given as a 500 mL bolus in under 15 minutes, followed by reassessment.

Dextrose solutions provide water and some calories. 5% dextrose in water is isotonic in the bag, but once the body uses the glucose, what remains is free water. It is therefore physiologically hypotonic and can lower serum sodium (Baxter Corporation, 2021). It is not used for resuscitation (NICE, 2017a).

Hypotonic crystalloids, such as **0.45% sodium chloride** (sodium 77 mmol/L), move water into cells (Baxter Corporation, 2018b). Hypotonic and dextrose-containing fluids are used in some maintenance regimens, with close monitoring of sodium. Combinations such as 5% dextrose in 0.45% sodium chloride are hypertonic in the bag (406 mOsmol/L, above the normal range of about 280 to 310 mOsmol/L) but hypotonic once the glucose is used (Baxter Corporation, 2018c).

Hypertonic crystalloids, such as **3% sodium chloride** (sodium 513 mmol/L), draw water out of cells (Baxter Corporation, 2018a). They are used for severe, symptomatic hyponatremia (see the sodium section later in this chapter). The Canadian monograph warns that the solution can damage veins and recommends a large central vein. It also warns that rapid correction of sodium can cause serious neurologic harm (Baxter Corporation, 2018a). Accreditation standards limit where concentrated sodium chloride is stocked, and hospital policy restricts where and how 3% sodium chloride is given (Accreditation Canada, 2021).

Colloids

Colloids contain large molecules that stay mostly in the blood vessels and raise plasma oncotic pressure. **Albumin**, made from pooled human plasma, is a colloid that comes as 5% and 25% solutions. The 5% solution is about isotonic with plasma, while the 25% solution is hyperoncotic, with about four times the oncotic effect of plasma (CSL Behring Canada, 2025). Its uses include

restoring blood volume, shock and burns. During hypovolemia, crystalloids restore volume nearly as well as colloids (Woodcock & Michel, 2021), and NICE (2017a) advises against tetrastarch for resuscitation. Albumin can cause circulatory overload, so the nurse monitors blood pressure, pulse, lung sounds and urine output and stops the infusion at the first signs of overload (CSL Behring Canada, 2025).

Table 3.2 Common IV solutions (Baxter Corporation, 2018a, 2018b, 2018c, 2018e, 2019a, 2021; CSL Behring Canada, 2025; NICE, 2017a; Omega Laboratories, 2020)

Solution	Tonicity	Common uses	Nursing cautions
0.9% sodium chloride	Isotonic	Resuscitation and replacement	Fluid overload; high chloride with large volumes can cause metabolic acidosis
Ringer's lactate	Close to isotonic (272 mOsmol/L, slightly below plasma)	Resuscitation, replacement, surgery and burns	Contains potassium and calcium; do not give with ceftriaxone in the same line; caution in severe liver disease
Plasma-Lyte A (balanced solution)	Isotonic	Resuscitation and replacement	Contains potassium; caution in kidney failure and with potassium-sparing drugs
5% dextrose in water	Isotonic in the bag; hypotonic once glucose is used	Source of water and some calories	Not for resuscitation; can lower sodium and raise glucose
0.45% sodium chloride	Hypotonic	Maintenance in some regimens; diluent	Can lower sodium; risk of cerebral edema; watch for headache, nausea, confusion
5% dextrose in 0.45% sodium chloride	Hypertonic in the bag; hypotonic once glucose is used	Maintenance in some regimens	Hyponatremia with high volumes; hyperglycemia; do not run with blood
3% sodium chloride	Hypertonic	Severe symptomatic hyponatremia	High-alert; central line recommended; frequent sodium checks; too-rapid correction causes neurologic harm
Albumin 5% or 25%	Colloid (25% is hyperoncotic)	Blood volume restoration, shock, burns	Made from human plasma; circulatory overload; stop at first signs of overload

Monitoring Patients Receiving IV Fluids

Patients receiving IV fluids need their fluid status, urea, creatinine and electrolytes, and fluid balance charts reviewed at least daily, and more often when the patient's condition calls for it (NICE, 2017a). At the bedside the nurse:

- checks vital signs, mental status and oxygen saturation at the frequency ordered or set by policy;
- listens to lung sounds and looks for edema and jugular venous distension;
- totals intake and output and weighs the patient as ordered;
- reviews electrolyte, glucose, urea and creatinine results and reports values outside the ordered parameters;
- confirms that the infusion matches the order: right fluid, right rate and right volume, on a pump where policy requires one (Figure 3.2).

Risks of IV Fluid Therapy

Fluid overload. Large volumes or rapid infusions can cause hypervolemia, with pulmonary and peripheral edema (Baxter Corporation, 2018d). Older and frail adults and those with heart or kidney disease are at highest risk. NICE (2017a) suggests lower maintenance volumes for these groups. New shortness of breath, crackles, a falling oxygen saturation or rapid weight gain call for prompt action and escalation.

Hyponatremia from hypotonic fluids. Many hospitalized patients, especially after surgery, release ADH for reasons other than osmolality (non-osmotic ADH release), so they cannot excrete free water normally (Baxter Corporation, 2018c). Giving hypotonic or dextrose-containing fluids to these patients can lower sodium quickly. Acute hyponatremia can cause brain swelling, with headache, nausea, vomiting, lethargy and seizures, and can lead to permanent brain injury (Baxter Corporation, 2018c). Children, older adults,

women and postoperative patients are at higher risk (Baxter Corporation, 2018c). NICE (2017a) notes that prescribing more than 2.5 L of maintenance fluid a day increases the risk. Any new headache, nausea or confusion in a patient on IV fluids should prompt the nurse to check the sodium result and report.

Infiltration and extravasation. Infiltration occurs when IV fluid leaks into the tissue around the vein, usually because the catheter has moved or the vein is damaged. **Extravasation** is leakage of a drug or solution that can damage tissue, such as concentrated potassium, hypertonic solutions or some chemotherapy drugs (Baxter Corporation, 2018a, 2019b; RNAO, 2021). Signs include swelling, coolness, tightness, pain or burning at the site and an infusion that slows. On darker skin, redness may not be visible, so the nurse compares the site with the other limb for swelling, warmth or coolness and firmness. If infiltration or extravasation is suspected, the nurse stops the infusion (Baxter Corporation, 2019a), assesses the site and follows policy, which may include removing the catheter, elevating the limb and notifying the prescriber.

Figure 3.2 An electronic infusion pump delivers IV fluid at a set rate. The nurse checks the fluid, rate and volume on the pump against the order. (credit: "Electronic infusion device (EID)" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

IV Site Care

The nurse assesses the peripheral IV site regularly (Figure 3.3). RNAO (2021) recommends a peripheral IV care protocol that includes at least a daily review of the device by health providers, together with patients and families. The nurse looks for redness, cording, swelling or pain that suggests **phlebitis**, inflammation of the vein, or infiltration. The nurse avoids areas of flexion where possible and does not use peripheral catheters for solutions with an osmolarity above 900 mOsmol/L or continuous vesicant therapy (RNAO, 2021). The nurse teaches the patient to report pain, swelling or leaking at the site (RNAO, 2021). Chapter 4 describes infection prevention for vascular access devices.

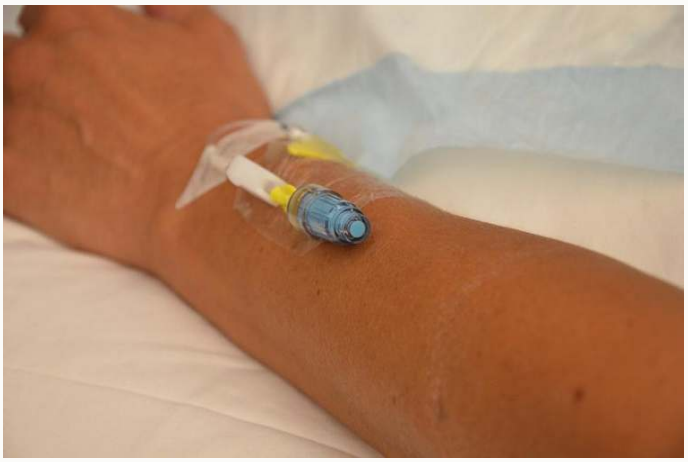

Figure 3.3 A peripheral IV catheter in the forearm, held in place with a clear dressing so the site can be seen. The nurse looks at the site and the skin around it at every assessment. (credit: "Peripheral intravenous (IV) catheter (PIV)" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

SCOPE IN PRACTICE

Who Starts, Adjusts and Gives IV Fluids and Electrolytes

The College of Nurses of Ontario (CNO) Scope of Practice standard asks nurses to consider authority, competence and context (see Chapter 1, section 1.3).

- **Authority:** Inserting a peripheral IV is a procedure below the dermis, and giving IV fluids and drugs is administering a substance by injection. RNs and RPNs are authorized to perform both controlled acts with an order or directive, and cannot initiate them in a public hospital (CNO, 2025b). Nurses accept only orders that are clear, complete and appropriate, and follow up with the prescriber when an order is not (CNO, 2025a). "KCl 40 mmol IV now" is incomplete: it gives no diluent or rate (Institute for Safe Medication Practices Canada [ISMP Canada], 2005).
- **Competence:** The nurse needs the knowledge, skill and judgment for the specific activity, including the drug's purpose, risks and monitoring (CNO, 2025a). Many employers require extra education before nurses insert IVs, use central lines, give IV push drugs or manage high-alert infusions. These are employer requirements, not CNO rules.
- **Context:** The nurse considers whether the practice setting has the resources to support safe care. Employer policy may limit, but never widen, scope (CNO, 2025b). An RPN consults the RN as needs change; any nurse who notices deterioration acts at once. Rules differ by province or territory. Revised CNO standards take effect March 1, 2027 (CNO, 2026).

CLINICAL SAFETY

Concentrated Potassium Is a High-Alert Medication

IV potassium is a high-alert medication (see Chapter 1, section 1.6). Too much, given too fast, can cause life-threatening hyperkalemia and cardiac arrest, which may develop with no warning symptoms (Baxter Corporation, 2019b).

- **Never IV push.** Potassium salts must never be given by IV push (Baxter Corporation, 2018e).
- **Use premixed solutions.** ISMP Canada (2005) recommends standardized premixed potassium solutions on nursing units, stored apart from plain IV fluids, and oral potassium whenever possible.
- **Concentrates stay out of patient care areas.** Accreditation Canada's Required Organizational Practice (ROP) on concentrated electrolytes limited formats such as potassium salts of 2 mmol/mL or more in patient care areas, allowing them only where a committee approved them with safeguards (Accreditation Canada, 2021). In the 2024 ROPs, this practice is consolidated into the ROP on managing high-alert medications, and the former stand-alone ROP is being phased out (*2024 Required Organizational Practices*, 2024; Health Standards Organization, 2024). Hospital policy names the products kept on each unit.
- **Infusion pump.** Give IV potassium only by a calibrated infusion device, slowly and at a controlled rate (Baxter Corporation, 2019b).
- **Rate and concentration.** The monograph for premixed potassium chloride in 0.9% sodium chloride states that infusion rates generally stay at or below 10 mmol/h and 120 mmol/day, and that without cardiac monitoring the rate should not go above 20 mmol/h (Baxter Corporation, 2018e). Other monographs give different limits. Higher concentrations are given by central line (Baxter Corporation, 2019b). Hospital policy sets the limits for each unit.
- **Double check.** Perform an independent double check as policy requires, and check the site often for pain or infiltration.

3.4 Sodium Imbalances

Sodium is the main cation of the extracellular fluid (ECF). Serum sodium mostly reflects water relative to sodium, so a sodium disorder is usually a water disorder (Yun et al., 2023; section 3.1). A typical adult serum sodium is about 136 to 144 mmol/L, although reference ranges vary by laboratory (University of Ottawa, 2022). Because water follows solute across cell membranes, sodium changes alter cell volume, and the brain, enclosed in the skull, is most at risk.

Hyponatremia

Hyponatremia is a serum sodium below the reference range. The European clinical practice guideline grades it as mild (130 to 135 mmol/L), moderate (125 to 129 mmol/L) or profound (below 125 mmol/L) (Spasovski et al., 2014). As serum sodium falls, water moves into cells and brain cells swell.

The guideline sorts causes by the patient's ECF volume, which the nurse assesses using the cues in section 3.2 (Spasovski et al., 2014):

- **Low ECF volume:** vomiting, diarrhea, third spacing, adrenal insufficiency and diuretics.
- **Normal ECF volume:** SIADH (described next), secondary adrenal insufficiency, hypothyroidism and unrecognized diuretic use.

- **High ECF volume:** heart failure (Chapter 18), cirrhosis (Chapter 26) and nephrotic syndrome, in which the body holds water as well as sodium.
- **Too much water for the solute taken in:** very high water intake or a very low-solute diet. In hospital, prescribing more than 2.5 litres of IV fluid a day increases the risk (National Institute for Health and Care Excellence [NICE], 2017a). Hypotonic solutions such as 0.45% sodium chloride can cause acute hyponatremia with brain swelling, especially in older adults and after surgery (Baxter Corporation, 2018b; section 3.3).

In the **syndrome of inappropriate antidiuretic hormone secretion (SIADH)**, which the guideline calls the syndrome of inappropriate antidiuresis, antidiuretic hormone (ADH; section 3.1) keeps acting even though the plasma is dilute. The kidneys keep reabsorbing water, the urine stays concentrated, and the patient looks neither dry nor overloaded. Triggers common on medical-surgical units include pneumonia and small cell lung cancer (Chapter 13), stroke, head injury and subarachnoid hemorrhage, and drugs such as selective serotonin reuptake inhibitor (SSRI) antidepressants, carbamazepine, opioids and some cancer drugs. Nausea, pain, stress and general anesthesia are strong non-specific stimuli, so SIADH is a risk after surgery (Spasovski et al., 2014). It is a diagnosis of exclusion. Typical findings are a serum osmolality below 275 mOsm/kg, urine osmolality above 100 mOsm/kg, urine sodium above 30 mmol/L and a normal volume status, with no adrenal, thyroid, pituitary or kidney cause and no recent diuretic use (Spasovski et al., 2014).

Diuretics often contribute, and patients do not always know they take one (Spasovski et al., 2014). The Canadian monograph for hydrochlorothiazide warns that dilutional hyponatremia may occur in patients with edema in hot weather (Sanis Health, 2026).

Manifestations depend on how low the sodium is and how fast it fell. The guideline lists nausea without vomiting, confusion and headache as moderately severe symptoms, and vomiting, cardiorespiratory distress, deep somnolence, seizures and coma as severe symptoms (Spasovski et al., 2014). In an older adult, new confusion may be the first cue.

Diagnostics include serum sodium and osmolality, urine osmolality (the guideline's first step), urine sodium, and tests to exclude thyroid and adrenal causes (Spasovski et al., 2014).

Nursing Care for Hyponatremia

The nurse applies the CJMM (Chapter 1, section 1.4):

- **Recognize and analyze cues:** level of consciousness, orientation, headache, nausea and vomiting; volume status; the medication list (thiazides, SSRIs, carbamazepine, opioids); and all oral and IV intake.
- **Prioritize:** severe or moderately severe symptoms are an emergency that needs immediate treatment, whatever the cause (Spasovski et al., 2014; Society for Endocrinology, 2022). The nurse stays with the patient, gets help, reports using SBAR and calls the rapid response team if criteria are met (Chapter 6). A PN consults the RN as the patient's needs change.
- **Generate solutions and act:** for severe symptoms, the prescriber orders small boluses of 3% hypertonic saline with close monitoring, aiming for a rise of about 5 mmol/L in the first hour (Society for Endocrinology, 2022). Without severe symptoms there is time to find and treat the cause: volume replacement for losses (section 3.3), stopping a causative drug as ordered, or fluid restriction, the suggested first-line treatment for SIADH (Spasovski et al., 2014). The nurse helps the patient keep to a fluid limit by spreading it over the waking hours, offering mouth care and explaining why it matters. Confused patients need falls precautions (Chapter 8) and, if seizures are a risk, precautions as policy directs.
- **Evaluate outcomes:** the nurse tracks sodium results at the ordered times, intake and output, and neurologic status, and reports a fast rise at once (see the Clinical Safety box).

Older adults often take several sodium-lowering drugs, so medication review is essential.

> CLINICAL SAFETY
>
> **Correcting Sodium Too Quickly**
>
> When hyponatremia develops slowly, brain cells adapt over about 24 to 48 hours by moving solutes out, so they swell less (Spasovski et al., 2014). Once the brain has adapted, a rise in sodium that is too fast can damage the myelin that insulates nerve fibres: **osmotic demyelination syndrome (ODS)** (Society for Endocrinology, 2022). Signs include altered consciousness, difficulty speaking (dysarthria) and swallowing (dysphagia), limb weakness, and in severe cases coma or a "locked-in" state (Almeida-

Arvizu et al., 2025). Reported risk factors include a sodium below 120 mmol/L, low potassium, chronic alcohol use, malnutrition and liver disease (Almeida-Arvizu et al., 2025).

- **Know the limits:** expert guidance sets a limit on the rise in sodium: at most 10 mmol/L in the first 24 hours and at most 8 mmol/L in each later 24 hours (Society for Endocrinology, 2022). These are limits, not targets.
- **Monitor:** sodium at the ordered intervals (one guidance suggests 6 hours, 12 hours, then daily), strict intake and output, and a sudden rise in dilute urine output, which can signal a rapid sodium rise (Society for Endocrinology, 2022).
- **Escalate:** report a rise nearing the limit at once. The prescriber may stop treatment and order hypotonic fluid, with or without desmopressin (Society for Endocrinology, 2022).

Hypernatremia

Hypernatremia is a serum sodium above the reference range, defined in one review as above 145 mmol/L. It usually means the body has too little water for its sodium, which makes the ECF hyperosmolar and draws water out of cells (Yun et al., 2023).

- **Water loss not replaced:** water can be lost through the kidneys or other routes. People who depend on others for drinks, such as a person with advanced dementia, after a stroke, or under sedation, are at greatest risk. Older adults are also at risk because thirst perception declines with age-related changes in brain osmoreceptors (Yun et al., 2023).
- **Kidney water loss:** central or nephrogenic diabetes insipidus (Chapter 23), and osmotic diuresis from high blood glucose (Chapter 22) (Yun et al., 2023).
- **Sodium gain:** less often, from hypertonic sodium-containing treatments or accidental sodium loading (Yun et al., 2023).

Manifestations range from thirst, weakness, muscle irritability, brisk reflexes and lethargy to confusion, seizures and coma. When hypernatremia develops within 48 hours, brain cells shrink quickly and the stretched blood vessels can rupture and bleed (Yun et al., 2023).

Nursing care focuses on replacing water as ordered (by mouth, as free water through a feeding tube, or as an IV hypotonic or dextrose solution; section 3.3) and treating the cause. For chronic hypernatremia (present more than 48 hours or of unknown duration), one review advises lowering sodium by less than 0.5 mmol/L per hour (12 mmol/L per day), with repeated sodium measurements to guide treatment (Yun et al., 2023). The nurse offers fluids often to patients who cannot get their own, records intake and output and daily weights, monitors neurologic status, gives frequent mouth care and reports new confusion or seizures at once. Prevention matters most: a hydration plan for every dependent patient, and extra attention during extreme heat (section 3.2).

3.5 Potassium Imbalances

Potassium is the main cation inside cells. The gradient between high intracellular and low extracellular potassium sets the electrical state of nerve and muscle cells, so small changes in serum potassium can disturb muscle strength and heart rhythm. A typical adult serum potassium is about 3.5 to 5.1 mmol/L, although ranges vary by laboratory (University of Ottawa, 2022). Platelets release potassium as blood clots, so a serum result reads about 0.2 to 0.5 mmol/L above a plasma result; this is one reason laboratories set different ranges for each sample type (Alberta Health Services, 2013).

Hypokalemia

Hypokalemia is a serum potassium below the reference range; a level below 2.5 mmol/L is severe and can be life-threatening (Kardalas et al., 2018). Causes include:

- **Kidney loss:** loop and thiazide diuretics are a common cause (Kardalas et al., 2018; see the Medications box).
- **Gastrointestinal loss:** vomiting and diarrhea.
- **Shift into cells:** insulin, sympathetic stimulation and thyrotoxicosis move potassium from the blood into cells (Kardalas et al., 2018). Refeeding has the same effect (section 3.6).
- **Low magnesium:** more than half of patients with clinically significant hypokalemia also have a magnesium deficit, and their hypokalemia often resists replacement until magnesium is corrected (Kardalas et al., 2018).

Manifestations include leg cramps, muscle weakness and, in severe cases, ascending paralysis. Constipation, paralytic ileus and respiratory failure are signs of severe hypokalemia, and muscle breakdown (rhabdomyolysis) can occur (Kardalas et al., 2018). On the electrocardiogram (ECG), the ST segment becomes depressed, the T wave flattens, a U wave (a small rounded wave after the T wave) becomes prominent, and the QT interval may lengthen. These changes raise the risk of dysrhythmias, fainting and sudden death (Kardalas et al., 2018; Chapter 16). Low potassium and low magnesium also make digoxin toxicity more likely (Sanis Health, 2026).

Nursing care. The nurse recognizes cues by assessing muscle strength, bowel function, breathing effort and heart rhythm, and reviews the patient's diuretics, digoxin and magnesium result. Potassium should be replaced gradually, by mouth when possible. IV replacement is used when the level is below 2.5 mmol/L or the patient cannot take it orally, with repeated potassium levels and cardiac monitoring as the rate and hospital policy require (Kardalas et al., 2018; Baxter Corporation, 2018e). IV potassium is a high-alert medication; the safety rules are in the Clinical Safety box in section 3.3. The nurse also expects magnesium to be checked and corrected.

Hyperkalemia

Hyperkalemia is a serum potassium above the reference range. The UK Kidney Association guideline defines it as 5.5 mmol/L or higher and grades it as mild (5.5 to 5.9 mmol/L), moderate (6.0 to 6.4 mmol/L) or severe (6.5 mmol/L or higher) (Alfonzo et al., 2026). Causes include:

- **Reduced kidney excretion:** acute kidney injury and chronic kidney disease (Chapter 27); people with diabetes or heart failure are at higher risk.
- **Drugs:** angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers, spironolactone, amiloride, trimethoprim, nonsteroidal anti-inflammatory drugs (NSAIDs) and potassium supplements (Alfonzo et al., 2026).
- **Other causes:** acidosis and poorly controlled diabetes (Alfonzo et al., 2026), and release of potassium from large numbers of damaged cells, as in tumour lysis syndrome (Emergency Care BC, 2024; Chapter 9).
- **Too much given:** potassium infused too fast (Baxter Corporation, 2019b).

Hyperkalemia can develop quickly and cause no symptoms before a dangerous rhythm (Baxter Corporation, 2019b); some patients report generalized weakness. Typical ECG changes are tall, peaked T waves, flattened P waves and a widened QRS complex (Figure 3.4). Severe hyperkalemia can cause a slow wide-complex rhythm, a sine-wave pattern, ventricular tachycardia and cardiac arrest (Alfonzo et al., 2026). A normal ECG does not rule hyperkalemia out (AA Pharma, 2025).

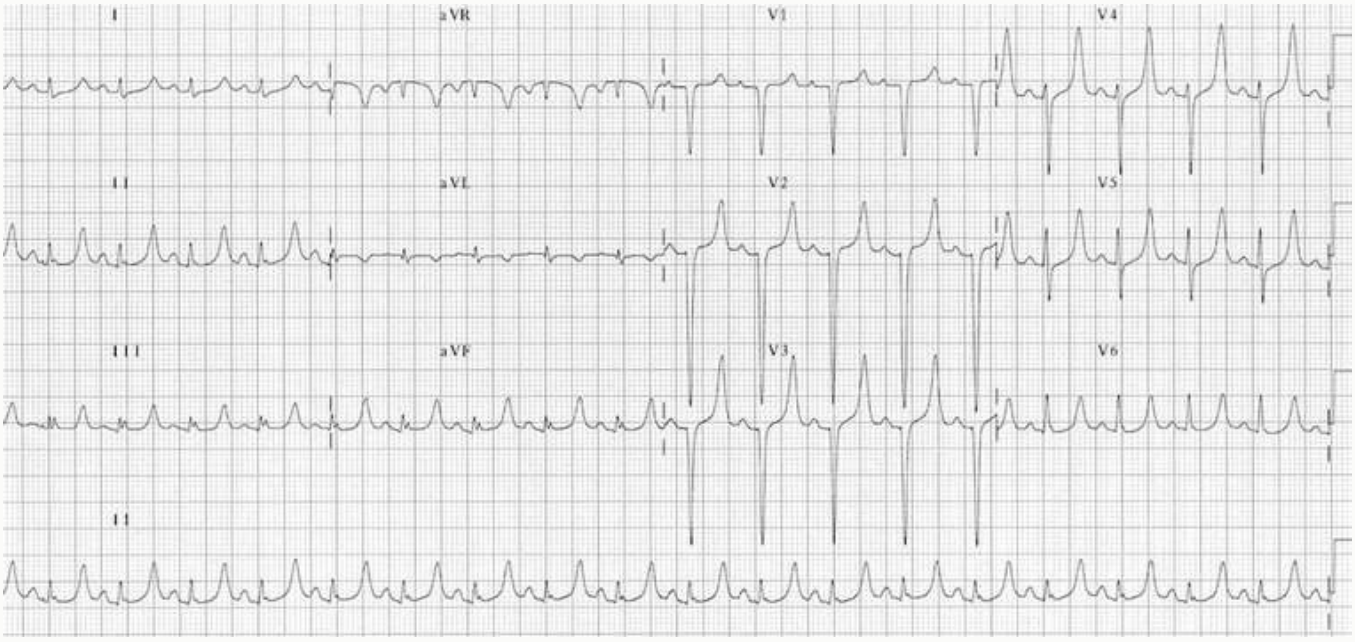

Figure 3.4 A 12-lead ECG from a patient with a serum potassium of 7.0 mmol/L, showing tall, peaked T waves. (credit: "ECG Hyperkalaemia peaked T waves serum potassium 7.0" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

Pseudohyperkalemia

Pseudohyperkalemia is a high potassium result caused by the sample, not the patient. Red cells, platelets or white cells release potassium after the blood is drawn. Causes include hemolysis from a difficult draw or small needle, a prolonged tourniquet, fist clenching, very high platelet or white cell counts, and delays or rough handling in transport (Le & Geary, 2020; Alfonzo et al., 2026). The nurse draws samples gently from a good vein and sends them promptly. An unexpected result is repeated, but the nurse still assesses the patient and reports it. A high potassium with ECG changes is treated as real.

Treating Hyperkalemia

Treatment follows a sequence (Alfonzo et al., 2026):

- **Protect the heart:** IV calcium (calcium gluconate or calcium chloride) is given when ECG changes are present. It counters the effect of high potassium on the heart (SteriMax, 2025) but does not lower the potassium level, so the next steps are still needed.
- **Shift potassium into cells:** IV insulin with glucose (dextrose), with nebulized salbutamol as an add-on. Sodium bicarbonate is not routinely recommended.
- **Remove potassium:** an oral potassium binder such as sodium zirconium cyclosilicate, or dialysis for patients with kidney failure.
- **Monitor:** potassium is rechecked at intervals over the next 24 hours because it can rebound.

The guideline advises an urgent 12-lead ECG for any inpatient with potassium of 6.0 mmol/L or higher, and continuous cardiac monitoring at 6.5 mmol/L or higher or with any ECG change (Alfonzo et al., 2026). Nursing actions include:

- **Calcium:** the Canadian monograph calls for ECG and vital sign monitoring during IV calcium gluconate, a slow rate, and a secure line, because extravasation can cause tissue necrosis. IV calcium is contraindicated in patients taking cardiac glycosides such as digoxin, so the nurse tells the prescriber if the patient takes one (SteriMax, 2025).
- **Insulin with dextrose:** this can cause hypoglycemia, so the nurse checks capillary glucose often for several hours, as ordered (Alfonzo et al., 2026).
- **Binders:** sodium zirconium cyclosilicate starts lowering potassium about an hour after a dose, so it is not an emergency treatment on its own. Each dose contains sodium, so the nurse watches for edema (AstraZeneca Canada, 2026).
- **Prevention:** holding potassium-raising drugs as ordered and reviewing them before discharge.

MEDICATIONS

Diuretics and Potassium

- **Loop diuretic (furosemide):** strong, fast diuresis. It can lower potassium, sodium, magnesium and calcium, and too vigorous a diuresis can cause orthostatic or acute hypotension. Tinnitus and reversible hearing loss have been reported (JAMP Pharma Corporation, 2022).
- **Thiazide diuretic (hydrochlorothiazide):** can cause low potassium and low sodium. It reduces calcium excretion and increases magnesium excretion (Sanis Health, 2026).
- **Potassium-sparing diuretics (spironolactone; amiloride):** conserve potassium and can cause hyperkalemia, especially in older adults, people with diabetes or kidney impairment, and with ACE inhibitors or angiotensin receptor blockers. Patients taking spironolactone avoid potassium supplements, salt substitutes and high-potassium foods unless the prescriber advises otherwise (Pfizer Canada, 2022; AA Pharma, 2025).

Nursing actions:

- Review the potassium and sodium results before giving a dose, and report abnormal values.
- Weigh the patient daily, at the same time and on the same scale (section 3.2).
- Check lying and standing blood pressure, and teach the patient to rise slowly.
- Give doses at a consistent time each day (Sanis Health, 2026), and plan the timing with the patient so that night-time urination does not disrupt sleep.
- Teach the signs to report: muscle cramps or weakness, palpitations, dizziness and ringing in the ears.

PRACTICE STORY

A Weak Morning

Names and details are fictional; this is a composite story.

Nurse: Grace Mensah, RPN. Years in practice: 7. Setting: medical unit, community hospital, Ontario.

Mr. Albert Lachance is 84. He came in four days ago with heart failure, and his IV furosemide was increased two days ago. Yesterday he walked to the bathroom with his walker. This morning he could not lift his legs to swing them out of bed. "My legs feel like rubber," he told me.

His radial pulse was irregular, so I counted his apical pulse for a full minute: 96 and irregular. His blood pressure was 104/62, lower than his usual 128/74. He had not had a bowel movement in three days. His morning blood work had just come back: potassium 2.9 mmol/L, down from 3.6 mmol/L two days ago. His magnesium had not been drawn.

I knew his weakness and new irregular pulse could be his potassium, and that low potassium can lead to dangerous rhythms. I stayed with him, put his call bell in his hand and asked a colleague to find our RN, Sam. When Sam came, I used SBAR (Chapter 6). "Situation: Mr. Lachance in bed 12 has new leg weakness and an irregular apical pulse of 96. Background: he's 84, admitted with heart failure, and his IV furosemide went up two days ago. Assessment: his potassium is 2.9, down from 3.6, his pressure is 104/62 and he's constipated. I'm worried about his rhythm. Recommendation: could you assess him now and call the physician? He may need an ECG, cardiac monitoring, potassium replacement and a magnesium level."

Sam assessed him and called the hospitalist. The orders came quickly: a 12-lead ECG, which showed flattened T waves and U waves, telemetry, oral and IV potassium replacement, a magnesium level, and a review of his furosemide dose. Sam took over the IV potassium. I gave his oral potassium, kept him in bed with the bed alarm on and checked on him every hour.

By evening his potassium was 3.5 mmol/L and he could lift his legs again.

Reflect: Which of my actions were within my scope as an RPN, and at what point did Mr. Lachance's changing condition call for the RN to take over parts of his care? How might employer policy change who gives his IV potassium?

3.6 Calcium, Magnesium and Phosphate

Calcium, magnesium and phosphate share regulation by parathyroid hormone (PTH), vitamin D and the kidneys, so a problem with one often disturbs another. All five electrolytes in this chapter are summarized at the end of this section (Table 3.3).

Calcium

About half of the calcium in plasma is **ionized calcium**, the free, physiologically active form. About 40% travels bound to proteins, chiefly albumin, and about 10% is bound to small anions (Yap & Goldwasser, 2022). A typical adult total calcium is about 2.12 to 2.52 mmol/L and ionized calcium about 1.14 to 1.28 mmol/L, although ranges vary by laboratory (University of Ottawa, 2022).

Because so much calcium travels on albumin, a low albumin lowers the total calcium even when ionized calcium is normal. An albumin-adjusted ("corrected") calcium allows for this, but such estimates often perform poorly and ignore pH (Yap & Goldwasser, 2022). Hydrogen ions reduce calcium binding to albumin, so acidosis raises the ionized fraction and alkalosis lowers it (Yap & Goldwasser, 2022). In critical illness, or when results do not fit, ionized calcium is more reliable.

Hypocalcemia is a calcium below the reference range. In hospital, the most common cause is parathyroid damage during thyroid surgery (Chapter 23). Others include severe vitamin D deficiency, parathyroid surgery, low magnesium, pancreatitis, rhabdomyolysis and large-volume transfusion (Society for Endocrinology Clinical Committee, 2013). In chronic kidney disease, retained phosphate reduces activated vitamin D and leads to hypocalcemia (Sridharan, 2023). Furosemide can also lower calcium (JAMP Pharma Corporation, 2022).

Low calcium makes nerves and muscles overexcitable. Early cues are tingling around the mouth and fingertips; muscle spasm, tetany, laryngeal spasm, seizures, a prolonged QT interval and dysrhythmias can follow. Symptoms usually appear when adjusted calcium falls below about 1.9 mmol/L, depending on how fast it falls (Society for Endocrinology Clinical Committee, 2013). Two bedside signs suggest latent tetany:

- **Chvostek's sign:** twitching of the facial muscles when the facial nerve is tapped. It is less specific than Trousseau's sign (Rehman & Wunder, 2011).
- **Trousseau's sign:** spasm of the hand (the knuckles flex, the finger joints straighten and the thumb draws across the palm) within 3 minutes of inflating a blood pressure cuff above systolic pressure (Figure 3.5). It can be absent in true hypocalcemia and is positive in 1% to 4% of healthy people (Rehman & Wunder, 2011).

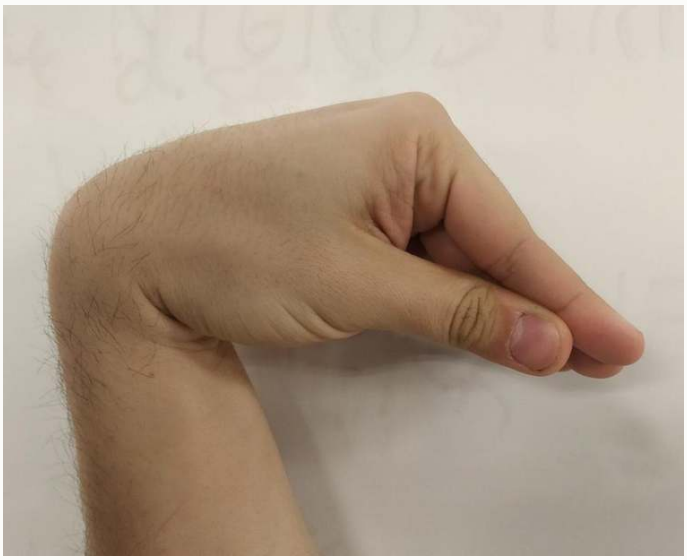

Figure 3.5 A re-creation of the hand posture of a positive Trousseau's sign: the wrist and knuckles flex, the fingers straighten and the thumb draws in. (credit: “Trousseau's Sign of Latent Tetany” by Tmdswan/Wikimedia Commons, CC BY-SA 4.0)

Severe or symptomatic hypocalcemia is an emergency, treated with IV calcium gluconate under ECG monitoring, with magnesium checked and corrected (Society for Endocrinology Clinical Committee, 2013). The nurse follows the precautions in section 3.5 (SteriMax, 2025). Milder cases receive oral calcium and vitamin D as ordered. After thyroid or parathyroid surgery, the nurse asks about tingling at every assessment.

Hypercalcemia is a calcium above the reference range. About 90% of cases are due to primary hyperparathyroidism (Chapter 23) or cancer (Chapter 9). Less common causes include thiazides, lithium, excess vitamin D and immobilization (Walsh et al., 2016). Symptoms include thirst, frequent urination, nausea, constipation and confusion; severe hypercalcemia can cause kidney injury, stones, pancreatitis, a shortened QT interval, dysrhythmias and coma. An adjusted calcium above 3.5 mmol/L needs urgent correction (Walsh et al., 2016). Treatment starts with IV 0.9% sodium chloride, then an IV bisphosphonate if needed. The nurse monitors intake and output, weight, lung sounds and mental status, because older adults and people with kidney impairment can become overloaded during rehydration (Walsh et al., 2016; section 3.2).

Magnesium

A typical adult serum magnesium is about 0.74 to 1.03 mmol/L, varying by laboratory (University of Ottawa, 2022).

Hypomagnesemia is common with alcohol use disorder (Chapter 11), diabetes and chronic gastrointestinal disease. Loop and thiazide diuretics, digoxin, aminoglycosides and long-term proton pump inhibitors increase magnesium loss (Bobrowicz et al., 2024). Refeeding also lowers magnesium (see below). Manifestations include numbness, muscle cramps, tetany, seizures and dysrhythmias (Bobrowicz et al., 2024). About half of patients with hypomagnesemia also have hypokalemia, which may not correct until magnesium is replaced. Low magnesium also suppresses PTH, causing hypocalcemia that resists calcium replacement (Bobrowicz et al., 2024). Magnesium is replaced by mouth or, for acute deficiency, as IV magnesium sulfate (Sandoz Canada, 2026).

Hypermagnesemia is a risk whenever magnesium is given, especially to patients with kidney impairment; the Canadian monograph for magnesium sulfate advises caution in impaired kidney function (Sandoz Canada, 2026). Rising levels cause flushing and hypotension, then loss of deep tendon reflexes, respiratory depression and, at very high levels, heart block. Flushing can be hard to see on darker skin, so the nurse also asks about warmth. Before each dose, the monograph advises checking that the patellar reflex is present, respirations are at least 16 per minute and urine output was at least 100 mL in the previous 4 hours. Lost patellar reflexes are an early sign of toxicity; IV calcium gluconate reverses respiratory depression or heart block (Sandoz Canada, 2026). The nurse stops the infusion and reports at once.

Phosphate

A typical adult serum phosphate is about 0.81 to 1.58 mmol/L, varying by laboratory (University of Ottawa, 2022).

Hypophosphatemia occurs especially when a malnourished person starts eating again, and in alcohol use disorder (Fung & Rimmer, 2005). Phosphate is needed for cell energy and for red cells to release oxygen. Severe deficiency can cause muscle weakness, respiratory failure from diaphragm weakness, heart failure, dysrhythmias, red cell breakdown (hemolysis), rhabdomyolysis and seizures. Replacement is oral or IV as ordered; too much IV phosphate can cause low calcium and tetany (Fung & Rimmer, 2005).

Hyperphosphatemia is most often caused by chronic kidney disease, because failing kidneys retain phosphate (Sridharan, 2023). It also occurs when large numbers of cells break down, as in tumour lysis syndrome (Emergency Care BC, 2024; Chapter 9). Phosphate itself causes few symptoms, but calcium falls, so the nurse watches for hypocalcemia. In chronic kidney disease, care includes limiting high-phosphate foods such as soft drinks and processed foods, and taking phosphate binders with meals (Sridharan, 2023; Chapter 27).

Refeeding Syndrome

Refeeding syndrome is a fall of 10% or more in serum phosphate, potassium or magnesium, with or without organ dysfunction, within 5 days of starting or greatly increasing nutrition in a person who has been starved or malnourished (da Silva et al., 2020). Carbohydrate raises insulin, which drives phosphate, potassium and magnesium into cells (Fung & Rimmer, 2005), causing heart failure, dysrhythmias, respiratory failure or death. Thiamine stores are often low as well.

High-risk patients include those with very low body mass index (BMI), recent unintentional weight loss, little or no intake for many days, low prefeeding potassium, phosphate or magnesium, an alcohol or other substance use disorder, an eating disorder such as anorexia nervosa, or past bariatric surgery (NICE, 2017b; da Silva et al., 2020). Prevention is a team task (Chapter 24):

- **Identify risk** at admission with a nutrition screen, and check potassium, phosphate and magnesium before feeding begins.
- **Give thiamine before feeding** begins, or before dextrose-containing IV fluids are started, in a patient at risk (da Silva et al., 2020; NICE, 2017b).
- **Start low and go slow:** feeding starts at a reduced energy level and is increased over several days (NICE, 2017b; da Silva et al., 2020).
- **Monitor:** electrolytes twice a day for the first 3 days when risk is high (da Silva et al., 2020), plus fluid balance, heart rhythm and breathing (NICE, 2017b). The nurse reports falling levels, new edema, shortness of breath or an irregular pulse.

Table 3.3 Electrolyte imbalances at a glance (Alfonzo et al., 2026; Bobrowicz et al., 2024; Fung & Rimmer, 2005; Kardalas et al., 2018; Sandoz Canada, 2026; Society for Endocrinology Clinical Committee, 2013; Spasovski et al., 2014; University of Ottawa, 2022; Walsh et al., 2016; Yun et al., 2023)

Imbalance	Typical adult range (varies by laboratory)	Common causes	Key signs	Nursing actions
Low sodium (hyponatremia)	Sodium 136–144 mmol/L	SIADH, diuretics, heart failure, large volumes of hypotonic fluid, vomiting and diarrhea	Nausea, headache, confusion, seizures	Neurologic checks, fluid restriction if ordered, report a fast rise in sodium
High sodium (hypernatremia)	Sodium 136–144 mmol/L	Water loss not replaced, impaired thirst or access to water, diabetes insipidus, high glucose	Thirst, weakness, lethargy, confusion, seizures	Offer and replace water as ordered, intake and output, lower sodium gradually
Low potassium (hypokalemia)	Potassium 3.5–5.1 mmol/L	Loop and thiazide diuretics, vomiting, diarrhea, insulin, low magnesium	Weakness, cramps, constipation, flat T waves and U waves	Cardiac monitoring, oral replacement when possible, IV safety rules, check magnesium
High potassium (hyperkalemia)	Potassium 3.5–5.1 mmol/L	Kidney injury or disease, potassium-sparing diuretics, ACE inhibitors, acidosis	Often none; weakness, peaked T waves, wide QRS	Cardiac monitoring, IV calcium, insulin with glucose and glucose checks, rule out hemolysis
Low calcium (hypocalcemia)	Total 2.12–2.52 mmol/L; ionized 1.14–1.28 mmol/L	Thyroid or parathyroid surgery, vitamin D deficiency, low magnesium, kidney disease	Tingling, tetany, Chvostek's and Trousseau's signs, long QT	Report tingling, IV calcium with ECG monitoring, check magnesium
High calcium (hypercalcemia)	Total 2.12–2.52 mmol/L; ionized 1.14–1.28 mmol/L	Primary hyperparathyroidism, cancer, thiazides, immobility	Thirst, polyuria, constipation, confusion, short QT	IV rehydration, watch for fluid overload, mobilize as able
Low magnesium (hypomagnesemia)	Magnesium 0.74–1.03 mmol/L	Alcohol use disorder, diuretics, long-term proton pump inhibitors, refeeding	Cramps, tetany, seizures, dysrhythmias; low potassium and calcium	Replace magnesium as ordered, recheck potassium and calcium
High magnesium (hypermagnesemia)	Magnesium 0.74–1.03 mmol/L	IV magnesium, kidney impairment	Flushing, low blood pressure, lost reflexes, slow breathing	Check reflexes, respirations and urine output; stop infusion and report
Low phosphate (hypophosphatemia)	Phosphate 0.81–1.58 mmol/L	Refeeding, alcohol use disorder	Weakness, breathing difficulty, heart failure, hemolysis	Refeeding precautions, replace as ordered, monitor breathing
High phosphate (hyperphosphatemia)	Phosphate 0.81–1.58 mmol/L	Chronic kidney disease, tumour lysis syndrome, excess phosphate replacement	Few direct signs; signs of low calcium	Phosphate binders with meals, diet teaching, watch for low calcium

3.7 Acid–Base Balance

Enzymes, heart muscle and nerve cells work only within a narrow range of hydrogen ion concentration, measured as **pH**. The pH scale runs in the opposite direction to hydrogen ions: as hydrogen ions rise, pH falls. Normal metabolism produces acid every day, so the body must buffer and remove it continuously (Hamm et al., 2015). A blood pH below the normal range is **acidemia** and a pH above it is **alkalemia**. The processes that push pH in those directions are called **acidosis** and **alkalosis**. A patient can have more than one process at once, which is why the pH reflects their combined effect (Farley & Licari, 2019).

How the Body Keeps pH Normal

Three systems work together:

- **Buffers** are chemicals that take up or release hydrogen ions within seconds. The main buffer in the blood is the bicarbonate system: bicarbonate (HCO_3^-) combines with hydrogen ions to form carbonic acid, which breaks down into water and carbon dioxide (CO_2).
- **The lungs** control CO_2, which acts as an acid in the blood. Faster, deeper breathing removes CO_2 and raises pH; slower, shallower breathing retains CO_2 and lowers pH. Changes in breathing begin to alter pH within minutes (Farley & Licari, 2019).
- **The kidneys** control bicarbonate. They reabsorb almost all the bicarbonate filtered from the blood and make new bicarbonate to replace what is used in buffering acids from metabolism (Hamm et al., 2015). The kidneys' response is slow, taking 2 to 4 days to reach its full effect (Farley & Licari, 2019).

An **arterial blood gas (ABG)** measures pH, the partial pressure of carbon dioxide (**$PaCO_2$**), the partial pressure of oxygen (PaO_2) and bicarbonate (HCO_3^-). Typical adult arterial values are a pH of 7.35 to 7.45 and a $PaCO_2$ of 35 to 45 mm Hg (Farley & Licari, 2019; University of Ottawa, 2022), and an HCO_3^- of 22 to 26 mmol/L (Farley & Licari, 2019). Reference ranges vary by laboratory; for example, one Canadian list gives an arterial pH range of 7.38 to 7.46 and an HCO_3^- range of 22 to 27 mmol/L (Medical Council of Canada, 2024). The nurse therefore uses the range on the patient's report. A venous blood gas is sometimes drawn instead; its HCO_3^- and lactate agree well with arterial values only when results are near normal (Farley & Licari, 2019). Oxygenation and PaO_2 are covered in Chapter 12. An ABG sample is arterial (Figure 3.6), so after the puncture the nurse applies firm pressure to the site and checks it and the circulation beyond it, as policy directs.

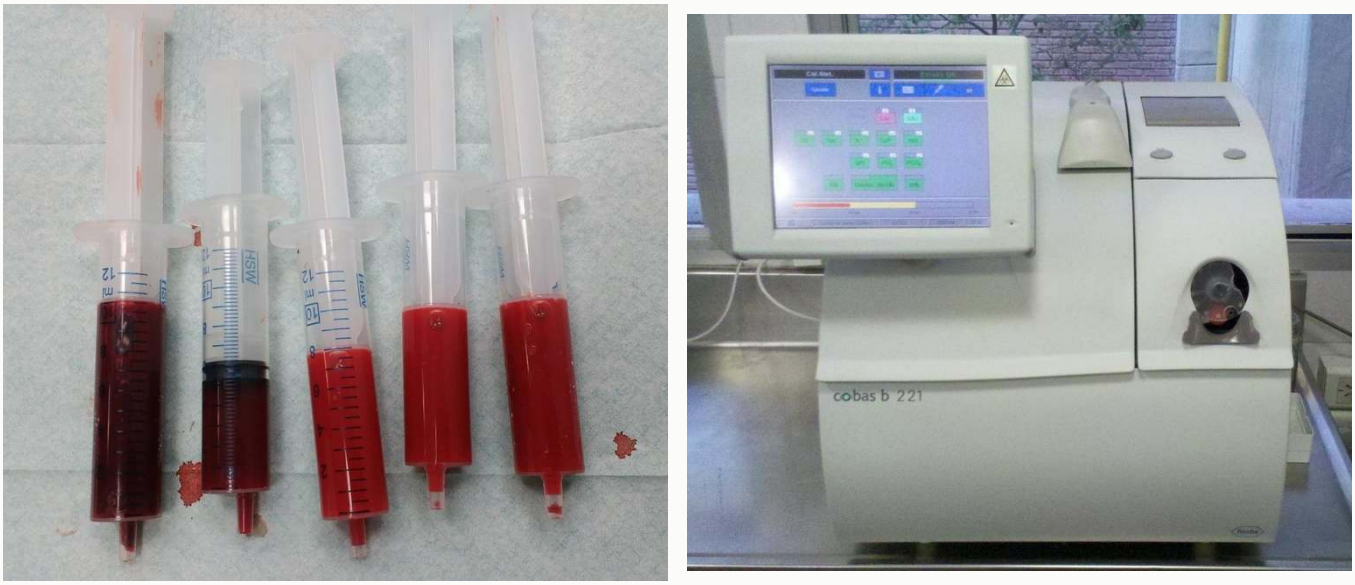

Figure 3.6 (a) Blood samples in syringes: venous blood is darker and arterial blood brighter red. (b) A blood gas analyzer, which measures pH, blood gases and electrolytes in a small sample of blood. (credit: (a) “Venous and arterial blood rotated and cropped” by Wesalius/Wikimedia Commons, CC BY 4.0; (b) “Cobas221A” by J3D3/Wikimedia Commons, CC BY-SA 3.0)

The Four Primary Disorders

A **respiratory** disorder starts with a change in $PaCO_2$, and a **metabolic** disorder starts with a change in HCO_3^- (Table 3.4).

- **Respiratory acidosis** (high $PaCO_2$) occurs when breathing is too slow or too shallow to remove CO_2. Causes include opioid and benzodiazepine sedation, chronic obstructive pulmonary disease (COPD; Chapter 14), severe asthma or pneumonia, and neuromuscular weakness (Farley & Licari, 2019; Chapter 15).
- **Respiratory alkalosis** (low $PaCO_2$) occurs when breathing removes too much CO_2. Causes include pain, anxiety, fever, pneumonia, pulmonary embolism (Chapter 15) and pulmonary edema (Farley & Licari, 2019). A rising respiratory rate is also an early warning sign of sepsis (Chapter 4).

- **Metabolic acidosis** (low HCO_3^-) occurs when acids build up or bicarbonate is lost. Acids build up in lactic acidosis from poor tissue perfusion (Chapters 4 and 6), diabetic ketoacidosis (Chapter 22) and kidney failure (Chapter 27). Bicarbonate is lost in diarrhea (Farley & Licari, 2019).
- **Metabolic alkalosis** (high HCO_3^-) occurs when acid is lost or bicarbonate is retained, as in vomiting, high nasogastric drainage, loop and thiazide diuretics, and volume depletion (Farley & Licari, 2019).

Table 3.4 The four primary acid–base disorders (Farley & Licari, 2019)

Disorder	pH	Primary change	Common causes	Nursing focus
Respiratory acidosis	Below 7.35	$PaCO_2$ above 45 mm Hg	Opioid or sedative excess, COPD, severe pneumonia, neuromuscular weakness	Sedation level, respiratory rate and depth, airway, escalate early
Respiratory alkalosis	Above 7.45	$PaCO_2$ below 35 mm Hg	Pain, anxiety, fever, pneumonia, pulmonary embolism	Find and treat the cause, assess for hypoxemia and sepsis, coach slow breathing only once serious causes are ruled out
Metabolic acidosis	Below 7.35	HCO_3^- below 22 mmol/L	Lactic acidosis, diabetic ketoacidosis, kidney failure, diarrhea	Perfusion, glucose, urine output, potassium, rapid deep breathing as a cue
Metabolic alkalosis	Above 7.45	HCO_3^- above 26 mmol/L	Vomiting, nasogastric suction, diuretics, volume depletion	Fluid replacement as ordered, potassium, accurate drainage measurement

Identifying the Primary Disorder

The core method has three steps (Farley & Licari, 2019):

1. **Look at the pH.** Below 7.35 is acidemia; above 7.45 is alkalemia.

2. **Look at the $PaCO_2$.** If it is abnormal, a respiratory process is present. A high $PaCO_2$ pushes toward acidosis; a low $PaCO_2$ pushes toward alkalosis.

3. **Look at the HCO_3^-.** If it is abnormal, a metabolic process is present. A low HCO_3^- pushes toward acidosis; a high HCO_3^- pushes toward alkalosis.

The primary disorder is the one that matches the direction of the pH. Two examples:

- A pH of 7.26, $PaCO_2$ of 58 mm Hg and HCO_3^- of 25 mmol/L show acidemia with a high $PaCO_2$ and a normal HCO_3^-: respiratory acidosis.
- A pH of 7.50, $PaCO_2$ of 42 mm Hg and HCO_3^- of 32 mmol/L show alkalemia with a high HCO_3^- and a normal $PaCO_2$: metabolic alkalosis.

If both $PaCO_2$ and HCO_3^- are abnormal, the value that matches the pH is the primary disorder, and the other value usually reflects the body's response. Judging that response is RN-level content (see the Going Deeper box). When results do not fit this simple pattern, or the pH is normal but other values are not, the nurse reports them rather than guessing.

Nursing Care and Escalation

The ABG result supports what the nurse sees at the bedside. The nurse recognizes cues such as a falling level of consciousness, slow or shallow breathing, rapid deep breathing, new confusion, dysrhythmias and changes in potassium. An oxygen saturation that looks normal does not rule out a high $PaCO_2$, especially in a patient receiving oxygen. The nurse analyzes cues by linking the result to the history: a patient who received opioids, a patient with diabetes and high glucose, a patient with heavy nasogastric drainage. Care treats the cause, not the number: reversing opioid oversedation, supporting ventilation, restoring perfusion, treating ketoacidosis or replacing losses. For respiratory disorders, the nurse positions the patient upright, encourages deep breathing and coughing where appropriate, and monitors sedation before giving more opioid. For metabolic disorders, the nurse measures all losses accurately and monitors intake and output, glucose and electrolytes. Older adults have less respiratory and kidney reserve, so they may decompensate faster. Acid–base changes also move potassium. Acidosis can raise serum potassium (Alfonzo et al., 2026), so the

nurse watches the potassium closely as acidosis is corrected. Every nurse who finds a deteriorating patient acts at once and escalates using SBAR and the rapid response team (Chapter 6). A PN consults the RN when ABG results are abnormal or the patient's condition changes.

GOING DEEPER

Interpreting a Blood Gas Fully

Required for RN students; optional for PN students.

Compensation. The body responds to a primary disorder by changing the other system in the opposite direction: the lungs adjust $PaCO_2$ for a metabolic disorder within minutes to hours, and the kidneys adjust HCO_3^- for a respiratory disorder over 2 to 4 days (Farley & Licari, 2019). In metabolic acidosis, the $PaCO_2$ falls; in chronic respiratory acidosis, the HCO_3^- rises. When pH is still abnormal but the other value has begun to move, compensation is partial. Published formulas predict the expected compensation (Farley & Licari, 2019).

Mixed disorders. If the second value moves the wrong way, or more or less than predicted, a second primary disorder is present. A high $PaCO_2$ and a low HCO_3^- together mean both respiratory and metabolic acidosis. A normal pH does not exclude a problem: two opposing disorders can cancel out (Farley & Licari, 2019).

Anion gap. In metabolic acidosis, the anion gap estimates unmeasured anions: sodium minus (chloride plus HCO_3^-). Some laboratories add potassium. Normal ranges differ between laboratories and methods (Kraut & Madias, 2007); one review gives 8 to 16 mmol/L for the formula that includes potassium (Farley & Licari, 2019). A high gap points to added acid: lactate, ketones, kidney failure or toxins. A normal gap points to bicarbonate loss, as in diarrhea. Albumin is the main unmeasured anion, so each 10 g/L fall in albumin lowers the gap by about 2.3 to 2.5 mmol/L and can hide a high gap (Kraut & Madias, 2007; Farley & Licari, 2019).

Lactate. A high lactate is a common cause of a high gap and a marker of poor perfusion (Chapters 4 and 6).

Worked example. A patient with sepsis has pH 7.29, $PaCO_2$ 28 mm Hg, HCO_3^- 13 mmol/L, sodium 138 mmol/L and chloride 100 mmol/L. The low pH and low HCO_3^- show metabolic acidosis; the low $PaCO_2$ is partial respiratory compensation. The anion gap is 138 − (100 + 13) = 25 mmol/L, which is high. With a high lactate, this fits lactic acidosis.

CANADIAN CONTEXT

Lab Values in SI Units

Canadian laboratories report results in SI units, while many US sources use conventional units. When reading a US source, convert before comparing:

- **Sodium and potassium:** 1 mEq/L equals 1 mmol/L, so 140 mEq/L is 140 mmol/L.
- **Glucose:** divide mg/dL by 18 (multiply by 0.0555) to get mmol/L, so 180 mg/dL is about 10.0 mmol/L.
- **Creatinine:** multiply mg/dL by 88.4 to get µmol/L, so 1.0 mg/dL is 88.4 µmol/L (Labcorp, n.d.).

The 2027 REx-PN test plan lists the laboratory values candidates are expected to know: sodium, potassium, glucose, glycosylated hemoglobin (HbA1c), creatinine, blood urea nitrogen (BUN), total cholesterol, hemoglobin, hematocrit, platelets, white blood cell count, international normalized ratio (INR), prothrombin time, partial and activated partial thromboplastin times, and ABGs (pH, PO_2, PCO_2, SaO_2 and HCO_3^-) (National Council of State Boards of Nursing, 2026). Reference ranges still vary by laboratory, and Canadian clinical chemists are working to harmonize them (Bohn et al., 2023). The nurse always uses the range printed on the patient's report.

Chapter 3 Summary

3.1 Body Fluids and How They Are Regulated

- Water is about 50% to 60% of adult body weight; about two-thirds is inside cells and one-third outside, in interstitial fluid and plasma.
- Tonicity, set mainly by sodium, decides whether water moves into or out of cells; isotonic, hypotonic and hypertonic fluids have different effects.
- Starling forces govern exchange between plasma and tissues; edema forms when filtration exceeds lymphatic drainage.
- Thirst, ADH, the RAAS and natriuretic peptides regulate water and sodium, and the kidneys carry out their signals.

- Older adults have weaker thirst and less ability to concentrate urine, which raises their risk of dehydration.

3.2 Fluid Volume Deficit and Excess

- Deficit results from losses, poor intake or third spacing; excess usually results from heart, kidney or liver failure or excess IV fluid.
- No single cue is reliable; the nurse combines vital signs, orthostatic changes, urine output, weight, lung sounds, edema, mental status and laboratory results.
- Skin turgor and capillary refill are unreliable in adults, especially older adults; swelling, pallor and cyanosis can be harder to see on darker skin.
- Accurate intake and output and daily weights on the same scale at the same time are core nursing measures.
- Care includes oral or IV replacement for deficit, and fluid and sodium restriction, diuretics, positioning and skin care for excess, with prompt escalation of deterioration.

3.3 IV Fluids and Fluid Management

- IV fluids are prescribed like medications and need a complete order; the 5 Rs (resuscitation, routine maintenance, replacement, redistribution, reassessment) explain their purpose.
- Isotonic crystalloids are used for resuscitation; dextrose and hypotonic solutions can lower sodium; 3% sodium chloride is a hypertonic high-alert fluid.
- Monitoring includes vital signs, lung sounds, intake and output, weight and electrolyte, urea and creatinine results.
- Main risks are fluid overload, hyponatremia from hypotonic fluids, and infiltration or extravasation.
- Concentrated potassium is never given by IV push; premixed solutions, limited stocking of concentrates, infusion pumps, rate limits and independent double checks per policy keep patients safe.

3.4 Sodium Imbalances

- Serum sodium mainly reflects water balance; a typical adult range is about 136 to 144 mmol/L, varying by laboratory.
- Hyponatremia has many causes, including SIADH, diuretics, heart failure and too much hypotonic fluid; severe symptoms such as vomiting, seizures or coma are an emergency.
- Chronic hyponatremia must be corrected slowly: the rise is limited to 10 mmol/L in the first 24 hours and 8 mmol/L in each later 24 hours, to avoid osmotic demyelination.
- Hypernatremia usually means water loss that has not been replaced, especially in older or dependent adults; water is replaced gradually as ordered.

3.5 Potassium Imbalances

- Small changes in potassium affect muscles and the heart; hypokalemia flattens T waves and causes U waves, and hyperkalemia causes peaked T waves and a wide QRS.
- Diuretics, vomiting, diarrhea and low magnesium cause hypokalemia; replacement is oral when possible, and IV potassium follows the high-alert rules in section 3.3.
- Hyperkalemia from kidney injury or potassium-sparing drugs is treated with IV calcium, insulin with glucose, removal of potassium and close monitoring of potassium and glucose.
- Hemolysis can cause pseudohyperkalemia, but a high potassium with ECG changes is always treated as real.

3.6 Calcium, Magnesium and Phosphate

- Ionized calcium is the active fraction; low albumin lowers total calcium, and ionized calcium is more reliable when results do not fit.
- Hypocalcemia causes tingling, tetany, Chvostek's and Trousseau's signs and long QT; hypercalcemia, usually from hyperparathyroidism or cancer, causes thirst, polyuria, constipation and confusion.

- Low magnesium often travels with low potassium and low calcium; magnesium sulfate toxicity is detected by lost reflexes, slow breathing and low urine output.
- Refeeding syndrome is prevented by identifying risk, giving thiamine before feeding, starting nutrition slowly and monitoring phosphate, potassium and magnesium.

3.7 Acid–Base Balance

- Buffers act in seconds, the lungs adjust $PaCO_2$ in minutes, and the kidneys adjust bicarbonate over days.
- Typical arterial values are pH 7.35 to 7.45, $PaCO_2$ 35 to 45 mm Hg and HCO_3^- 22 to 26 mmol/L; ranges vary by laboratory.
- To identify the primary disorder, look at the pH, then find the $PaCO_2$ or HCO_3^- change that matches its direction.
- The nurse treats the ABG as one part of the bedside assessment and escalates deterioration at once.

Key Terms (58)

acidemia: A blood pH below the normal range.

acidosis: A process that adds acid or removes base, tending to lower pH.

albumin: A plasma protein, also given as a colloid solution made from pooled human plasma, that raises plasma oncotic pressure and holds fluid in the blood vessels.

aldosterone: A hormone from the adrenal cortex that causes the kidneys to keep sodium, and with it water.

alkalemia: A blood pH above the normal range.

alkalosis: A process that removes acid or adds base, tending to raise pH.

anion gap: A calculated value (sodium minus chloride and bicarbonate, with or without potassium) that estimates unmeasured anions; a high gap suggests added acid.

antidiuretic hormone (ADH): A hormone, also called vasopressin, released from the posterior pituitary when osmolality rises or blood volume falls; it makes the kidneys return more water to the blood.

arterial blood gas (ABG): A test of arterial blood that measures pH, $PaCO_2$, PaO_2 and bicarbonate.

balanced solution: An isotonic crystalloid, such as Plasma-Lyte A, whose electrolyte content is closer to plasma than that of 0.9% sodium chloride.

buffer: A chemical system, such as bicarbonate and carbonic acid, that takes up or releases hydrogen ions to limit changes in pH.

Chvostek's sign: Twitching of the facial muscles when the facial nerve is tapped; a sign of hypocalcemia, though less specific than Trousseau's sign.

colloid: An IV solution containing large molecules, such as albumin, that stay mostly in the blood vessels.

compensation: The body's response to a primary acid–base disorder, in which the other system (lungs or kidneys) changes in the opposite direction to move pH back toward normal.

crystalloid: An IV solution of water with electrolytes, glucose or both.

daily weight: A weight taken at the same time each day on the same scale with similar clothing, used to track short-term changes in body fluid.

edema: Excess fluid in the interstitial space.

extracellular fluid (ECF): All body water outside the cells, made up mainly of interstitial fluid and plasma.

extravasation: Leakage of a drug or solution that can damage tissue from a vein into the surrounding tissue.

fluid volume deficit: A loss of extracellular fluid volume (hypovolemia).

fluid volume excess: Too much sodium and water in the extracellular fluid (hypervolemia).

hypercalcemia: A serum calcium above the reference range.

hyperkalemia: A serum potassium above the reference range; it can cause peaked T waves and fatal dysrhythmias.

hypernatremia: A serum sodium above the reference range, usually from too little water relative to sodium.

hypertonic: Having a higher tonicity than plasma, so water moves out of cells.

hypocalcemia: A serum calcium below the reference range, causing nerve and muscle overexcitability.

hypokalemia: A serum potassium below the reference range; it can cause weakness, ileus and dysrhythmias.

hypomagnesemia: A serum magnesium below the reference range, often with low potassium and low calcium.

hyponatremia: A serum sodium below the reference range, usually from too much water relative to sodium.

hypotonic: Having a lower tonicity than plasma, so water moves into cells.

infiltration: Leakage of IV fluid from the vein into the surrounding tissue.

interstitial fluid: Fluid in the spaces between cells in the tissues.

intracellular fluid (ICF): Body water inside the cells, about two-thirds of the total.

intravascular fluid: The fluid within blood vessels; the plasma.

ionized calcium: The free, physiologically active fraction of plasma calcium, about half of the total.

isotonic: Having about the same tonicity as plasma, so cells keep their size.

jugular venous distension: Visible filling of the neck veins with the head raised 30 to 45 degrees, a sign of high venous pressure.

metabolic acidosis: An acid–base disorder with a low pH caused by a primary fall in bicarbonate.

metabolic alkalosis: An acid–base disorder with a high pH caused by a primary rise in bicarbonate.

natriuretic peptides: Hormones (ANP and BNP) released by stretched heart muscle that increase sodium and water excretion and oppose the renin–angiotensin–aldosterone system.

orthostatic hypotension: A fall in systolic blood pressure of at least 20 mm Hg, or diastolic of at least 10 mm Hg, within 3 minutes of standing.

osmolality: The concentration of dissolved particles per kilogram of water, reported in mOsm/kg.

osmolarity: The concentration of dissolved particles per litre of solution, reported in mOsmol/L.

osmosis: Movement of water across a membrane from an area of lower to higher solute concentration.

osmotic demyelination syndrome (ODS): Damage to the myelin of brain nerve fibres caused by too rapid a rise in serum sodium in chronic hyponatremia.

$PaCO_2$: The partial pressure of carbon dioxide in arterial blood, the respiratory component of an ABG.

phlebitis: Inflammation of a vein, often related to IV therapy.

pseudohyperkalemia: A falsely high potassium result caused by release of potassium from blood cells after the sample is drawn.

refeeding syndrome: A fall of 10% or more in serum phosphate, potassium or magnesium, with or without organ dysfunction, within 5 days of starting or increasing nutrition after starvation or malnutrition.

renin–angiotensin–aldosterone system (RAAS): A hormone system, started by renin from the kidney, that raises blood pressure and keeps sodium and water.

respiratory acidosis: An acid–base disorder with a low pH caused by a primary rise in $PaCO_2$ from inadequate breathing.

respiratory alkalosis: An acid–base disorder with a high pH caused by a primary fall in $PaCO_2$ from excessive breathing.

Starling forces: The hydrostatic and oncotic pressures that govern fluid movement between plasma and the interstitial space.

syndrome of inappropriate antidiuretic hormone secretion (SIADH): Continued ADH action despite dilute plasma, causing water retention and hyponatremia in a patient with normal volume status.

third spacing: A shift of fluid out of the circulation into spaces where it cannot support blood pressure, such as the bowel, abdomen or inflamed tissue.

tonicity: The effect of a fluid on cell volume, determined by solutes that cannot cross cell membranes freely.

Trousseau's sign: Spasm of the hand and wrist within 3 minutes of inflating a blood pressure cuff above systolic pressure; a sign of hypocalcemia.

urine specific gravity: A measure of urine concentration compared with water.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Tomas Silva (Questions 1–4): Mr. Tomas Silva, 68, is on day 2 after a bowel resection on a surgical unit in an Ontario hospital, cared for by an RPN. He is nil by mouth and receiving 0.9% sodium chloride with potassium chloride 20 mmol/L at 80 mL/h by pump through a left forearm peripheral IV. His morning serum potassium is 3.3 mmol/L; vital signs are at his baseline.

1. [CORE] The surgeon writes a new order: "KCl 40 mmol IV now." What should the RPN do first?

a. Ask pharmacy for a vial of concentrated potassium chloride to dilute on the unit

b. Contact the surgeon to clarify the diluent, volume and infusion rate

c. Give the dose slowly by IV push over 10 minutes

d. Ask the RN to give the dose because potassium is a high-alert medication

Answer: b — The order gives no diluent, volume or rate, so the RPN does not carry it out and follows up with the prescriber (section 3.3, Scope in Practice box). Concentrated potassium is kept out of patient care areas, and premixed solutions are used instead (a). Potassium is never given by IV push (c). RPNs are authorized to give IV medications with an order; the problem is the order, not the nurse's category (d).

2. [CORE] The surgeon rewrites the order as potassium chloride 20 mmol in a premixed minibag from pharmacy, to infuse over 2 hours. Which action best reflects safe practice for this high-alert medication?

a. Have a second nurse independently check the drug, dose, rate and pump settings

b. Run the minibag by gravity and count the drip rate every 15 minutes

c. Program the pump while a second nurse watches and confirms the numbers on the screen

d. Hang the minibag without a pump because it will finish within 2 hours

Answer: a — In an independent double check, done as policy requires, the second nurse verifies the drug, dose, rate and pump settings without seeing the first nurse's work (section 3.3; Chapter 1, section 1.6). Watching the first nurse program the pump (c) is not independent. IV potassium needs a calibrated infusion device, so gravity infusion (b) and running without a pump (d) are unsafe.

3. [CORE] Thirty minutes into the minibag infusion, Mr. Silva says his arm "burns." The skin around the IV site is swollen, cool and tight compared with his other arm. What should the RPN do first?

a. Stop the infusion and assess the site
b. Slow the infusion rate by half and reassess in an hour
c. Apply a warm compress and continue the infusion
d. Flush the catheter firmly to confirm it is still patent

Answer: a — Swelling, coolness, tightness and burning suggest infiltration of a solution that can damage tissue, so the RPN stops the infusion, assesses the site and follows policy, including notifying the prescriber (section 3.3). Slowing the rate (b), continuing with a compress (c) or flushing firmly (d) pushes more fluid into the tissue.

4. [CORE] That afternoon, Mr. Silva's blood pressure is 92/54 (124/76 this morning), heart rate 116, and urine output 15 mL/h for 2 hours. He is newly confused. Which action by the RPN is most appropriate?

a. Continue hourly vital signs, because the patient remains on the RPN's assignment
b. Increase the IV rate to 150 mL/h to treat the low blood pressure
c. Stay with him, get help and report at once to the RN and surgeon using SBAR
d. Ask the charge nurse to arrange a transfer to a higher level of care, then report the findings

Answer: c — Falling blood pressure, tachycardia, low urine output and new confusion signal deterioration. Every nurse who notices deterioration acts at once and escalates, calling the rapid response team if criteria are met; the RPN also consults the RN as needs change (section 3.2; Scope in Practice box, section 3.3). Routine checks (a) delay care. Increasing the rate (b) needs an order. Arranging a transfer before reporting (d) delays treatment.

5. [CORE] A nurse is assessing a 78-year-old patient with heart failure. Which findings are cues of fluid volume excess? Select all that apply.

a. Weight gain of 2.1 kg over 2 days
b. Crackles at both lung bases
c. Distended neck veins with the head of the bed at 45 degrees
d. Deep sock marks and tight, shiny skin over the ankles
e. Dry axillae and dry oral mucous membranes
f. A fall in systolic blood pressure of 24 mm Hg on standing

Answer: a, b, c, d — Rapid weight gain (a), crackles (b), jugular venous distension (c) and edema, which may show as tight, shiny skin and deep sock marks (d), are cues of fluid excess (section 3.2, Table 3.1). Dry axillae and mucous membranes (e) and orthostatic hypotension (f) are cues of deficit.

6. [CORE] A patient weighed 72.4 kg at 0600 yesterday and 74.0 kg at 0600 today on the same scale. Intake for 24 hours was 2,400 mL and output 1,350 mL. How should the nurse interpret these findings?

a. The gain is normal day-to-day variation from meals
b. The patient is probably retaining fluid and needs further assessment
c. The scale is probably wrong, so the patient should be reweighed on a bed scale
d. The patient is likely developing a fluid volume deficit

Answer: b — Because 1 L of water weighs about 1 kg, a gain of 1.6 kg in a day mostly reflects fluid, and a positive measured balance of about 1 L supports this (unmeasured intake may explain the rest). The nurse assesses lung sounds and edema and reports per the ordered parameters (section 3.2). Food does not explain a gain this large (a). Weighing at the same time on the same scale makes results comparable; switching scales (c) would not. Weight gain does not suggest a deficit (d).

7. [CORE] A 59-year-old patient has vomited for 2 days. Blood pressure is 88/50 and heart rate 118. The prescriber orders a fluid bolus. Which solution should the nurse expect?

a. 5% dextrose in water
b. 0.45% sodium chloride
c. 3% sodium chloride
d. 0.9% sodium chloride

Answer: d — Resuscitation uses an isotonic crystalloid with 130 to 154 mmol/L of sodium, such as 0.9% sodium chloride, which stays in the ECF (section 3.3, Table 3.2). 5% dextrose in water (a) becomes free water that moves into cells. 0.45% sodium chloride (b) is hypotonic and expands the circulation poorly. 3% sodium chloride (c) is reserved for severe symptomatic hyponatremia.

8. [CORE] An 82-year-old patient receiving 0.9% sodium chloride at 125 mL/h after hip surgery becomes short of breath, with a respiratory rate of 28, oxygen saturation 89% and new crackles. What should the nurse do first?

a. Document the findings and recheck the respiratory rate and oxygen saturation in one hour
b. Encourage the patient to cough, breathe deeply and use the incentive spirometer every hour
c. Sit the patient upright, slow the infusion as policy allows and call for help
d. Ask the patient to limit oral fluids for the rest of the shift and record all intake

Answer: c — These cues suggest fluid overload with fluid in the lungs, which needs immediate action and escalation (section 3.3). Sitting upright eases breathing, slowing the infusion as policy allows limits further overload, and the nurse calls for help. Waiting an hour (a) delays care. Coughing and deep breathing (b) do not treat overload. Limiting oral fluids (d) does not address the IV fluid or the urgent breathing problem.

9. [CORE] On day 1 after surgery, a 45-year-old patient receiving 5% dextrose in 0.45% sodium chloride at 125 mL/h has a headache, nausea and new confusion. Which laboratory result is most important for the nurse to check?

a. Potassium
b. Hemoglobin
c. Glucose
d. Sodium

Answer: d — Hypotonic and dextrose-containing fluids can lower sodium quickly after surgery, when ADH release is often increased; this patient is receiving about 3 L a day. Headache, nausea and confusion suggest hyponatremia with brain swelling (section 3.3). Potassium (a), hemoglobin (b) and glucose (c) matter but do not explain this pattern as well.

Case: Mrs. Lillian Okafor (Questions 10–15): Mrs. Lillian Okafor, 81, is admitted to a medical unit in an Ontario hospital after 3 days of vomiting and diarrhea with poor fluid intake. She takes spironolactone and an ACE inhibitor for heart failure. On admission she is drowsy but oriented. Vital signs: temperature 37.4 °C, heart rate 54 and regular, respiratory rate 18, blood pressure 102/60 mm Hg (her baseline is 136/78 mm Hg), oxygen saturation (SpO_2) 96% on room air. Her mucous membranes are dry. Laboratory results: potassium 6.6 mmol/L (no hemolysis reported), sodium 133 mmol/L, creatinine 172 µmol/L (92 µmol/L three months ago), urea 15.8 mmol/L, glucose 6.4 mmol/L, HCO_3^- 19 mmol/L. A 12-lead ECG shows peaked T waves.

10. [CORE] Which findings require immediate follow-up? Select all that apply.

a. Potassium 6.6 mmol/L
b. Peaked T waves on the ECG
c. Glucose 6.4 mmol/L
d. Creatinine 172 µmol/L, up from 92 µmol/L
e. Blood pressure 102/60 mm Hg
f. SpO_2 96% on room air

Answer: a, b, d, e — Recognize cues (sections 3.2 and 3.5). Severe hyperkalemia with ECG changes is life-threatening. The rising creatinine shows a sudden fall in kidney function, and the blood pressure is well below her baseline, fitting volume loss. A glucose of 6.4 mmol/L is not an urgent concern. An SpO_2 of 96% on room air is acceptable.

11. [CORE] Which combination of factors most likely explains Mrs. Okafor's high potassium?

a. Vomiting and diarrhea that removed potassium-rich fluid from the gastrointestinal tract
b. Reduced kidney function from volume loss, plus two drugs that reduce potassium excretion
c. A high-sodium diet at home combined with several days of poor fluid intake
d. Hemolysis of the blood sample caused by a difficult or prolonged blood draw

Answer: b — Analyze cues (section 3.5). Volume loss lowered kidney blood flow (the creatinine has nearly doubled), and spironolactone and ACE inhibitors both reduce potassium excretion. Vomiting and diarrhea lose potassium, so they would lower it (a). Sodium intake does not explain a high potassium (c). No hemolysis was reported, and peaked T waves show the high potassium is real (d).

12. [CORE] Which problem should the nurse treat as the priority?

a. Fluid volume deficit related to vomiting and diarrhea
b. Risk for falls related to drowsiness and low blood pressure
c. Risk for a life-threatening dysrhythmia related to hyperkalemia
d. Deficient knowledge about heart failure medications

Answer: c — Prioritize hypotheses (section 3.5). A potassium of 6.6 mmol/L with peaked T waves can progress quickly to a fatal rhythm. Fluid deficit (a) is real and contributes, but the immediate threat to life is cardiac. Falls (b) and teaching (d) matter but come later.

13. [CORE] Which orders should the nurse anticipate for Mrs. Okafor? Select all that apply.

a. Continuous cardiac monitoring
b. IV calcium gluconate
c. IV insulin with dextrose, with frequent glucose checks
d. Oral potassium chloride with breakfast
e. Holding spironolactone and the ACE inhibitor
f. IV isotonic crystalloid to restore volume

Answer: a, b, c, e, f — Generate solutions (section 3.5). Calcium protects the heart when ECG changes are present, and insulin with dextrose shifts potassium into cells, with glucose checks because of the hypoglycemia risk. Monitoring is needed at this level. Holding drugs that raise potassium and restoring volume to improve kidney function treat the causes. Oral potassium (d) would make her hyperkalemia worse.

14. [CORE] Mrs. Okafor receives IV insulin with dextrose. Which nursing action is most important over the next several hours?

a. Check capillary blood glucose at the ordered intervals
b. Encourage her to drink at least 2 litres of fluid
c. Assess for Chvostek's and Trousseau's signs every hour
d. Offer high-potassium foods once her nausea settles

Answer: a — Take action (section 3.5). Insulin can cause hypoglycemia for several hours after it is given, so the nurse checks glucose as ordered. Large oral fluid volumes (b) are not ordered and may not suit a patient with heart failure. Chvostek's and Trousseau's signs (c) assess low calcium, not this risk. High-potassium foods (d) are inappropriate.

15. [CORE] Which findings 6 hours later best show that treatment is working?

a. Potassium 6.3 mmol/L, glucose 3.6 mmol/L, heart rate 52
b. Potassium 5.2 mmol/L, T waves no longer peaked, urine output 45 mL/h
c. Potassium 4.0 mmol/L, new confusion, urine output 10 mL/h
d. Potassium 5.6 mmol/L, peaked T waves, blood pressure 98/58 mm Hg

Answer: b — Evaluate outcomes (section 3.5). A falling potassium, a normalizing ECG and adequate urine output show response to both the shift therapy and rehydration. Option a shows little change and hypoglycemia. Option c has new confusion and oliguria, which need escalation even with a normal potassium. Option d shows persistent ECG changes and low blood pressure.

16. [CORE] A patient taking furosemide has a potassium of 2.8 mmol/L. Which ECG change should the nurse expect?

a. Tall, peaked T waves
b. A widened QRS complex with a sine-wave pattern
c. A shortened QT interval
d. Flattened T waves with prominent U waves

Answer: d — Hypokalemia flattens the T wave, depresses the ST segment and makes U waves prominent (section 3.5). Peaked T waves (a) and a sine-wave pattern (b) are signs of hyperkalemia. A shortened QT (c) is linked with hypercalcemia (section 3.6).

17. [CORE] A patient with chronic hyponatremia had a sodium of 116 mmol/L at 0800 and is being treated in a monitored unit. At 1800 the sodium is 127 mmol/L and the urine output has risen sharply. What should the nurse do first?

a. Document the result as a good response and continue the plan
b. Encourage oral fluids to replace the urine output
c. Recheck the sodium at the next routine morning draw
d. Report the rise to the prescriber at once

Answer: d — The sodium has risen 11 mmol/L in 10 hours, already beyond the recommended limit of 10 mmol/L in the first 24 hours, and the rising dilute urine output suggests it is still climbing (section 3.4, Clinical Safety box). Rapid correction risks osmotic demyelination, so the nurse reports at once. Option a misreads the danger. The nurse does not give unordered fluids (b). Waiting until morning (c) delays action.

18. [CORE] A patient with severe malnutrition and alcohol use disorder started tube feeding 2 days ago. Which result most suggests refeeding syndrome?

a. Phosphate 0.42 mmol/L, down from 0.95 mmol/L on admission
b. Sodium 144 mmol/L, up from 140 mmol/L
c. Potassium 4.6 mmol/L, unchanged from admission
d. Albumin 30 g/L, unchanged from admission

Answer: a — Refeeding syndrome is a fall in phosphate, potassium or magnesium within 5 days of starting nutrition (section 3.6). A drop of more than half in phosphate is a severe fall. The small sodium rise (b) is within range. The unchanged potassium (c) and albumin (d) do not suggest refeeding syndrome.

19. [CORE] A patient who received IV morphine for pain is difficult to rouse. ABG: pH 7.24, $PaCO_2$ 60 mm Hg, HCO_3^- 25 mmol/L. Which disorder is present?

a. Metabolic acidosis
b. Respiratory acidosis
c. Respiratory alkalosis
d. Metabolic alkalosis

Answer: b — The pH is low (acidemia), the $PaCO_2$ is high and matches the pH, and the HCO_3^- is normal: respiratory acidosis from opioid-related hypoventilation (section 3.7). Metabolic acidosis (a) would show a low HCO_3^-. Both alkaloses (c, d) need a high pH.

20. [CORE] A patient after bowel surgery has had nasogastric suction for 4 days. ABG: pH 7.51, $PaCO_2$ 44 mm Hg, HCO_3^- 34 mmol/L. Which disorder is present?

a. Respiratory alkalosis
b. Metabolic acidosis
c. Metabolic alkalosis
d. Respiratory acidosis

Answer: c — The pH is high, the HCO_3^- is high and matches the pH, and the $PaCO_2$ is normal: metabolic alkalosis from loss of gastric acid (section 3.7). Respiratory alkalosis (a) would show a low $PaCO_2$. The two acidoses (b, d) need a low pH.

21. [CORE] The nurse teaches a patient newly prescribed spironolactone. Which statement shows a need for more teaching?

a. "I'll use a salt substitute instead of regular salt."
b. "I'll go for my blood tests when they're due."
c. "I'll get up slowly if I feel dizzy."
d. "I'll call if my muscles feel weak or my heart races."

Answer: a — The spironolactone monograph advises patients to avoid salt substitutes, potassium supplements and high-potassium foods because of the risk of hyperkalemia (section 3.5, Medications box). Regular blood tests (b), rising slowly (c) and reporting weakness or palpitations (d) are correct.

22. [CORE] A patient with small cell lung cancer has a sodium of 124 mmol/L, mild fatigue, no nausea, headache or confusion, and no signs of fluid deficit or excess. Urine osmolality is high. Which order should the nurse anticipate first?

a. Fluid restriction
b. A 1-litre bolus of 0.9% sodium chloride
c. IV furosemide
d. Encouraging extra oral fluids

Answer: a — These findings suggest SIADH, and fluid restriction is the suggested first-line treatment (section 3.4). Without volume loss, a saline bolus (b) is not the first choice. Furosemide (c) is not the first-line treatment. Extra fluids (d) would lower the sodium further.

23. [CORE] Four hours after a total thyroidectomy, a patient reports tingling around the mouth and in the fingertips. What should the nurse do first?

- **a.** Reassure the patient that this is expected after anesthesia
- **b.** Assess for other signs of hypocalcemia and report promptly
- **c.** Give the next dose of oral calcium early
- **d.** Encourage slow, deep breathing into a paper bag

Answer: b — Perioral and fingertip tingling are early cues of hypocalcemia, the most common cause of which in hospital is parathyroid damage during thyroid surgery (section 3.6). The nurse assesses for spasm and Trousseau's sign and reports so calcium can be checked. Reassurance (a) misses a dangerous cause. The nurse does not change a dose time without an order (c). Rebreathing (d) is not a treatment for hypocalcemia.

24. [CORE] A patient receiving an IV magnesium sulfate infusion has absent patellar reflexes and a respiratory rate of 11. What should the nurse do first?

- **a.** Slow the infusion by half and reassess in an hour
- **b.** Document the findings as an expected effect
- **c.** Give oral fluids to increase urine output
- **d.** Stop the infusion and report at once

Answer: d — Loss of the patellar reflex and slowed breathing are signs of magnesium toxicity (section 3.6). The nurse stops the infusion and escalates; IV calcium gluconate reverses respiratory depression. Slowing the infusion (a) or documenting only (b) delays care, and oral fluids (c) do not treat toxicity.

25. [CORE] A patient's potassium is reported as 6.1 mmol/L with a comment that the sample was hemolyzed. The patient feels well, and a 12-lead ECG is normal. Which action is best?

- **a.** Ignore the result because hemolysis makes it invalid
- **b.** Give the patient's scheduled oral potassium supplement
- **c.** Report the result and expect a carefully drawn repeat sample
- **d.** Start continuous cardiac monitoring and ask for IV calcium

Answer: c — Hemolysis can falsely raise potassium (pseudohyperkalemia), but a real rise must be ruled out (section 3.5). The nurse reports the result and a repeat sample is drawn gently and sent promptly. Ignoring it (a) is unsafe. Giving potassium (b) before the result is clarified could cause harm. Emergency treatment (d) is not indicated with a normal ECG and a likely false result, though it would be if the ECG were abnormal.

26. [CORE] A patient with advanced dementia, unable to get drinks without help, has a sodium of 152 mmol/L. Which nursing action is most important?

- **a.** Restrict free water intake to 1 litre a day
- **b.** Add extra table salt to the patient's meals
- **c.** Offer water often and record all intake
- **d.** Request an order for a hypertonic saline bolus

Answer: c — Hypernatremia in a dependent person usually reflects too little water (section 3.4). Regular offering of fluids and accurate records address the cause. Restricting water (a), adding salt (b) and hypertonic saline (d) would all raise the sodium further.

27. [RN] A patient with diabetic ketoacidosis has pH 7.25, $PaCO_2$ 28 mm Hg, HCO_3^- 12 mmol/L. Which interpretation is correct?

- **a.** Respiratory alkalosis with partial metabolic compensation
- **b.** Metabolic acidosis with partial respiratory compensation
- **c.** Mixed metabolic and respiratory acidosis
- **d.** Metabolic acidosis with full respiratory compensation

Answer: b — The low pH and low HCO_3^- show metabolic acidosis; the low $PaCO_2$ is the lungs blowing off CO_2 in the expected opposite direction (section 3.7, Going Deeper). The pH is still low, so compensation is partial, not full (d). A respiratory alkalosis would raise the pH (a). A mixed acidosis would show a high $PaCO_2$ (c).

28. [RN] A patient with sepsis who received opioids has pH 7.08, $PaCO_2$ 56 mm Hg, HCO_3^- 16 mmol/L. Which interpretation is correct?

- **a.** Respiratory acidosis with metabolic compensation
- **b.** Metabolic acidosis with respiratory compensation
- **c.** Mixed respiratory and metabolic acidosis
- **d.** Metabolic alkalosis with respiratory acidosis

Answer: c — Both values push toward acidosis: the $PaCO_2$ is high and the HCO_3^- is low (section 3.7, Going Deeper). Compensation would move the second value in the opposite direction, so options a and b are wrong. HCO_3^- is low, not high, so there is no metabolic alkalosis (d). A mixed disorder like this causes severe acidemia and needs urgent escalation.

29. [RN] A patient with metabolic acidosis has sodium 140 mmol/L, chloride 104 mmol/L and HCO_3^- 12 mmol/L. The laboratory calculates the anion gap without potassium. What is the anion gap, and what does it suggest?

- **a.** 24 mmol/L, suggesting added acid such as lactate or ketones
- **b.** 12 mmol/L, suggesting bicarbonate loss from diarrhea
- **c.** 36 mmol/L, suggesting a laboratory error
- **d.** 116 mmol/L, suggesting severe kidney failure

Answer: a — Anion gap = 140 − (104 + 12) = 24 mmol/L, which is high and points to added acid such as lactate, ketones, kidney failure or toxins (section 3.7, Going Deeper). Option b simply repeats the HCO_3^- value. Option c subtracts chloride but leaves out HCO_3^-. Option d adds chloride and HCO_3^- but does not subtract them from sodium.

30. [RN] A patient with sepsis has a calculated anion gap of 13 mmol/L, which is within the laboratory's normal range, but the albumin is 20 g/L. How should the nurse interpret this?

- **a.** The normal gap rules out lactic acidosis
- **b.** The low albumin has raised the gap falsely
- **c.** Albumin has no effect on the anion gap
- **d.** The low albumin may be hiding a high anion gap

Answer: d — Albumin is the main unmeasured anion, so a low albumin lowers the gap by about 2.3 to 2.5 mmol/L for each 10 g/L fall (section 3.7, Going Deeper). An albumin about 20 g/L below a typical 40 g/L adds back about 5 mmol/L, giving an adjusted gap near 18 mmol/L, which would be high, so the nurse checks the lactate and reports. A normal gap does not rule out lactic acidosis here (a). Low albumin lowers the gap; it does not raise it (b), and it does affect it (c).

04 Inflammation, Infection and Sepsis

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain the acute inflammatory response and the phases of wound healing, and identify factors that delay healing.
2. Recognize local and systemic cues of infection, including atypical presentations in older adults, and describe the nurse's role in specimen collection and in reviewing common blood tests.
3. Apply routine practices and additional precautions, including the point-of-care risk assessment, hand hygiene and safe use of personal protective equipment.
4. Describe the nurse's role in outbreaks and in reporting diseases of public health significance in Ontario.
5. Describe common antibiotic-resistant organisms and Clostridioides difficile infection, and the precautions and care each needs.
6. Explain the nurse's role in antimicrobial stewardship, including assessing a reported penicillin allergy and teaching safe antibiotic use.
7. Recognize early cues of sepsis, escalate promptly and carry out first-hour nursing care consistent with the 2026 Surviving Sepsis Campaign guideline.
8. Distinguish RN and RPN roles in infection and sepsis care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 5	Clinician; Scholar	Foundations of Practice
3, 4	Clinician; Leader; Advocate	Foundations of Practice; Professional Practice
6	Educator; Leader	Foundations of Practice; Collaborative Practice
7, 8	Clinician; Coordinator; Communicator	Foundations of Practice; Collaborative Practice; Accountability

Introduction

Infection is one of the most common complications on a medical-surgical unit. Patients arrive already ill, many are older adults, and most receive treatments that break the body's defences: surgery, intravenous (IV) catheters, urinary catheters, drains and medications that suppress immunity. A **health care-associated infection (HAI)** is an infection a person acquires while receiving health care (Provincial Infectious Diseases Advisory Committee [PIDAC], 2025). In a 2024 point prevalence survey of adult inpatients in 62 acute care hospitals in the Canadian Nosocomial Infection Surveillance Program, 8.1% of patients had at least one HAI on the survey day, almost unchanged from 8.4% in 2017 (Mitchell et al., 2025).

Nurses are at the bedside when infection begins. They clean their hands, choose protective equipment, care for devices and wounds, and notice the first cues: a warm, swollen incision, a new fever, a patient who is "not himself." Early recognition matters because an infection that is missed can progress to sepsis, a life-threatening emergency covered in section 4.6.

This chapter begins with inflammation and healing (section 4.1), then covers recognizing infection and its diagnostics (section 4.2) and infection prevention and control on the unit (section 4.3). Later sections address antibiotic-resistant organisms and *Clostridioides difficile*, antimicrobial stewardship and sepsis.

4.1 Inflammation and Healing

The Acute Inflammatory Response

Inflammation is the body's protective response to tissue injury or infection. It brings fluid, proteins and white blood cells to the injured area, contains and removes the cause, and prepares the tissue for repair. Microorganisms, surgery, trauma, burns, loss of blood supply and chemicals can all start it. This section covers only the innate (non-specific) response; immunity is covered in Chapter 21.

The response follows a similar sequence whatever the trigger. Receptors on cells detect damaged tissue or microbes, signalling pathways switch on, chemical messengers are released, and white cells are drawn to the site (Chen et al., 2018).

Vascular phase. Small blood vessels near the injury widen, so more blood flows to the area. The walls of the smallest vessels then become leaky. Plasma, proteins and fluid move out into the tissue, forming an **exudate** (Chen et al., 2018). The extra blood flow causes redness and heat; the leaked fluid causes swelling.

Cellular phase. White cells leave the bloodstream through the vessel walls and move toward the injury, following chemical signals. Neutrophils arrive first, followed by monocytes, which mature into macrophages in the tissue; lymphocytes and mast cells follow (Chen et al., 2018). Neutrophils and macrophages engulf and destroy microbes and dead cells. Pus is a thick exudate made of these cells, debris and microbes.

Figure 4.1 Cellulitis of the toes and forefoot. Spreading redness and swelling are local signs of inflammation and infection; on darker skin, redness can be harder to see, so the nurse also checks warmth, swelling and pain.

Chemical mediators. Mast cells release histamine and prostaglandins, which widen vessels and increase their leakiness. Immune cells release **cytokines**, small proteins that carry signals between cells. Some cytokines, such as interleukin-1β, interleukin-6 and tumour necrosis factor-α, promote inflammation; others damp it down (Chen et al., 2018). When cytokines reach the bloodstream in large amounts, they produce whole-body effects.

Local and Systemic Signs

The local signs of inflammation are redness, heat, swelling, pain and loss of function (Chen et al., 2018). Redness is harder to see on darker skin. On many skin tones, inflammation does not look red, so the nurse looks for any change from the surrounding skin or the same area on the other side and relies on warmth, swelling, skin tightness and pain (Wounds International, 2023). Warmth is felt by comparing the area with nearby skin, using the same hand. Good lighting and asking the patient what is normal for their skin help on every skin tone (Figure 4.1).

Systemic signs appear when inflammation is widespread or caused by infection. They include fever, a raised white cell count, malaise, fatigue and loss of appetite. The blood also contains more acute-phase proteins, such as C-reactive protein (Chen et al., 2018; see section 4.2). Table 4.1 summarizes these signs and what the nurse assesses.

Table 4.1 Local and systemic signs of inflammation and infection (BC Provincial Nursing Skin and Wound Committee, 2011; Chen et al., 2018; Evans et al., 2015; High et al., 2009; Wounds International, 2023)

Sign	What causes it	What the nurse assesses and documents
Redness (erythema)	Widened vessels bring more blood to the area	Colour compared with surrounding skin and the other side; on darker skin, any change in colour rather than redness; size of the affected area and whether it is spreading

Sign	What causes it	What the nurse assesses and documents
Heat	Increased blood flow to the area	Warmth compared with nearby skin and the other side, using the same hand
Swelling (edema)	Fluid and proteins leak from vessels into the tissue	Size or limb circumference, tightness, shine, firmness; change since the last assessment
Pain or tenderness	Chemical mediators and swelling stimulate nerve endings	Pain score, location and character; pain that is new or increasing rather than settling
Loss of function	Pain and swelling limit movement and use	Range of motion, ability to bear weight or use the limb, effect on mobility and self-care
Drainage (exudate)	Fluid, cells and debris leave the tissue; pus contains white cells and microbes	Amount, colour, consistency and odour; type (serous, bloody, purulent); drainage from incisions or drains
Fever	Cytokines raise body temperature as part of the response	Temperature, route, time and trend; recent antipyretic doses; comparison with the patient's baseline
Raised white cell count	Bone marrow releases more white cells, mostly neutrophils	White cell count and differential, and the trend over days
Malaise, fatigue, poor appetite	Circulating cytokines affect the whole body	Energy, intake, ability to do usual activities; in older adults, new confusion, falls or functional decline
Faster heart and breathing rates	Fever and infection raise the body's demand for oxygen	Vital signs trend; new or worsening changes, which may signal sepsis (section 4.6)

Acute and Chronic Inflammation

Acute inflammation is short-lived. Neutrophils dominate, the cause is removed, and the response switches off as neutrophils leave and macrophages shift from attacking to repairing (Chen et al., 2018). **Chronic inflammation** persists when the cause is not removed or the response fails to switch off. Macrophages and lymphocytes dominate, and ongoing damage and scarring can follow. Uncontrolled acute inflammation can become chronic and contribute to many chronic diseases (Chen et al., 2018), such as rheumatoid arthritis (Chapter 34) and wounds that fail to heal (Chapter 35).

Phases of Wound Healing

Wound healing has four overlapping phases, which must occur in the right order and time frame (Guo & DiPietro, 2010):

- **Hemostasis:** injured vessels constrict, platelets clump, and a fibrin clot seals the wound.
- **Inflammation:** neutrophils and then macrophages clear bacteria and debris; macrophages also release signals that start repair.
- **Proliferation:** fibroblasts lay down new collagen, new capillaries grow, and moist red granulation tissue fills the wound. Skin cells move across the surface, and the wound edges pull together.
- **Maturation (remodelling):** collagen is reorganized and the scar strengthens, flattens and fades over months.

In a closed surgical incision, a **healing ridge** is a normal sign of the proliferation phase. It is a firm, slightly swollen area under the incision line caused by new collagen. It starts on about postoperative days 2 to 4, should run the full length of the incision by days 5 to 9, and gradually softens and flattens over the following weeks (BC Provincial Nursing Skin and Wound Committee, 2011). A missing ridge is a warning sign, because it can be followed by separation of the incision (dehiscence) or infection (BC Provincial Nursing Skin and Wound Committee, 2011).

Healing by Primary, Secondary and Tertiary Intention

- **Healing by primary intention:** the wound edges are brought together with sutures, staples or tape, and the wound heals without needing to fill with granulation tissue, as in most surgical incisions.
- **Healing by secondary intention:** the edges cannot be closed, so the wound heals by filling with granulation tissue from the base up, as in a pressure injury or an opened, infected incision. Healing takes longer and leaves a larger scar.

- **Healing by tertiary intention (delayed primary closure):** the wound is left open for about 4 to 6 days, then closed before granulation tissue forms. Surgeons use it most often for contaminated or infected wounds (BC Provincial Nursing Skin and Wound Committee, 2011).

Factors That Delay Healing

Many factors can disturb one or more phases of healing (BC Provincial Nursing Skin and Wound Committee, 2011; Guo & DiPietro, 2010):

- **Diabetes:** high blood glucose impairs white cell function and circulation (Chapter 22).
- **Poor nutrition:** healing depends on protein and energy; one Canadian guideline notes that healing is impaired when serum albumin is below 35 g/L (BC Provincial Nursing Skin and Wound Committee, 2011; Chapter 24).
- **Smoking:** reduces oxygen delivery to the wound.
- **Older age:** healing is slower, and older adults more often have other conditions that delay it.
- **Medications:** systemic corticosteroids, nonsteroidal anti-inflammatory drugs, antineoplastic drugs and anticoagulants.
- **Other factors:** infection, poor blood flow or oxygenation, anemia, obesity, poor mobility, and long surgery or heavy blood loss.

The nurse identifies these factors on admission and before surgery and plans care to reduce them. Wound assessment and care are covered in Chapter 35.

4.2 Infection: Recognition and Diagnostics

The Chain of Infection

An **infection** occurs when microorganisms enter the body's tissues and multiply there (PIDAC, 2025). A person can also carry an organism that grows on or in the body without invading tissue or causing illness, which is called **colonization** (PIDAC, 2025); colonized patients can still spread the organism to others.

The **chain of infection** (also called the chain of transmission) is a model of how infection spreads. Transmission happens only when all six links are present, so breaking any one link stops it (PIDAC, 2025). The links and the nurse's actions are:

- **Infectious agent:** bacteria, viruses, fungi or parasites. The nurse helps identify the agent early with correct specimens and gives treatment as ordered.
- **Reservoir:** where the agent lives and multiplies, such as people, equipment, surfaces or water. The nurse cleans shared equipment, supports environmental cleaning, and stays home when ill.
- **Portal of exit:** how the agent leaves the reservoir, such as respiratory secretions, stool, blood or wound drainage. The nurse covers draining wounds, contains body fluids and teaches respiratory etiquette.
- **Mode of transmission:** how the agent travels, by contact, droplets or the airborne route. Hand hygiene, personal protective equipment and additional precautions break this link (section 4.3).
- **Portal of entry:** how the agent enters a new host, such as broken skin, mucous membranes or invasive devices. The nurse uses aseptic technique, cares for devices and asks daily whether each device is still needed. A Choosing Wisely Canada nursing recommendation warns against inserting or keeping an indwelling urinary catheter without daily assessment (Canadian Nurses Association, 2024).
- **Susceptible host:** a person who cannot resist the agent. The nurse supports immunization, nutrition, mobility, skin integrity and blood glucose control.

Host Risk Factors in Hospital

Patients on medical-surgical units are susceptible for several reasons:

- **Invasive devices:** IV and central venous catheters, urinary catheters, drains and breathing tubes bypass the skin and mucous membranes. In the Canadian surveys, bloodstream infections increased between 2017 and 2024, and central line-associated bloodstream infections roughly doubled (Mitchell et al., 2025).

- **Surgery:** an incision breaks the skin, and anesthesia and immobility raise the risk of pneumonia and urinary tract infection (Chapter 7).
- **Immunosuppression:** chemotherapy, corticosteroids, transplant medications, human immunodeficiency virus (HIV) infection and some chronic illnesses blunt the body's defences (Chapters 9 and 21).
- **Older age:** older adults often have several chronic conditions and may show infection differently. In one study of adults with bacteremia (bacteria in the blood), atypical symptoms such as new confusion, falls or declining function became more common with age (Wester et al., 2013).

Fever

Fever is a rise in body temperature that is a core part of the body's response to infection; cytokines such as interleukin-6 help trigger it (Evans et al., 2015). There is no single threshold used everywhere; hospital policy sets the value that triggers action. A guideline for evaluating new fever in critically ill adults suggests oral or rectal temperatures over less reliable sites, such as axillary, tympanic or temporal artery readings, when no central temperature device is in place (O'Grady et al., 2023). Older adults may not mount a high fever. A guideline for older adults in long-term care defines fever as a single oral temperature above 37.8 °C, repeated oral temperatures above 37.2 °C or rectal temperatures above 37.5 °C, or a rise of more than 1.1 °C above the person's baseline (High et al., 2009).

Antipyretics such as acetaminophen and ibuprofen lower temperature. A patient who received one for pain may have a normal temperature despite infection. The nurse checks the medication record when interpreting a temperature, and remembers that the absence of fever does not rule out infection.

Specimen Collection for Cultures

A **culture** grows organisms from a specimen so the laboratory can identify them and test which antimicrobials work against them (culture and sensitivity). The nurse collects specimens with aseptic technique, labels them at the bedside, and sends them promptly. When possible, cultures are collected before the first antimicrobial dose, as long as this does not delay treatment (Figure 4.2).

- **Blood cultures:** for an adult with suspected bacteremia, at least two sets are collected from separate sites (Alberta Precision Laboratories, 2024; O'Grady et al., 2023). Drawing from two sites helps the laboratory tell skin contamination from true infection, and the volume of blood is the most important factor in detecting bacteria (Alberta Precision Laboratories, 2024). In suspected sepsis, blood cultures are collected promptly, preferably before the first antimicrobial dose (Prescott et al., 2026). The nurse follows the hospital's skin antisepsis and bottle-filling procedure.
- **Urine from an indwelling catheter:** the nurse cleans the sampling port, clamps the tubing below it briefly, and withdraws urine from the port with a syringe. Urine is never taken from the drainage bag, and the closed drainage system is not opened (Alberta Precision Laboratories, n.d.).
- **Wound swabs:** a swab for culture is taken as ordered when a wound shows three or more signs of infection or is not improving with treatment (BC Provincial Nursing Skin and Wound Committee, 2011, 2015). In the Levine technique, the nurse cleanses the wound thoroughly with sterile normal saline or sterile water, then rotates the swab for 5 seconds over a 1 cm^2 area of viable (living) wound bed, pressing hard enough to draw out tissue fluid. Pus, slough and dead tissue are not swabbed because they can give misleading results; if no viable tissue is visible, the nurse does not take the swab and consults the prescriber or wound clinician (BC Provincial Nursing Skin and Wound Committee, 2015).
- **Stool for C. difficile:** only unformed stool is tested (PIDAC, 2013b; see section 4.4).

Blood Tests

- **White blood cell count and differential:** a typical adult reference range is 3.5 to 10.5 × 10^9/L, with segmented neutrophils 2.0 to 7.5 × 10^9/L (University of Ottawa, 2022); ranges vary by laboratory. Bacterial infection often raises the neutrophil count, sometimes with more immature band forms. A low count can also signal severe infection or a weakened immune system.
- **C-reactive protein (CRP):** an acute-phase protein whose blood level rises with inflammation (Chen et al., 2018). It is not specific to infection, so the trend over time is more useful than a single value.

- **Procalcitonin:** a blood marker of bacterial infection. For critically ill adults, a guideline suggests measuring it alongside clinical assessment when the likelihood of bacterial infection is low to intermediate, and supports using biomarkers to help decide when antibiotics can be stopped (O'Grady et al., 2023). Current sepsis guidelines suggest that clinicians decide whether to start antimicrobials on clinical evaluation rather than procalcitonin (Prescott et al., 2026).
- **Lactate:** a marker of tissue hypoxia and organ dysfunction, central to sepsis screening (section 4.6; acid–base in Chapter 3, section 3.7).

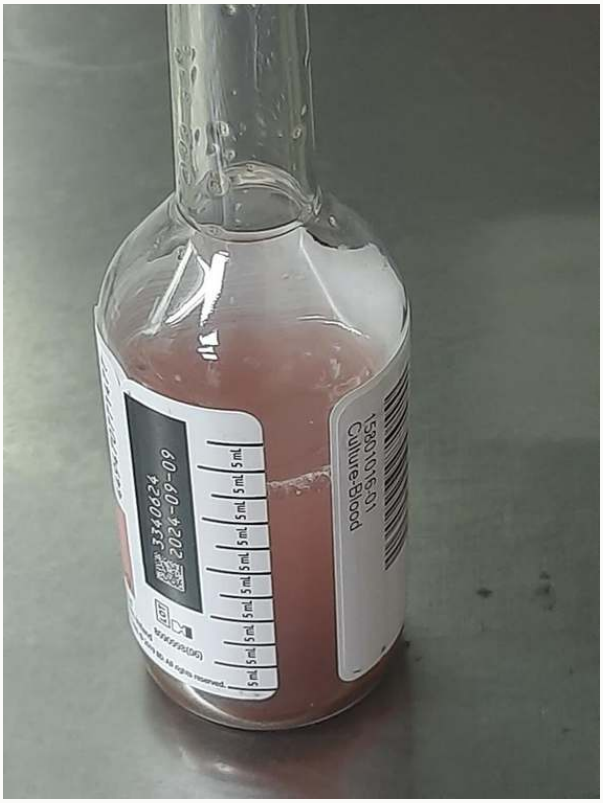

Figure 4.2 A blood culture bottle that has turned cloudy because organisms are growing in it. The laboratory then identifies the organism and tests which antimicrobials work against it.

CLINICAL JUDGMENT

A Surgical Site Infection on Postoperative Day 4

Mrs. Lucia Mendes, 67, has type 2 diabetes and is on postoperative day 4 after an open bowel resection. She has medium-brown skin.

Recognize cues: At 0800 her temperature is 38.4 °C (37.0 °C yesterday), heart rate 104, respiratory rate 20, blood pressure 128/76 (her baseline) and oxygen saturation (SpO2) 96% on room air. She is alert and oriented. Incision pain is 6/10, up from 3/10. The skin along the lower third of the incision is a deeper brown than the surrounding skin, swollen, firm, tight and warmer than the upper incision. Cloudy, yellow, foul-smelling drainage stains the dressing. White blood cell count is 13.8 × 10^9/L (9.2 × 10^9/L on day 2); capillary glucose is 12.4 mmol/L.

Analyze cues: Local signs (colour change, warmth, swelling, purulent drainage, rising pain) plus systemic signs (fever, rising heart rate and white cell count) point to infection. A healing ridge would be firm but would not drain pus or worsen.

Prioritize hypotheses: A surgical site infection is most likely. Early sepsis must be considered because her heart rate and temperature are rising. High glucose may slow healing.

Generate solutions: Report promptly to the surgeon using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6); request orders for a wound swab, blood cultures and antibiotics; screen for sepsis using the hospital's tool; increase vital sign frequency.

Take action: The nurse reports, collects the wound swab and blood cultures as ordered, then gives the first antibiotic dose without delay. The nurse applies a dry dressing as ordered and reports the glucose.

Evaluate outcomes: Four hours later, temperature is 37.9 °C, heart rate 96 and mentation unchanged. The nurse documents the extent of the colour change and plans to escalate at once if blood pressure falls, breathing quickens or confusion appears.

4.3 Infection Prevention and Control on the Unit

Routine Practices

Routine practices are the infection prevention and control (IPAC) practices used with every patient, during all care, whether or not an infection is known or suspected. They are the minimum standard for all patients (Public Health Ontario [PHO], n.d.-c). Chapter 1, section 1.6, introduced them; this section covers them in full. PIDAC (2025) groups routine practices into five elements:

- **Risk assessment** before each interaction with a patient or the patient's environment.
- **Hand hygiene.**
- **Personal protective equipment (PPE).**
- **Control of the environment:** patient placement, cleaning, and engineering controls such as sinks, hand rub dispensers and ventilation.
- **Administrative controls:** policies and procedures, education for staff, healthy workplace policies (such as staying home when ill and staff immunization), respiratory etiquette, and monitoring compliance with feedback.

Point-of-Care Risk Assessment

A **point-of-care risk assessment (PCRA)** is the quick check a health care provider makes before every interaction to judge the risk of spreading or acquiring infection, and to choose the right actions. It considers the task, the patient and the environment. The risk can change during care, so the assessment is repeated as care goes on (PIDAC, 2025). Before entering, the nurse asks:

- Will my hands, skin or clothing touch blood, body fluids, secretions, excretions, non-intact skin, mucous membranes or contaminated equipment or surfaces?
- Could the task cause splashes or sprays?
- Does the patient have signs of a possible infection, such as new cough, fever, diarrhea, vomiting, rash or draining wounds?
- Could the patient be carrying an antibiotic-resistant organism?
- Can the patient follow hand hygiene and respiratory etiquette?

The answers decide which PPE to wear, where the patient should be placed, and whether additional precautions are needed. Published tables list the minimum precautions for each condition; the PCRA can call for more (PIDAC, n.d.).

Hand Hygiene

Hand hygiene is removing or killing microorganisms on the hands, with alcohol-based hand rub (ABHR) or with soap and running water. It is central to every other routine practice. Ontario's Ministry of Health launched the Just Clean Your Hands program for hospitals in 2008 (PHO, n.d.-b). It teaches four moments for hand hygiene (Ontario Ministry of Health and Long-Term Care, 2011; Figure 4.3):

- **Moment 1, before initial contact with the patient or the patient's environment:** on entering, before touching the patient or anything around them. This protects the patient from organisms on the provider's hands.
- **Moment 2, before an aseptic procedure:** immediately before tasks such as changing a dressing, providing mouth care, drawing blood or giving IV medication. This protects the patient from organisms, including their own, entering the body.
- **Moment 3, after a risk of body fluid exposure:** immediately afterward, including after removing gloves. This protects the provider and the health care environment.
- **Moment 4, after contact with the patient or the patient's environment:** on leaving. This protects the provider and the next patient.

ABHR is the preferred method when hands are not visibly soiled (PIDAC, 2025). It works quickly and can be placed at the point of care. Soap and water is needed when hands are visibly soiled. It is also preferred after caring for a patient with *C. difficile* infection when a dedicated staff sink is immediately available, because soap and water is thought to remove the bacterium's spores better than ABHR; if no staff sink is close by, ABHR is used after glove removal. Hand hygiene is never done at the patient's sink (PIDAC,

2013b; see section 4.4). Gloves never replace hand hygiene. The nurse also helps patients clean their hands, for example before meals and after using the toilet.

Figure 4.3 A wall-mounted alcohol-based hand rub dispenser in a hospital in the United States. (credit: "Purell hand sanitizer device at Memorial Regional Hospital" by Claudia Brauer/Wikimedia Commons, CC BY 2.0)

Personal Protective Equipment

Personal protective equipment (PPE) is clothing and equipment that act as a barrier between the provider and infectious material. The PCRA guides the choice. PPE is put on just before the interaction and removed promptly afterward (PIDAC, 2025).

- **Gloves:** worn when hands may touch blood, body fluids, mucous membranes, non-intact skin or contaminated items. Gloves are single-use and specific to one task. They are changed between tasks on the same patient, such as moving from a soiled to a clean site.
- **Gowns:** worn when splashes or sprays are likely or when clothing may touch the patient or contaminated surfaces. A gown should have long sleeves with cuffs and be tied at the neck and waist (PIDAC, 2025).
- **Facial protection:** a mask with eye protection (goggles, a face shield or a mask with a visor) protects the mucous membranes of the eyes, nose and mouth during tasks likely to splash, such as suctioning. It is also worn within 2 metres of a coughing patient. Prescription glasses alone are not eye protection (PIDAC, 2025).
- **N95 respirator:** a close-fitting respirator that filters 95% of particles about 1 micron in size. It protects the wearer from breathing in small infectious particles (PIDAC, 2025). Each provider must be fit-tested at least every two years, and again if the face piece or the person's face changes. The wearer does a seal check every time it is put on (PIDAC, 2025; PHO, 2024).

CLINICAL SAFETY

Removing PPE Safely

Taking PPE off is the moment of highest risk. The outside of gloves, gown, eye protection and mask may be contaminated, and a hurried or out-of-order removal can transfer organisms to the nurse's skin, face or clothing. PIDAC (2025) calls for removal to follow a formal protocol exactly. Public Health Ontario's recommended sequence (PHO, 2024) is:

- **Gloves first:** remove them without letting bare skin touch the outside of the glove.
- **Gown:** untie, pull it away from the body, roll it inside out and discard it.
- **Hand hygiene.**
- **Eye protection:** remove it by lifting it up and away from the face without touching the front.
- **Mask or N95 respirator:** remove it by the ear loops or straps, pulling forward and away from the face.
- **Hand hygiene** again.

When only gloves and a gown are worn, as for contact precautions, hand hygiene follows removal of the gown (PHO, 2024). Hand hygiene uses ABHR, or soap and water if hands are visibly soiled. Each item goes straight into the correct waste or reprocessing container. The nurse follows the hospital's posted sequence and location for removal, which may differ for an N95 respirator.

Additional Precautions

Additional precautions are measures used on top of routine practices for certain organisms or clinical presentations (PIDAC, 2025). The three types are contact, droplet and airborne precautions, and some infections need a combination. Precautions start as soon as an infection is suspected from the patient's symptoms, not when test results return. For example, contact precautions begin at the

onset of diarrhea, before *C. difficile* results are known (PIDAC, 2013b). A sign at the door tells everyone entering what is required. Table 4.2 compares the precautions.

- **Contact precautions** reduce spread by direct contact with the patient or indirect contact with the patient's surroundings and equipment. They are used for antibiotic-resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE) and carbapenemase-producing Enterobacterales (CPE), covered in section 4.4.
- **Droplet precautions** are for organisms spread by large respiratory droplets, produced by coughing or sneezing, which travel a short distance before falling.
- **Airborne precautions** are for organisms carried on very small particles that stay suspended in the air and can travel on air currents (PIDAC, 2025).
- **Droplet and contact precautions** combine all elements of both, for organisms such as common respiratory viruses that spread by droplets and by contaminated hands and surfaces (PHO, n.d.-a).

Table 4.2 Additional precautions compared (PHO, n.d.-a; PIDAC, 2025, n.d.)

Precaution	How the organism spreads	Examples	Room	PPE and key actions
Contact	Direct contact with the patient, or indirect contact with contaminated surfaces and equipment	MRSA, VRE, CPE, C. difficile, norovirus, acute infectious gastroenteritis	Single room (with own toilet for diarrhea), or shared with patients who have the same laboratory-confirmed organism	Gown and gloves on entering; dedicated equipment; enhanced cleaning for C. difficile and VRE
Droplet	Large respiratory droplets travel a short distance (within about 2 metres) and land on mucous membranes	Pertussis, invasive meningococcal disease, mumps	Single room, or at least 2 metres from others with the curtain drawn	Mask and eye protection within 2 metres; dedicated equipment; patient wears a mask outside the room
Droplet and contact	Droplets plus contaminated hands, surfaces and equipment	Influenza, respiratory syncytial virus, COVID-19, invasive group A streptococcal wound infection	Single room	All droplet and contact elements combined: gown, gloves, mask and eye protection
Airborne	Small particles stay suspended in the air and travel on air currents	Pulmonary tuberculosis, measles, chickenpox, disseminated shingles (measles also needs droplet and contact precautions; chickenpox and disseminated shingles also need contact precautions)	Airborne infection isolation room (negative pressure) with the door kept closed	Fit-tested, seal-checked N95 respirator (for measles, also gloves, gown and eye protection); only staff with presumptive immunity care for patients with measles, chickenpox or disseminated shingles; patient wears a mask outside the room

An **airborne infection isolation room (AIIR)**, also called a negative pressure room, is designed and ventilated to keep airborne organisms from spreading beyond it (PIDAC, 2025). When airborne spread is suspected, the patient moves as soon as possible to a single room, ideally a negative pressure room (PIDAC, 2025).

Visitors receive teaching on hand hygiene. Visitors who help with care follow the same precautions as staff (PIDAC, 2013b). Additional precautions can leave patients feeling lonely or stigmatized. The nurse explains why the precautions are needed, keeps the call bell in reach, and checks on the patient as often as on any other patient. Precautions stop only when the criteria for the organism are met, in consultation with the IPAC team.

Cleaning the Environment and Shared Equipment

Organisms survive on bed rails, call bells, commodes, vital sign machines and glucometers, so the environment is a reservoir. Control of the environment is one of the five elements of routine practices (PIDAC, 2025). Shared equipment is cleaned and disinfected between patients with a hospital-approved product, following the manufacturer's instructions and hospital policy. Patients

on contact precautions have dedicated equipment that stays in the room. Rooms of patients with *C. difficile* or VRE need enhanced cleaning (PIDAC, 2025). For *C. difficile*, PIDAC recommends a sporicidal agent, cleaning twice daily, and double cleaning at discharge or transfer (PIDAC, 2013b). Nurses work with environmental services staff, report spills and soiled items promptly, and never move used equipment from one room to another without cleaning it.

Outbreaks and the Nurse's Role

An **outbreak** is a rise in cases of an infection above what is expected in a particular place and time. Each infection has its own outbreak definition. In Ontario, for example, a confirmed respiratory infection outbreak in a public hospital is defined as two or more patients with health care-associated, test-confirmed acute respiratory infection whose symptoms began within 48 hours of each other and who share an epidemiological link (for example, the same unit) that suggests spread within the hospital. Cases among staff alone do not make an outbreak. Either the hospital or the medical officer of health can declare an outbreak (Ontario Ministry of Health, 2024).

The nurse's role is to:

- **Recognize:** notice clusters, such as two patients on the same unit with new diarrhea or a new cough, or several staff members ill with similar symptoms.
- **Act and report:** start additional precautions based on symptoms, collect specimens as ordered, and report promptly to the charge nurse and the IPAC team.
- **Follow outbreak measures:** the IPAC team and public health may direct measures such as stricter precautions, cohorting, closing the unit to admissions, limiting visits, or enhanced cleaning. The nurse follows them consistently and explains them to patients and families.
- **Protect others:** stay home when ill and report symptoms to occupational health.

> CANADIAN CONTEXT
>
> **Reportable Diseases and Outbreaks in Ontario**
>
> In Ontario, the *Health Protection and Promotion Act* and its regulations require reports of certain infections to the medical officer of health for the area. Ontario Regulation 135/18 lists these designated **diseases of public health significance**. Examples are tuberculosis, measles, CPE and invasive group A streptococcal disease. The list also includes outbreaks of respiratory infection and of gastroenteritis in institutions and public hospitals, and *C. difficile* outbreaks in public hospitals (Peel Region, n.d.).
>
> Public health unit guidance names laboratories, physicians, and the administrators of hospitals, schools and institutions among those who must report suspected or confirmed cases (Middlesex-London Health Unit, 2026). Some diseases must be reported immediately; others by the next working day (Peel Region, n.d.). Each hospital's policy sets out how it meets its reporting duties and how it works with the local public health unit during an outbreak. A nurse who suspects a reportable disease or a cluster tells the charge nurse and the IPAC team at once and follows that policy. Each province and territory has its own public health law and list of reportable diseases; nurses learn the rules where they work.

4.4 Antibiotic-Resistant Organisms and C. difficile

Some bacteria survive the drugs meant to kill them. An **antibiotic-resistant organism (ARO)** is a microorganism that has changed so that one or more antibiotics that once treated it no longer work well against it. Resistance spreads mainly through the overuse and misuse of antimicrobial drugs, because each exposure gives resistant strains an advantage over susceptible ones. Infections caused by AROs are linked to longer hospital stays, more complications and more deaths (Canadian Nurses Association [CNA], n.d.; Public Health Agency of Canada [PHAC], 2017).

A person can carry an ARO on the skin, in the nose or in the bowel without being ill. This is colonization (section 4.2); when the organism invades tissue and causes illness, the person has an infection. The difference matters for care: a colonized patient has no symptoms but can still pass the organism to others, so the same precautions apply to both (PIDAC, 2013a).

Three Organisms to Know

- **Methicillin-resistant Staphylococcus aureus (MRSA):** a strain of *S. aureus* that resists methicillin and related beta-lactam antibiotics. It lives on the skin and in the front of the nose. In hospitals it travels mainly on the briefly contaminated hands of health care workers, and on shared equipment and surfaces (Canadian Nosocomial Infection Surveillance Program [CNISP], 2026; PIDAC, 2013a).
- **Vancomycin-resistant enterococci (VRE):** enterococci are bowel bacteria; VRE no longer respond to vancomycin. The patient's bowel is the main reservoir, and the room becomes more heavily contaminated when the patient has diarrhea (PIDAC, 2013a).
- **Carbapenemase-producing organisms (CPO):** bacteria that make carbapenemases, enzymes that make carbapenem antibiotics ineffective, which leaves few treatment options. The best-known group is the **carbapenemase-producing Enterobacterales (CPE)**, which colonize the lower bowel. CPE spread by direct and indirect contact, and sinks and drains have been the source of some hospital outbreaks (CNISP, 2026; PIDAC, 2013a).

The key features of each organism, and of *C. difficile*, are compared in Table 4.3.

What Canadian Surveillance Shows

The **Canadian Nosocomial Infection Surveillance Program (CNISP)**, run by PHAC with sentinel hospitals across the country, tracks healthcare-associated infections and resistance. Its most recent report covers 2020 to 2024, with 109 sentinel acute care hospitals taking part across 10 provinces and 1 territory. Over those five years, rates of MRSA bloodstream infection and *C. difficile* infection stayed stable. Rates of VRE bloodstream infection rose significantly, from 0.30 to 0.42 per 10,000 patient days. Carbapenemase-producing Enterobacterales infections remained uncommon but rose significantly, from 0.05 to 0.20 per 10,000 patient days, with yearly cases climbing from 39 to 218 (CNISP, 2026). These figures describe participating hospitals, not every hospital in Canada.

Screening on Admission

Many hospitals screen patients for AROs on admission. Screening usually targets risk factors such as a previous positive result, a stay in any health care facility within the past year, health care received outside Canada, transfer from another facility, or contact with a unit having an outbreak (PIDAC, 2013a). MRSA screening uses swabs of the nose and the perianal or groin area, plus any wounds or device sites; VRE and CPE screening uses a rectal swab or stool. Who is screened, which organisms are included and when precautions start are set by each hospital's IPAC team, so the nurse follows local policy. A patient at high risk may be placed on Contact Precautions while results are pending. Contact Precautions and personal protective equipment are taught in section 4.3. Patients with CPE need a single room with their own toilet or commode and dedicated equipment (PIDAC, 2013a).

Clostridioides difficile Infection

Clostridioides difficile (often shortened to *C. difficile*) is a gram-positive, anaerobic bacterium that releases toxins in the colon. It is the most common cause of infectious diarrhea acquired in Canadian health care settings. Illness ranges from mild diarrhea to severe inflammation of the colon (pseudomembranous colitis), bowel perforation and sepsis (PHAC, 2013; Figure 4.4).

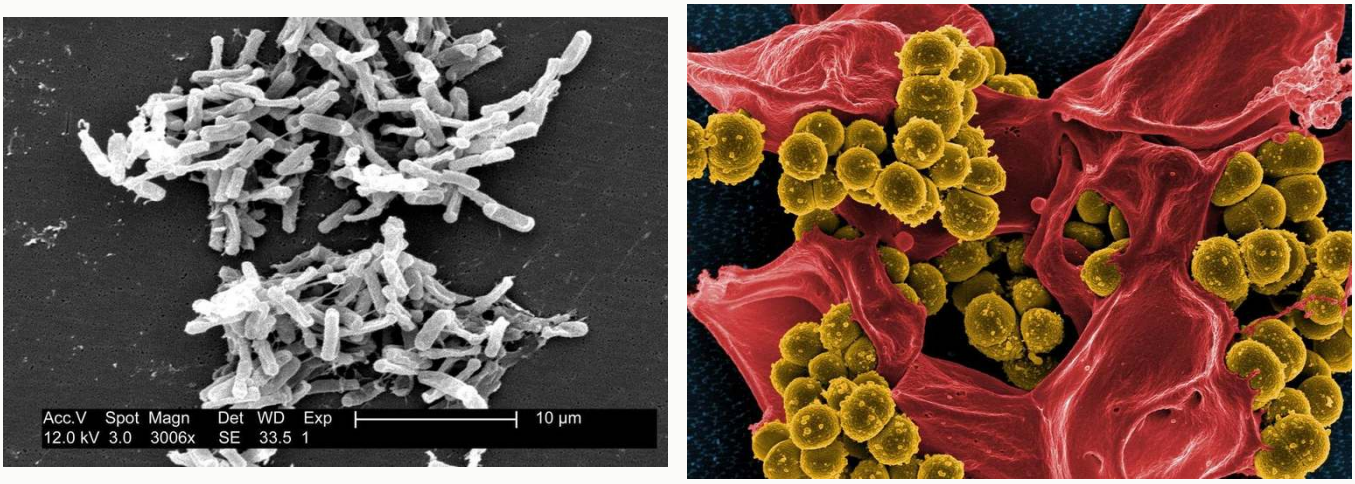

Figure 4.4 (a) *Clostridioides difficile* bacteria from a stool sample, seen with a scanning electron microscope. (b) Methicillin-resistant *Staphylococcus aureus* (MRSA, gold) and a dead human neutrophil (red), with colour added. (credit: (b) "Scanning electron micrograph of Methicillin-resistant Staphylococcus aureus (MRSA) and a dead Human neutrophil" by NIAID/Wikimedia Commons, CC BY 2.0)

The organism forms **spores**: dormant, thick-walled forms that survive for months on surfaces, resist many chemical disinfectants and become active again once swallowed. Spores move from patient to patient by the fecal–oral route, carried on hands and on contaminated equipment, bed rails and especially bathrooms (PHAC, 2013; PIDAC, 2013b).

Risk factors. Recent antibiotic use is the strongest risk factor, because antibiotics disturb the normal bowel bacteria that keep *C. difficile* in check. Other factors include proton pump inhibitors, hospitalization, chemotherapy, bowel disease or bowel surgery, and immune-suppressing drugs after transplant. Older age and a previous episode increase the risk of severe disease (PIDAC, 2013b).

Recognition and testing. For *C. difficile* testing, diarrhea means loose or watery stool that takes the shape of its container, is unusual for the patient and has no other likely cause, such as a laxative. The patient may also have fever, cramping, abdominal tenderness or nausea. The nurse sends a stool specimen as soon as diarrhea begins. Only unformed stool is tested; formed stool is not sent, and testing is not repeated to prove cure (PIDAC, 2013b).

Precautions. The nurse starts Contact Precautions at the first episode of unexplained diarrhea, without waiting for results. The patient needs a single room with a dedicated toilet, or a dedicated commode, and dedicated equipment such as a blood pressure cuff and stethoscope (PHAC, 2013). Hand hygiene changes: spores resist many chemicals, and soap and running water are preferred over ABHR because washing physically removes spores from the hands. The nurse removes gloves and washes at a staff sink, never the patient's sink. If no staff sink is close by, the nurse uses ABHR and then washes with soap and water as soon as a staff sink is available (PHAC, 2013; PIDAC, 2013b). Environmental services clean the room with a sporicidal agent, such as a chlorine-based product of 1,000 parts per million or more (PHAC, 2013; PIDAC, 2013b). Precautions usually continue until the patient has had no diarrhea for at least 48 hours and the room has had a final sporicidal cleaning, decided with IPAC (PIDAC, 2013b).

Nursing care. The nurse records the number, volume and character of stools and watches fluid balance, since diarrhea can quickly cause dehydration and potassium loss, especially in older adults (see Chapter 3). The perineal skin needs gentle cleansing after each stool and a barrier product to prevent breakdown. Disposable bedpans reduce spread. The nurse asks the prescriber to review antibiotics, proton pump inhibitors and any laxatives still ordered. Worsening abdominal pain or distension, high fever, a falling blood pressure or a sudden stop in diarrhea with a swelling abdomen can signal severe disease and need immediate escalation. Treatment and other bowel disorders are covered in Chapter 25.

Table 4.3 Common antibiotic-resistant organisms and C. difficile (PHAC, 2013; PIDAC, 2013a, 2013b)

Organism	How it spreads in hospital	Precautions	Nursing points
MRSA	Hands of staff after touching a colonized patient; shared equipment and surfaces	Contact Precautions; single room preferred	Screen as hospital policy directs (nose, perianal or groin, wounds); colonized patients can spread it without symptoms

Organism	How it spreads in hospital	Precautions	Nursing points
VRE	From bowel carriage to hands, equipment and surfaces; more spread when the patient has diarrhea	Contact Precautions; single room with own toilet or commode	Clean high-touch surfaces; take extra care with toileting and incontinence care
CPO (including CPE)	Direct and indirect contact from bowel carriage; sinks and drains have caused outbreaks	Contact Precautions; single room with own toilet or commode; dedicated equipment	Ask about health care received outside Canada; contacts may need screening; few antibiotics remain effective
C. difficile	Spores on hands, equipment and surfaces, mainly bathrooms; fecal–oral route	Contact Precautions from first diarrhea; dedicated equipment; sporicidal cleaning	Wash with soap and water at a staff sink; test only unformed stool; manage fluids and perineal skin

4.5 Antimicrobial Stewardship and the Nurse

Antimicrobial stewardship is the coordinated effort to use antimicrobial drugs only when they are needed, and then to choose the right drug, dose, route and duration. Its goals are better patient outcomes, fewer adverse drug reactions, fewer cases of *C. difficile* infection and slower growth of resistance (Alberta Health Services [AHS], n.d.). Every unnecessary course of antibiotics exposes the patient to side effects and gives resistant bacteria an advantage, as section 4.4 explains. Accreditation Canada lists an antimicrobial stewardship program as a required organizational practice for acute care sites (AHS, n.d.).

Stewardship is often pictured as the work of infectious disease physicians and pharmacists, but nurses give most doses, collect most specimens and spend the most time with patients. The CNA has published a pan-Canadian framework of stewardship competencies for all categories of nurses. It names roles such as monitoring for infection and side effects, acting as stewards of laboratory testing, recording allergies accurately, preventing infection and teaching patients (CNA, n.d.).

Before and at the First Dose

- **Collect cultures first, without causing delay.** When an infection is suspected, the nurse collects ordered cultures before the first dose whenever this can be done quickly. Antibiotics can sterilize a specimen within hours and hide the cause. In serious infection, the dose is not held back for a culture that cannot be collected promptly (Prescott et al., 2026).
- **Collect good specimens.** A contaminated blood culture or a urine sample sent without symptoms can lead to treatment the patient does not need. Careful technique and specimen collection only when indicated are part of stewardship (CNA, n.d.).
- **Give the first dose on time.** A first dose that waits on the unit for hours undoes the benefit of a fast diagnosis. This matters most in sepsis, where minutes count (section 4.6).

While the Patient Is on Antimicrobials

- **Monitor the response.** The nurse tracks temperature, heart rate, white blood cell count, wound or sputum changes and how the patient feels, and reports whether the patient is improving.
- **Watch for adverse effects.** Rash, new diarrhea, signs of *C. difficile* infection, infusion-site problems and changes in kidney function are reported promptly.
- **Prompt an IV-to-oral review.** A switch from intravenous to oral therapy shortens hospital stays and reduces catheter complications such as line infection and clots. Patients are usually candidates when they are afebrile, their white cell count is returning to normal, they are clinically improving and they can eat and absorb oral drugs (PHO, 2016). The nurse who notices these signs raises the question with the prescriber or pharmacist; some hospitals have approved criteria-based switch programs.
- **Ask about duration and results.** When culture results return, the nurse makes sure the prescriber has seen them so that therapy can be narrowed to target the organism. Guidelines favour narrowing treatment once the organism is known and, when the source is controlled, shorter courses over longer ones (Prescott et al., 2026). Asking "What is the planned stop date?" at rounds is a simple stewardship act.

Assessing a Reported Penicillin Allergy

Penicillin allergy labels are common in health records, and most do not hold up when they are assessed. The Ontario Medical Association's Section on Allergy states that more than 80% of people whose penicillin allergy is suspected may be safely delabelled (Ontario Medical Association [OMA], 2025). A wrong label pushes prescribers toward alternative antibiotics, and delabelling has been linked to less antibiotic resistance and fewer *C. difficile* infections (Atkinson et al., 2023).

The nurse's role is a careful history, not a judgment. An **allergy** is an immune reaction, such as hives, swelling of the lips or throat, wheezing or a severe skin reaction. An **intolerance** is an expected side effect, such as nausea, diarrhea, abdominal pain or headache. Side effects are not allergic reactions (OMA, 2025). The nurse asks:

- Which drug was it, and when?
- What exactly happened, how soon after the dose, and how was it treated?
- Has the patient taken a penicillin, such as amoxicillin, since then without trouble?
- Is the "allergy" really a family member's reaction?

The nurse documents the answers in the patient's own words and shares them with the prescriber or pharmacist. The nurse never removes or changes an allergy label alone. Delabelling is a decision made by a prescriber or an allergist, sometimes after a supervised oral challenge or skin testing, following hospital policy (OMA, 2025). Allergy and drug reactions are covered further in Chapter 21.

PATIENT EDUCATION

Taking Antibiotics Safely

- Antibiotics treat bacteria. They do not help colds, flu or most sore throats, which are caused by viruses.
- Take each dose at the times and for the number of days your prescriber or pharmacist tells you. Do not stop early or change the dose on your own. If you feel better and wonder whether you still need it, ask first.
- Never share antibiotics, and never take someone else's or an old leftover supply.
- Take unused antibiotics back to a pharmacy. Do not keep them or flush them.
- If you miss a dose, check the medication label or call your pharmacist. Do not take two doses at once unless you are told to.
- Call your health care provider if you get a rash, swelling, trouble breathing or any reaction that worries you. For trouble breathing or swelling of the face or throat, call 9-1-1.
- New watery diarrhea during or after a course of antibiotics needs a call to your provider.

Sources: PHAC (2014, 2017).

4.6 Sepsis

Sepsis is "life-threatening organ dysfunction caused by a dysregulated host response to infection" (Singer et al., 2016, p. 801). "Dysregulated" is the key idea: the body's own response to an infection, not only the microbe, injures organs far from the source (Singer et al., 2016). Sepsis can start from any infection, such as pneumonia, a urinary tract infection, a wound or an abdominal leak after surgery. It is a medical emergency, and the nurse is usually the first to see it.

Definitions

The Third International Consensus Definitions (Sepsis-3) set the current definitions (Singer et al., 2016):

- **Sepsis:** suspected or confirmed infection plus acute organ dysfunction, measured as a rise of 2 or more points in the **Sequential Organ Failure Assessment (SOFA) score**. In patients with suspected infection, this change carries an in-hospital mortality of about 10%.
- **Septic shock:** a subset of sepsis in which circulatory, cellular and metabolic changes are severe enough to raise the risk of death substantially. Clinically, the patient needs a vasopressor to keep the mean arterial pressure (MAP) at 65 mm Hg or higher and has a serum lactate above 2 mmol/L, even after adequate fluid resuscitation. More than 40% of these patients die in hospital.

Older definitions used the **systemic inflammatory response syndrome (SIRS)** criteria: abnormal temperature, fast heart rate, fast breathing and an abnormal white cell count. Sepsis-3 dropped SIRS as part of the definition. Many patients in hospital meet SIRS criteria without infection or poor outcomes, while some patients with infection and organ failure do not meet them (Singer et al., 2016). SIRS criteria may still help identify infection, and some hospitals use them in screening. The older term "severe sepsis" is no longer used.

Sepsis in Canada

Sepsis is a common contributor to death. A Statistics Canada analysis of death certificates found that in 2011 about 1 in 18 deaths in Canada involved sepsis, as either the underlying or a contributing cause. From 2009 to 2011, death rates involving sepsis rose with age and were highest in people 85 and older (Navaneelan et al., 2016). Because the analysis relied on codes for septicemia, the authors note it may undercount sepsis.

Who Is at Risk

Anyone with an infection can develop sepsis, but risk is higher with (Healthcare Excellence Canada [HEC], n.d.):

- older age (see the Lifespan Considerations box);
- chronic disease, with or without organ dysfunction;
- weakened immune defences, from disease or from immune-suppressing drugs;
- implanted or invasive devices, such as intravascular catheters;
- changes to normal anatomy that block a passage or breach a sterile body space, such as an obstructed urinary tract;
- pregnancy.

People who cannot describe their symptoms often present later in their illness (HEC, n.d.).

Structural factors also shape risk. Living far from hospital, as many people in rural, remote and northern communities do, including many First Nations and Inuit communities, can delay assessment and treatment. Barriers such as language, cost of travel and past experiences of racism in health care can delay a person from seeking care (see Chapter 2). The nurse takes a person's concern seriously at first contact.

Recognizing Sepsis Early

Sepsis rarely announces itself with one dramatic sign. More often, several small changes appear together over hours. Trends matter more than single values: a respiratory rate that climbs from 16 to 24 over a shift is a warning, even if no single reading looks alarming. The nurse compares each finding with the patient's own baseline and takes concerns from family members and colleagues seriously, because they often notice changes first. Table 4.4 links each cue to its meaning and to the nurse's action. Key cues include:

- **Temperature:** fever, or a low temperature; a low temperature is a sign of serious illness, not reassurance, and in septic patients it is linked to higher mortality than a normal temperature or fever (Rumbus et al., 2017).
- **Heart rate and breathing:** a rising heart rate and a rising respiratory rate. Respiratory rate is one of the qSOFA items (see Screening Tools) and is easy to overlook if it is not counted carefully.
- **Blood pressure:** a falling systolic pressure or MAP compared with the patient's baseline.
- **Mental status:** new confusion, drowsiness, agitation or "just not themselves," often reported first by family.
- **Skin and perfusion:** cool, clammy skin; slow capillary refill; mottling. **Mottling** is a patchy, lace-like discolouration that usually begins around the knees. On lighter skin it appears purple or blue; on darker skin it can be hard to see, and a study of mottling scores excluded patients with dark skin for that reason (Dumas et al., 2019). The nurse therefore does not rely on colour alone: they press the nail bed or fingertip to time capillary refill, feel whether the knees, hands and feet are cooler than the trunk, and compare findings with the patient's usual appearance and the family's observations.
- **Urine output:** low or falling output, a sign that the kidneys are underperfused.
- **Oxygenation:** falling oxygen saturation or a rising oxygen need.
- **Laboratory values:** a **lactate** level above 2 mmol/L (the reference range varies by laboratory), rising creatinine, a falling platelet count, or a white cell count that is high or low. Lactate and acid–base balance are taught in Chapter 3, section 3.7.

Sepsis is a clinical diagnosis. No single test rules it in or out (Prescott et al., 2026).

Screening Tools

Hospitals use screening tools to catch sepsis earlier, and Ontario hospitals use different ones. The **quick SOFA (qSOFA)** score gives one point each for a respiratory rate of 22 breaths per minute or more, altered mentation, and a systolic blood pressure of 100 mm Hg or less; two or more points flag a higher risk of a poor outcome (Singer et al., 2016). qSOFA is specific but not sensitive: in the original study only about one in four infected patients scored 2 or more, so many patients who were developing sepsis scored lower (Evans et al., 2021). For this reason, the Surviving Sepsis Campaign recommended against qSOFA as a single screening tool in 2021 (Evans et al., 2021). Its 2026 update, for acutely ill hospital patients, recommends screening with the National Early Warning Score (NEWS or NEWS2), the Modified Early Warning Score (MEWS) or SIRS in preference to qSOFA when one tool is used alone (strong recommendation, moderate certainty; Prescott et al., 2026). A positive qSOFA should still prompt assessment. Early warning scores are taught in Chapter 6.

First-Hour Care

Treatment follows the most recent Surviving Sepsis Campaign guideline (Prescott et al., 2026). The guideline grades a **strong** recommendation ("we recommend") as one most clinicians should follow, and a **conditional** recommendation ("we suggest") as one that depends on the patient and setting. The first steps the nurse will see and help deliver are:

- **Measure lactate.** The guideline suggests measuring blood lactate in possible, probable or definite sepsis, and in septic shock, and, when lactate is raised or the patient is in shock, using repeat measurements to guide resuscitation (both conditional, low certainty).
- **Blood cultures before antimicrobials.** Cultures are collected as soon as possible and, when it can be done, before the first antimicrobial dose (strong, low certainty). Collecting cultures must not delay the first dose.
- **Give antimicrobials quickly.** For septic shock, or probable or definite sepsis, antimicrobials are given at once, ideally within 1 hour of the team recognizing it (strong, very low certainty). When sepsis is only possible and the patient is not in shock, the team does a rapid, time-limited assessment and, if infection is still a concern, gives antimicrobials no later than 3 hours after sepsis was first suspected (conditional, very low certainty).
- **Fluids for low perfusion.** For sepsis-induced hypoperfusion (for example, low blood pressure or a high lactate) or septic shock, the guideline suggests at least 30 mL/kg of crystalloid, given intravenously, within the first 3 hours (conditional, low certainty), with frequent reassessment to avoid giving too little or too much. Crystalloids are recommended as first-line fluid (strong, moderate certainty), with balanced crystalloids suggested over 0.9% sodium chloride (conditional, moderate certainty). IV fluids are taught in Chapter 3, section 3.3.
- **Vasopressors if hypotension persists.** If blood pressure stays low after the first fluid bolus, vasopressors are started; the guideline recommends an initial MAP target of 65 mm Hg (strong, moderate certainty) and suggests 60 to 65 mm Hg for adults 65 and older (conditional, low certainty). Shock and vasopressors are taught in Chapter 6.
- **Find and control the source.** Draining an abscess, removing an infected device or repairing a leak is done early, ideally within 6 hours of diagnosis (conditional, very low certainty).

Nursing Priorities and Escalation

The Clinical Judgment Measurement Model (CJMM; Chapter 1, section 1.4) gives the nurse's thinking a clear shape. The nurse **recognizes** cues and trends, not single values; **analyzes** them by asking, "Could this be infection causing organ dysfunction?"; and **prioritizes** perfusion and oxygenation. **Generating solutions** and **taking action** mean escalating at once, through the rapid response team or the most responsible provider as hospital policy directs, using SBAR (see Chapter 6). They also mean preparing for cultures, lactate and IV access, and giving antimicrobials and fluids as soon as they are ordered or allowed by a medical directive. The nurse **evaluates** by reassessing vital signs, mental status, skin perfusion and urine output often. The nurse also listens for crackles and watches for rising work of breathing or falling oxygen saturation, which can mean fluid overload.

Documenting exact times matters: when sepsis was first suspected, when the provider was called, and when cultures, lactate, antimicrobials and fluids were given. Many hospitals audit these times. If the patient does not improve, or the response team's plan is

not working, the nurse escalates again. Early talk about goals of care, which the guideline suggests within 72 hours (conditional; Prescott et al., 2026), helps patients and families make informed choices (see Chapter 10).

Life After Sepsis

Surviving sepsis is often the start of a long recovery. About half of survivors recover fully or nearly fully. About one in six have severe, lasting physical or cognitive impairment, and about one in three die within the following year (Prescott & Angus, 2018). New problems are common: weakness and new limits in daily activities, memory and thinking problems, anxiety, depression and post-traumatic stress symptoms. About 40% of survivors are readmitted within 90 days, most often for another infection, heart failure or kidney problems (Prescott & Angus, 2018). Researchers use the term **post-sepsis syndrome** for this emerging pattern of lasting physical, cognitive and psychological effects, with a higher risk of death and poorer quality of life (Mostel et al., 2019).

Before discharge, the nurse:

- screens for new limits in mobility, swallowing, thinking and mood, and asks for referrals to physiotherapy, occupational therapy or speech-language pathology;
- supports medication reconciliation, so that hospital-only drugs stop and long-term drugs restart at the right doses;
- teaches the patient and family the signs of a new infection and when to seek care;
- explains in plain words what happened in hospital, and names sepsis on the discharge teaching, so the patient can tell future providers;
- arranges follow-up, with mental health and peer support where available.

The guideline also suggests offering follow-up services after critical illness, physical rehabilitation after discharge for survivors who needed prolonged mechanical ventilation, and services that support mental health after discharge (conditional, low certainty; Prescott et al., 2026).

Table 4.4 Sepsis: cues to recognize and first-hour nursing actions (Singer et al., 2016; Rumbus et al., 2017; Prescott et al., 2026)

What the nurse sees	Why it matters	Nursing action
Rising respiratory rate (22 breaths per minute or more)	A qSOFA item; may reflect acidosis, lung injury or poor perfusion; easy to miss	Count for a full minute; check oxygen saturation; screen for sepsis; escalate
New confusion, drowsiness or agitation	The brain is underperfused; in older adults this may be the only sign	Compare with baseline and family report; screen for sepsis and delirium; escalate
Heart rate rising above the patient's baseline	Compensation for low blood volume or vasodilation	Trend vital signs; look for other cues; escalate if sepsis is possible
Low or falling blood pressure; MAP under 65 mm Hg	Organs are not perfused; may signal septic shock	Escalate immediately; prepare IV access and fluids as ordered
Fever or a low temperature	Both occur in sepsis; a low temperature carries a worse outlook	Measure core temperature where possible; look for a source of infection
Cool skin, slow capillary refill, mottling at the knees	Blood is diverted from the skin; mottling is hard to see on darker skin	Time capillary refill; compare limb and trunk temperature; reassess after fluids
Low or falling urine output	The kidneys are underperfused	Measure output hourly as ordered; check for retention; report
Lactate above 2 mmol/L	Marks severity and risk of death; repeat values guide care	Draw as ordered; report at once; arrange repeat measurement
Suspected infection with any of the above	Antimicrobials and cultures are time-critical	Collect blood cultures without delay; give the first antimicrobial dose on time
Crackles, rising work of breathing or falling oxygen saturation after fluids	Possible fluid overload or lung injury	Stop and reassess; raise the head of the bed; escalate before giving more fluid

SCOPE IN PRACTICE

Sepsis Screening, Blood Cultures and Escalation

Every nurse, RN or practical nurse, screens for sepsis, acts at once on concerning cues and escalates. Hospital policy sets how the rapid response team is called, but no classification of the patient changes the duty to escalate.

Collecting blood cultures, drawing a lactate or starting IV fluids and antimicrobials depends on the three parts of CNO's Scope of Practice standard (see Chapter 1, section 1.3):

- **Authority:** the nurse needs an order or a medical directive. In an Ontario public hospital, nurses do not initiate controlled acts on their own authority, so sepsis protocols often rely on medical directives, which name the nurses who may carry them out.
- **Competence:** the nurse must have the knowledge, skill and judgment for the procedure, such as aseptic venipuncture and culture technique, and for the patient's condition.
- **Context:** employer policy decides who collects cultures; in some hospitals laboratory staff do so, and a directive may name RNs only. Rules also differ by province or territory.

When an RPN suspects sepsis, the patient's needs have changed. The RPN escalates at once and consults the RN, who assesses the patient. The RPN keeps contributing care within their own scope.

GOING DEEPER

Inside Sepsis: Dysregulated Response, Lactate and SOFA

Required for RN students; optional for PN students.

In sepsis, the host's response becomes the problem. Sensing microbial products and damaged cells, immune and endothelial cells release inflammatory and anti-inflammatory messengers at once. These messengers alter cardiovascular, nervous, hormonal, metabolic and clotting pathways. Organs can fail even though relatively few of their cells die (Singer et al., 2016).

The endothelium, the inner lining of blood vessels, is central. Activated endothelial cells become sticky and clot-promoting. The glycocalyx, the protective sugar-rich layer on the vessel wall, is shed, and the gaps between cells widen. Fluid and protein leak into the tissues (capillary leak), causing edema that raises tissue pressure and worsens perfusion. Small clots and stiffer red cells obstruct capillaries. Blood flow in the microcirculation can stay poor even after blood pressure is restored, so a normal MAP does not prove that organs are perfused (Joffre et al., 2020).

Lactate is often explained as a product of oxygen-starved cells, and tissue hypoxia does contribute. Much of the rise in sepsis, however, likely comes from stress hormones: epinephrine stimulates faster glycolysis even when oxygen is available. Whatever the cause, a high or rising lactate signals more severe illness and a higher risk of death (Garcia-Alvarez et al., 2014). Lactate is not a direct measure of perfusion and is read in clinical context (Evans et al., 2021).

The SOFA score grades six organ systems: respiratory (ratio of arterial oxygen to inspired oxygen), coagulation (platelets), liver (bilirubin), cardiovascular (MAP and vasopressor need), central nervous system (Glasgow Coma Scale) and renal (creatinine and urine output). Sepsis-3 defines organ dysfunction as an acute rise of 2 or more points, assuming a baseline of zero unless the patient had organ dysfunction before (Singer et al., 2016).

LIFESPAN CONSIDERATIONS

Sepsis in Older Adults

Older adults have the highest death rates involving sepsis in Canada (Navaneelan et al., 2016), and their sepsis is easy to miss. In a hospital study of patients with bloodstream infections, unusual (atypical) symptoms were reported in about 36% of patients younger than 65, 54% of those aged 65 to 84 and 64% of those 85 and older. Reduced consciousness, falls and vague complaints became more common with age. A general decline in health predicted early organ failure (Wester et al., 2013).

The nurse looks for:

- new or worse confusion, which may be the first sign (see delirium in Chapter 8);
- a fall, new incontinence or a sudden loss of mobility;
- a fever that is mild or absent, or a low temperature;
- a respiratory rate or heart rate above the person's usual values.

Knowing the person's baseline is essential, so the nurse asks family and caregivers what is new. Urinary and respiratory infections are the most common sources in this group (Wester et al., 2013).

PRACTICE STORY

"She Said He Wasn't Himself"

Names and details are fictional; this is a composite story.

Nurse: Daniel Okafor, RN. Years in practice: 9. Setting: surgical unit, community hospital, Ontario.

It was just after 1500 on a busy day shift when Mei-Lin, an RPN I've worked beside for years, stopped me in the hallway. Her patient, Mr. Lalonde, was 74 and on day 3 after a bowel resection. "He wasn't himself at lunch," she said. "He called me by his daughter's name. His respiratory rate is 24, and he's only had 80 mL of urine since 1100." She had already rechecked his vital signs and wanted me to see him.

Mr. Lalonde was restless and picking at his blanket. His temperature was 38.3 °C, heart rate 116, blood pressure 98/56 mm Hg and oxygen saturation 92% on room air. His knees and feet were cool, and his capillary refill was about 4 seconds. His abdomen was more tender than at morning rounds. Our sepsis screen was positive.

I called the rapid response team and gave an SBAR report, saying clearly that I was concerned about sepsis with a possible abdominal source. While we waited, Mei-Lin started oxygen per protocol and stayed with him, reassuring him and his wife. I placed a second IV and collected blood cultures and a lactate under our sepsis medical directive.

The team arrived within minutes. The lactate came back at 3.6 mmol/L. The surgical resident ordered a crystalloid bolus and a broad-spectrum antibiotic, and the first dose was running 40 minutes after Mei-Lin first raised her concern. We planned to remeasure his lactate and recorded his urine output hourly. An imaging scan that evening found a leak at the bowel join, and he went back to the operating room.

Mr. Lalonde recovered and went home two weeks later. Before discharge, his wife told me she had also noticed he "wasn't himself" that morning. I added a line to my practice: ask the family what they've noticed.

Reflect: How did Mei-Lin's decision to act on subtle changes, and to consult the RN, fit her role and scope? What could the team do to make it easier for families to raise concerns early?

Chapter 4 Summary

Introduction

- In a 2024 Canadian survey, 8.1% of adult inpatients in participating acute care hospitals had at least one health care-associated infection on the survey day.

4.1 Inflammation and Healing

- Acute inflammation has a vascular phase (vessels widen and leak, causing redness, heat and swelling) and a cellular phase (neutrophils, then macrophages, clear microbes and debris).
- Local signs are redness, heat, swelling, pain and loss of function; on darker skin, the nurse looks for colour change and relies on warmth, swelling, tightness and pain. Systemic signs include fever, a raised white cell count and malaise.
- Wounds heal through hemostasis, inflammation, proliferation and maturation; a healing ridge along an incision is normal by days 5 to 9.
- Wounds heal by primary, secondary or tertiary intention; diabetes, poor nutrition, smoking, older age and medications such as corticosteroids delay healing.

4.2 Infection: Recognition and Diagnostics

- Infection spreads through a chain of six links; nurses break the chain with hand hygiene, PPE, cleaning, device care and support for the host's defences.
- Invasive devices, surgery, immunosuppression and older age raise the risk of infection in hospital; older adults may show confusion or decline rather than fever.
- Antipyretics can hide fever, and the absence of fever does not rule out infection.
- Two sets of blood cultures from separate sites are collected before antimicrobials when this does not delay treatment; catheter urine comes from the sampling port, never the bag; wound swabs use the Levine technique.

- The white cell count and differential, CRP and procalcitonin support clinical judgment but do not replace it; lactate is discussed with sepsis.

4.3 Infection Prevention and Control on the Unit

- Routine practices apply to every patient: risk assessment, hand hygiene, PPE, control of the environment and administrative controls.
- Before each interaction, a point-of-care risk assessment guides the choice of PPE, placement and precautions.
- Hand hygiene follows the four moments; alcohol-based hand rub is preferred unless hands are visibly soiled or after care of a patient with C. difficile, when soap and water at a staff sink is preferred.
- Contact, droplet, droplet and contact, and airborne precautions start on suspicion of infection; airborne precautions need a negative pressure room and a fit-tested N95 respirator.
- PPE removal follows a set sequence with hand hygiene, because removal is the highest-risk moment.
- Nurses recognize clusters, report to the IPAC team, and follow outbreak measures; Ontario law requires designated diseases and hospital outbreaks to be reported to public health.

4.4 Antibiotic-Resistant Organisms and C. difficile

- AROs, including MRSA, VRE and carbapenemase-producing organisms, spread mainly by contact; colonized patients can spread them without symptoms.
- CNISP data for 2020 to 2024 show stable MRSA bloodstream infection and C. difficile infection rates, and significant rises in VRE bloodstream infections and CPE infections.
- Admission screening for AROs targets risk factors and follows each hospital's IPAC policy.
- C. difficile spores survive on surfaces and resist many chemicals; soap and water are preferred over alcohol-based hand rub because they physically remove spores, so the nurse washes at a staff sink.
- C. difficile care includes Contact Precautions from the first diarrhea, dedicated equipment, sporicidal cleaning, testing of unformed stool only, fluid balance and perineal skin care.

4.5 Antimicrobial Stewardship and the Nurse

- Stewardship means using antimicrobials only when needed, at the right drug, dose, route and duration, to limit resistance, C. difficile and adverse effects.
- Nurses support stewardship by collecting cultures before the first dose without delaying it, giving first doses on time and monitoring response and adverse effects.
- Nurses prompt reviews of IV-to-oral switches, culture results and stop dates.
- Most penicillin allergy labels are not true allergies; the nurse takes a detailed history, and prescribers or allergists make delabelling decisions.
- Patients learn to take antibiotics as directed, never share or save them, and report rash or diarrhea.

4.6 Sepsis

- Sepsis-3 defines sepsis as infection with organ dysfunction (a SOFA rise of 2 or more points); septic shock adds vasopressor need and a lactate above 2 mmol/L despite fluids.
- Early cues include a rising respiratory rate, new confusion, low blood pressure, fever or low temperature, poor perfusion, low urine output and a high lactate; mottling is harder to see on darker skin.
- qSOFA is not recommended as a single screening tool; the 2026 guideline recommends NEWS, NEWS2, MEWS or SIRS instead, and hospitals use a range of screening tools.
- The 2026 Surviving Sepsis Campaign guideline recommends blood cultures before antimicrobials when this causes no delay and antimicrobials immediately (ideally within 1 hour) for probable sepsis or shock; it suggests lactate measurement and at least 30 mL/kg of crystalloid within 3 hours for hypoperfusion.
- Every nurse escalates suspected sepsis at once; the RPN consults the RN.

- Many survivors have lasting physical, cognitive and mental health effects and need follow-up.

Key Terms (46)

acute inflammation: A short-lived inflammatory response, dominated by neutrophils, that removes the cause of injury and then resolves.

additional precautions: Infection control measures used on top of routine practices for certain organisms or clinical presentations; contact, droplet and airborne precautions.

airborne infection isolation room (AIIR): A single room designed and ventilated (negative pressure) to keep airborne organisms from spreading beyond it.

airborne precautions: Precautions for organisms carried on small particles that stay suspended in the air; they require a negative pressure room with the door closed and a fit-tested N95 respirator.

allergy (drug): an immune reaction to a drug, such as hives, swelling, wheezing or a severe skin reaction.

antibiotic-resistant organism (ARO): a microorganism that has changed so that one or more antibiotics that once treated it no longer work well against it.

antimicrobial stewardship: coordinated actions to use antimicrobials only when needed, with the right drug, dose, route and duration, to improve outcomes and limit harm and resistance.

C-reactive protein (CRP): An acute-phase protein whose blood level rises with inflammation of any cause; it is not specific to infection.

Canadian Nosocomial Infection Surveillance Program (CNISP): the Public Health Agency of Canada's surveillance program, with sentinel hospitals, for healthcare-associated infections and antimicrobial resistance.

carbapenemase-producing organism (CPO): a bacterium that makes enzymes that break down carbapenem antibiotics, leaving few effective drugs; carbapenemase-producing Enterobacterales (CPE) are the main group.

chain of infection: A model of the six links needed for infection to spread (agent, reservoir, portal of exit, mode of transmission, portal of entry, susceptible host); breaking any link stops transmission.

chronic inflammation: Inflammation that persists because the cause is not removed or the response fails to switch off, with ongoing tissue damage and scarring.

Clostridioides difficile: a spore-forming, toxin-producing anaerobic bacterium that causes diarrhea and colitis, most often after antibiotic use.

colonization: The presence of an organism on or in the body without signs of illness; a colonized person can still spread the organism.

contact precautions: Precautions for organisms spread by direct or indirect contact; they include a gown, gloves, dedicated equipment and, usually, a single room.

cytokines: Small proteins released by immune cells that carry signals between cells and promote or damp down inflammation.

diseases of public health significance: Infections that Ontario law says must be reported to the area's medical officer of health.

droplet precautions: Precautions for organisms spread by large respiratory droplets over a short distance; they include a mask and eye protection within 2 metres and a single room or spatial separation.

exudate: Fluid, proteins and cells that leave blood vessels and collect in inflamed tissue.

fever: A rise in body temperature that occurs as part of the inflammatory response; the threshold for action is set by policy, and older adults may have lower readings.

hand hygiene: Removing or killing microorganisms on the hands with alcohol-based hand rub or soap and running water.

healing by primary intention: Healing of a wound whose edges are brought together with sutures, staples or tape, without the need for granulation tissue.

healing by secondary intention: Healing of an open wound that fills with granulation tissue from the base up.

healing by tertiary intention: Healing of a wound that is left open for several days and then closed (delayed primary closure), often used for contaminated wounds.

healing ridge: A firm area of new collagen under a healing incision that is a normal sign of the proliferation phase.

health care-associated infection (HAI): An infection a person acquires while receiving health care.

infection: Entry of microorganisms into body tissues, where they multiply.

inflammation: The body's protective response to tissue injury or infection, which brings fluid, proteins and white cells to the area, removes the cause and prepares for repair.

intolerance (drug): an expected, non-immune side effect of a drug, such as nausea, diarrhea or headache.

lactate: a product of glucose metabolism; a level above 2 mmol/L in sepsis marks greater severity and risk of death.

methicillin-resistant Staphylococcus aureus (MRSA): a strain of S. aureus that resists methicillin and related antibiotics; spread mainly by contact.

mottling: patchy, lace-like skin discolouration, usually starting at the knees, that signals poor skin perfusion; harder to see on darker skin.

N95 respirator: A close-fitting respirator that filters 95% of particles about 1 micron in size; it must be fit-tested and seal-checked.

outbreak: A rise in cases of an infection above what is expected in a particular place and time, defined for each infection.

personal protective equipment (PPE): Clothing and equipment, such as gloves, gowns, masks, respirators and eye protection, that form a barrier between the provider and infectious material.

point-of-care risk assessment (PCRA): A check made before every patient interaction of the task, the patient and the environment to judge the risk of transmission and choose the right precautions.

post-sepsis syndrome: lasting physical, cognitive and psychological problems after surviving sepsis.

procalcitonin: A blood marker used with clinical assessment when the likelihood of bacterial infection is uncertain and to help decide when antibiotics can be stopped.

quick SOFA (qSOFA): a three-item bedside score (respiratory rate 22 or more, altered mentation, systolic blood pressure 100 mm Hg or less); not recommended as a single screening tool.

routine practices: The infection prevention and control practices used with every patient during all care: risk assessment, hand hygiene, PPE, control of the environment and administrative controls.

sepsis: Organ dysfunction that threatens life, caused by the body's dysregulated response to an infection.

septic shock: a subset of sepsis with severe circulatory, cellular and metabolic changes; clinically, a vasopressor is needed to keep MAP at 65 mm Hg or higher and lactate is above 2 mmol/L despite adequate fluids.

Sequential Organ Failure Assessment (SOFA) score: a score that grades dysfunction in six organ systems; a rise of 2 or more points with infection defines sepsis.

spore: a dormant, hardy form of a bacterium that survives for months on surfaces and resists many disinfectants; hand washing with soap and water is preferred because it physically removes spores.

systemic inflammatory response syndrome (SIRS): a set of criteria (temperature, heart rate, respiratory rate, white cell count) once used to define sepsis; no longer part of the definition.

vancomycin-resistant enterococci (VRE): bowel bacteria (enterococci) that no longer respond to vancomycin.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Gérard Fournier (Questions 1–4): Mr. Gérard Fournier, 76, has been on a medical unit in an Ontario hospital for 5 days, receiving IV antibiotics for pneumonia. He shares a four-bed room and bathroom. Since last evening he has had five loose, watery stools; this morning his stool test is positive for C. difficile. An RPN is caring for him.

1. [CORE] Which action should the RPN take first?

a. Ask Mr. Fournier to use the shared bathroom after his roommates

b. Wait for a second positive stool test before starting additional precautions or moving him to another room

c. Place Mr. Fournier on contact precautions and arrange a single room with its own toilet

d. Place a droplet precautions sign on the room door

Answer: c — C. difficile spreads by contact with stool, spores and contaminated surfaces. Contact precautions start at the onset of diarrhea, ideally in a single room with its own toilet (sections 4.3 and 4.4). Option a is wrong because a shared bathroom spreads spores whatever the order of use. Option b is wrong because precautions start on symptoms, not after repeat testing. Option d is wrong because C. difficile is not spread by droplets.

2. [CORE] After perineal care, the RPN removes the gown and gloves. Which hand hygiene action is best?

a. Wash hands with soap and water at a dedicated staff sink

b. Use alcohol-based hand rub, which removes spores better than soap and water

c. Wash hands at the sink in Mr. Fournier's bathroom

d. Skip hand hygiene, because gloves were worn throughout care

Answer: a — Soap and running water removes C. difficile spores better than alcohol-based hand rub, so handwashing at a dedicated staff sink is preferred (section 4.3). Option b reverses this; hand rub is used only when a staff sink is not immediately available. Option c is wrong because hand hygiene is never done at a patient's sink. Option d is wrong because gloves do not replace hand hygiene; hands can be contaminated during glove removal.

3. [CORE] Which equipment and environmental actions are appropriate for Mr. Fournier? Select all that apply.

a. Keep a dedicated stethoscope and blood pressure cuff in his room

b. Use a dedicated commode if a private bathroom is not available

c. Clean the shared glucometer with an alcohol wipe, as for other patients

d. Disinfect any shared item leaving the room with a product approved for C. difficile

e. Move the unit's vital signs machine between rooms and clean it at shift end

f. Confirm his room and bathroom are cleaned twice daily with a sporicidal agent

Answer: a, b, d, f — C. difficile care calls for dedicated equipment, a dedicated commode when there is no private bathroom, disinfection of shared items before they leave the room, and twice-daily sporicidal cleaning (section 4.3). Option c is wrong because alcohol does not reliably kill spores. Option e is wrong because equipment is cleaned between patients, not at the end of the shift.

4. [CORE] Mr. Fournier's daughter visits daily and helps him wash. Which instruction should the RPN give her?

a. "You can use his bathroom, because family members are not at risk."

b. "Visitors do not need any precautions, because gowns and gloves are required only for the health care workers who look after him."

c. "Please wear an N95 respirator whenever you are in his room."

d. "Please wash your hands with soap and water when you leave, and wear a gown and gloves when you help him wash."

Answer: d — Visitors who provide care follow the same precautions as staff: here, hand hygiene plus a gown and gloves (section 4.3). Option a is wrong because visitors should not use the patient's bathroom. Option b is wrong because visitors who help with care can carry spores. Option c is wrong because C. difficile is not airborne.

5. [CORE] A 58-year-old patient is admitted with cellulitis of the right lower leg. Which findings are systemic signs of infection? Select all that apply.

a. Temperature 38.6 °C
b. Warmth over the right shin compared with the left
c. White blood cell count 14.2 × 10^9/L
d. Swelling of the right calf
e. Fatigue and loss of appetite
f. Pain in the right leg when walking

Answer: a, c, e — Fever, a raised white cell count and malaise reflect a whole-body response (section 4.1). Options b, d and f are local signs: warmth, swelling, and pain with loss of function at the site.

6. [CORE] A nurse removes an indwelling urinary catheter that is no longer needed. Which link in the chain of infection does this action break?

a. Reservoir
b. Portal of exit
c. Mode of transmission
d. Portal of entry

Answer: d — An indwelling catheter gives organisms a direct route into the bladder, so removing it closes a portal of entry (section 4.2). Option a is wrong because the reservoir is where the organism lives and multiplies. Option b is wrong because the portal of exit is how organisms leave a reservoir. Option c is wrong because mode of transmission is how organisms travel, which hand hygiene and PPE interrupt.

7. [CORE] A surgical patient has a new temperature of 38.7 °C and chills. The prescriber orders two sets of blood cultures and an IV antibiotic now. Which action is correct?

a. Give the antibiotic first and collect the blood cultures with the next morning's blood work
b. Collect two sets of blood cultures from separate sites, then give the antibiotic without delay
c. Draw both sets from one site at the same time to reduce the number of skin punctures
d. Collect one set now and the second set after the antibiotic infusion is complete

Answer: b — Two sets from separate sites, collected before the first dose when this does not delay treatment, best identify the organism and separate contamination from true infection (section 4.2). Option a is wrong because antibiotics given first can stop bacteria growing in the culture. Option c is wrong because two sites are needed to recognize skin contamination. Option d is wrong because a set drawn after the antibiotic has a lower yield.

8. [CORE] A 44-year-old patient is admitted with a 6-week cough, night sweats and a chest X-ray suggesting pulmonary tuberculosis. Which precautions should the nurse implement?

a. Droplet precautions in a shared room, with the curtain drawn and a surgical mask for anyone within 2 metres
b. Contact precautions with a gown and gloves for all care
c. Airborne precautions in a negative pressure room, door closed, with fit-tested N95 respirators
d. Routine practices, with a surgical mask worn by staff within 2 metres of the patient

Answer: c — Pulmonary tuberculosis spreads on small particles that stay suspended in the air, so airborne precautions start on suspicion: a negative pressure room with the door closed and a fit-tested, seal-checked N95 respirator (section 4.3). Option a is wrong because droplet precautions and a shared room do not stop airborne spread. Option b is wrong because tuberculosis is not mainly spread by contact. Option d is wrong because a surgical mask does not protect the wearer from airborne particles.

9. [CORE] A nurse is about to empty a full urinary drainage bag for a patient with no known infection and expects urine may splash. Based on a point-of-care risk assessment, which PPE should the nurse wear?

a. Gloves, a gown, and a mask with eye protection
b. An N95 respirator and gloves
c. No PPE, because the patient has no known infection
d. Gloves only, because routine practices apply only to blood

Answer: a — The point-of-care risk assessment asks whether hands, clothing or mucous membranes may be exposed to body fluids; an expected splash calls for gloves, a gown and facial protection (section 4.3). Option b is wrong because this task produces no airborne particles and an N95 gives no eye protection. Option c is wrong because routine practices apply to every patient. Option d is wrong because routine practices cover all body fluids, not only blood.

Case: Mrs. Rose Bérubé (Questions 10–15): Mrs. Rose Bérubé, 84, was admitted to a medical unit yesterday with dysuria, frequency and dehydration after a fall at home. Her weight is 52 kg. A urine culture is pending; an oral antibiotic was ordered late last evening, and the first dose is due at 0900. At 0800 today her daughter says, "Mom isn't making sense this morning." Assessment: temperature 35.9 °C, heart rate 114, respiratory rate 26, blood pressure 92/54 mm Hg (MAP 67 mm Hg; yesterday 132/76), oxygen saturation 93% on room air. She is oriented to person only (yesterday fully oriented). Her skin is cool, with capillary refill of about 4 seconds. Urine output is 60 mL over the past 4 hours. Laboratory results: white blood cells 16.4 × 10^9/L, creatinine 172 µmol/L (yesterday 94 µmol/L), lactate 3.8 mmol/L.

10. [CORE] The nurse reviews Mrs. Bérubé's findings. Which findings need immediate follow-up? Select all that apply.

a. Temperature 35.9 °C
b. Respiratory rate 26 breaths per minute
c. Oriented to person only
d. Urine output 60 mL over 4 hours
e. Dysuria and frequency on admission
f. Lactate 3.8 mmol/L

Answer: a, b, c, d, f — A low temperature (a), fast breathing (b), new confusion (c), low urine output (d) and a lactate above 2 mmol/L (f) are new changes suggesting organ dysfunction and possible sepsis (section 4.6, Table 4.4). Dysuria and frequency (e) explain the likely source but are not a new change this morning.

11. [CORE] The nurse analyzes the cues. Which explanation best fits Mrs. Bérubé's current findings?

a. A new stroke causing confusion and low blood pressure
b. Dehydration alone, which will correct with oral fluids
c. An expected side effect of her oral antibiotic
d. Sepsis, with organ dysfunction from a urinary source

Answer: d — A urinary infection plus new confusion, fast breathing, low blood pressure, rising creatinine, low urine output and a high lactate points to sepsis with organ dysfunction (section 4.6). Dehydration (b) may add to her low blood pressure but does not explain the low temperature, high white cell count and lactate, and oral fluids would not be enough. A stroke (a) does not explain the infection cues. Her antibiotic (c) has not yet been given.

12. [CORE] Which concern should the nurse treat as the highest priority?

a. Risk of another fall because of her confusion
b. Risk of skin breakdown from reduced mobility
c. Poor tissue perfusion from possible septic shock
d. Knowledge gap about her urinary tract infection

Answer: c — Low blood pressure, cool skin, slow capillary refill, low urine output and a high lactate show poor organ perfusion, a life-threatening problem that comes first (section 4.6). Falls (a) and skin breakdown (b) are real risks but come after perfusion. Teaching (d) waits until she is stable.

13. [CORE] The nurse calls the rapid response team. Which orders should the nurse expect for Mrs. Bérubé in the first hour? Select all that apply.

a. Blood cultures collected before the first antimicrobial dose, if this causes no delay
b. A broad-spectrum intravenous antimicrobial given as soon as possible
c. A crystalloid fluid bolus with frequent reassessment
d. Holding all antimicrobials until the urine culture result is known
e. A repeat lactate measurement
f. Acetaminophen and a recheck of vital signs in 4 hours

Answer: a, b, c, e — The guideline supports blood cultures before antimicrobials when this causes no delay (a), antimicrobials immediately, ideally within 1 hour, for probable sepsis (b), crystalloid for hypoperfusion with frequent reassessment (c) and repeat lactate (e) (section 4.6). Waiting for the urine culture (d) would delay treatment by a day or more. A 4-hour recheck (f) ignores the urgency, and her temperature is low.

14. [CORE] Blood cultures have been collected, and the pharmacy has sent the first dose of the prescribed intravenous antimicrobial. A second set of blood cultures has also been ordered, but the laboratory says it cannot come for 60 minutes. What should the nurse do?

a. Give the antimicrobial now and report the delay in the second set
b. Hold the antimicrobial until the second set of cultures has been collected
c. Change the antimicrobial to the oral route so it can be given sooner
d. Give half the dose now and the rest after the second set is collected

Answer: a — Collecting cultures must not delay the first dose in probable sepsis (section 4.6). One set is already collected, so the nurse gives the dose now and reports the delay (a). Holding the dose (b) loses an hour in an emergency. Changing the route (c) is a prescriber's decision. Splitting the dose (d) is not ordered and would underdose her.

15. [CORE] Three hours later, Mrs. Bérubé has received about 1,500 mL of crystalloid and her antimicrobial. Which findings show that her condition is improving? Select all that apply.

a. New crackles at both lung bases
b. MAP 72 mm Hg
c. Repeat lactate 2.1 mmol/L
d. Oxygen saturation 89% on 2 L/min oxygen
e. Urine output 30 mL in the past hour
f. Oriented to person and place

Answer: b, c, e, f — A higher MAP (b), a falling lactate (c), better urine output (e) and clearer thinking (f) show improved perfusion (section 4.6). New crackles (a) and low oxygen saturation on oxygen (d) suggest fluid overload or lung injury and need escalation before more fluid (Table 4.4).

16. [CORE] A patient with MRSA colonization is on Contact Precautions. Which action by the nurse is correct?

a. Wearing a gown and gloves only when touching the patient's wound
b. Removing precautions once the patient has no signs of infection
c. Wearing an N95 respirator for all care in the room
d. Using a dedicated stethoscope and blood pressure cuff in the room

Answer: d — Dedicated equipment stops MRSA travelling to others on shared items (d) (sections 4.3 and 4.4). Under Contact Precautions, gown and gloves are worn for contact with the patient and environment, not only the wound (a). A colonized patient can spread MRSA without symptoms (b). MRSA spreads by contact, so an N95 respirator is not routinely needed (c) (section 4.3).

17. [CORE] After caring for a patient with C. difficile infection, the nurse removes gloves and gown. What should the nurse do next?

a. Use alcohol-based hand rub, then leave the room
b. Wash hands with soap and water at the patient's sink
c. Wash hands with soap and water at a staff sink
d. Put on new gloves instead of performing hand hygiene

Answer: c — Soap and running water remove spores mechanically, so the nurse washes at a staff sink (c) (section 4.4). Hand rub (a) is used only when no staff sink is close by, followed by washing soon after. The patient's sink (b) can re-contaminate the hands. Gloves (d) never replace hand hygiene.

18. [CORE] A patient receiving antibiotics has had two loose, watery stools that take the shape of the container since breakfast. The patient takes no laxatives. What should the nurse do first?

a. Start Contact Precautions and send a stool specimen
b. Wait for a third stool before taking any action
c. Send a formed stool specimen later to confirm the result
d. Give an antidiarrheal drug from the patient's home supply

Answer: a — Contact Precautions start at the first unexplained diarrhea, without waiting for more stools or results, and an unformed stool is sent promptly (a) (section 4.4). Waiting (b) lets spores spread. Formed stool is not tested (c). Giving an unordered drug (d) is unsafe; the diarrhea is reported to the prescriber.

19. [CORE] A patient with a carbapenemase-producing Enterobacterales (CPE) infection is admitted. Which measures should the nurse expect? Select all that apply.

a. A single room with a dedicated toilet or commode
b. Sharing the commode with the patient in the next bed once it is wiped
c. Contact Precautions for care
d. Dedicated patient care equipment
e. Routine walks in the unit hallway to promote mobility
f. Asking whether the patient has received health care outside Canada

Answer: a, c, d, f — CPE needs a single room with its own toilet or commode (a), Contact Precautions (c) and dedicated equipment (d) (section 4.4). Care outside Canada is a screening risk factor (f). Sharing a commode (b) spreads bowel organisms. Under Contact Precautions, time outside the room is limited, so mobility is planned with the IPAC team rather than through routine hallway walks (e).

20. [CORE] A patient on day 4 of intravenous antibiotics for pneumonia has been afebrile for 48 hours, is eating meals and has a white cell count returning to normal. Which action by the nurse best supports antimicrobial stewardship?

a. Continue the IV antibiotic because the course was ordered for 7 days
b. Change the IV antibiotic to an oral form at the next dose
c. Ask the prescriber or pharmacist whether an IV-to-oral switch is appropriate
d. Hold the antibiotic because the infection has resolved

Answer: c — The patient meets common IV-to-oral criteria, so the nurse prompts a review (c) (section 4.5). Continuing without question (a) misses a chance to reduce catheter complications. Changing the route (b) or holding the drug (d) without an order is outside the nurse's authority.

21. [CORE] On admission, a patient says, "I'm allergic to penicillin. It upset my stomach when I was a teenager." What should the nurse do?

a. Document the reaction and its timing in detail and share it with the prescriber
b. Remove the penicillin allergy from the record, since nausea is not an allergy
c. Record the allergy as "penicillin: anaphylaxis" to be safe
d. Tell the patient that all penicillin allergies go away after 10 years

Answer: a — The nurse records exactly what happened and when, and shares it so the prescriber or pharmacist can assess the label (a) (section 4.5). Stomach upset sounds like an intolerance, but the nurse does not remove a label alone (b); delabelling is done by a prescriber or allergist under policy. Recording a reaction that did not happen (c) is inaccurate and leads to unneeded alternative antibiotics. Statement (d) promises something the nurse cannot know.

22. [CORE] A patient with suspected pneumonia has a new order for blood cultures and an IV antibiotic. Which order of actions is best?

a. Give the antibiotic, then collect cultures at the next routine laboratory round
b. Collect blood cultures promptly, then give the antibiotic without delay
c. Wait for the chest X-ray result before collecting cultures or giving the antibiotic
d. Collect cultures, then give the antibiotic when the culture result returns

Answer: b — Cultures collected before the first dose give the best chance of identifying the organism, and the dose follows without delay (b) (sections 4.5 and 4.6). Giving the antibiotic first and waiting hours for cultures (a) can sterilize the specimen. Waiting for imaging (c) or culture results (d) delays treatment.

23. [CORE] An 88-year-old resident admitted from long-term care has a temperature of 36.8 °C. The family says she has been more confused since yesterday and fell this morning. She has a urinary catheter. How should the nurse interpret these findings?

a. Infection is unlikely because she has no fever
b. The new confusion and fall may be early signs of infection or sepsis
c. Confusion is expected at her age and needs no action
d. The fall explains her confusion, so only a neurologic check is needed

Answer: b — In older adults, fever may be mild or absent, and new confusion, falls and functional decline may be the first signs of infection or sepsis; a urinary catheter adds risk (section 4.6, Lifespan Considerations box). A normal temperature does not rule out infection (a). New confusion is never simply age (c). A head injury must be considered (d), but the nurse also screens for sepsis.

24. [CORE] A nurse on a surgical unit is reviewing the hospital's sepsis screening tool. Which statement about the quick SOFA (qSOFA) score is accurate?

a. A qSOFA score of 0 or 1 rules out sepsis in a patient with a suspected infection
b. qSOFA is the screening tool that all Ontario hospitals are required to use
c. qSOFA cannot be scored until a serum lactate result is available from the laboratory
d. qSOFA is not recommended as a single screening tool because it misses many patients

Answer: d — qSOFA is specific but not sensitive, so the Surviving Sepsis Campaign advises against it as a single screening tool (d) (section 4.6). A low score does not rule out sepsis (a). Ontario hospitals use different tools (b). qSOFA uses no laboratory value (c).

25. [CORE] An RPN finds that a postoperative patient has a new respiratory rate of 28, a heart rate of 122 and new confusion. The RN is busy with another patient. What should the RPN do first?

a. Recheck the vital signs in 1 hour before telling anyone

b. Escalate at once to the RN and to the rapid response team per policy

c. Document the findings and report them at the end of the shift

d. Wait for the RN to finish with the other patient before taking any action

Answer: b — Every nurse who notices deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change (b) (Scope in Practice box; Chapter 1, section 1.3). Waiting an hour (a), until shift end (c) or until the RN is free (d) delays care for possible sepsis.

26. [CORE] Which statement by a nurse about first-hour sepsis care is accurate?

a. "For probable sepsis, the antimicrobial should be given immediately, ideally within an hour."

b. "Fluids are given only after the blood culture results return."

c. "Lactate is drawn once at the end of resuscitation to confirm recovery."

d. "Vasopressors are started before any fluid in every patient with sepsis."

Answer: a — The guideline strongly recommends antimicrobials immediately, ideally within 1 hour, for probable or definite sepsis (a) (section 4.6). Fluids are not delayed for cultures (b). Lactate is measured early and repeated (c). Vasopressors usually follow an initial fluid bolus when hypotension persists (d).

27. [RN] A patient with pneumonia had a baseline SOFA score of 0. Today the platelet count has fallen and the creatinine has risen, raising the SOFA score to 3. How does the nurse interpret this under Sepsis-3?

a. The patient has SIRS but not sepsis

b. The patient meets the definition of septic shock

c. SOFA changes are not relevant until a lactate is available

d. The patient meets the definition of sepsis

Answer: d — Sepsis-3 defines sepsis as infection with an acute rise of 2 or more SOFA points (d) (Going Deeper box). SIRS (a) no longer defines sepsis. Septic shock (b) also requires vasopressor need and a lactate above 2 mmol/L despite fluids. The SOFA change stands without a lactate (c).

28. [RN] A patient's lactate is 4.1 mmol/L, although oxygen saturation is 97% and MAP is 70 mm Hg. A student asks how lactate can be high when oxygenation looks normal. Which explanation is best?

a. "The result must be a laboratory error, because lactate rises only with hypoxia."

b. "Stress hormones such as epinephrine can speed up glycolysis and raise lactate even when oxygen is available."

c. "Lactate rises only when the liver has failed completely and can no longer clear it from the blood."

d. "A high lactate is a direct and reliable measure of how much blood is reaching each of the organs."

Answer: b — Much of the lactate rise in sepsis likely comes from adrenergic stimulation of glycolysis, though hypoxia also contributes (b) (Going Deeper box). Lactate does not rise only with hypoxia (a) or complete liver failure (c). It marks severity, but it does not directly measure perfusion (d).

29. [RN] After 2 L of crystalloid, a patient in septic shock has new generalized edema, yet the blood pressure remains low. Which mechanism best explains these findings?

a. Injury to the endothelium and glycocalyx lets fluid leak from vessels into tissues

b. The kidneys are retaining sodium and water because the patient is now overhydrated

c. The crystalloid given was hypotonic, so most of it moved into the patient's cells

d. Edema shows that the circulating blood volume is now adequate

Answer: a — Endothelial activation and glycocalyx shedding let fluid and protein leak into tissues (capillary leak) while the circulation stays underfilled (a) (Going Deeper box). Sodium retention from overhydration (b) does not explain persistent low pressure. Crystalloids used in sepsis are isotonic (c). Edema does not mean the circulation is filled (d); the leaked fluid is outside the vessels.

30. [RN] Which patient meets the Sepsis-3 clinical criteria for septic shock?

a. Suspected infection, MAP 62 mm Hg before any fluid has been given, lactate 1.6 mmol/L

b. Pneumonia, MAP 70 mm Hg after fluids with no vasopressor needed, lactate 3.2 mmol/L

c. Urinary infection, norepinephrine needed to keep MAP at 65 mm Hg after adequate fluids, lactate 3.0 mmol/L

d. Cellulitis, temperature 39.2 °C, heart rate 124, respiratory rate 24, white cells 18 × 10^9/L

Answer: c — Septic shock requires a vasopressor to keep MAP at 65 mm Hg or higher and a lactate above 2 mmol/L despite adequate fluids (c) (section 4.6). Patient a has had no fluids and a normal lactate. Patient b needs no vasopressor. Patient d meets SIRS criteria, which no longer define sepsis.

05 Pain

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how pain is produced and modulated, and distinguish nociceptive, neuropathic and nociplastic pain and acute from chronic pain.
2. Assess pain in adults who can self-report, using valid tools and goals based on function.
3. Assess pain in adults who cannot self-report, including people living with dementia and critically ill patients.
4. Plan multimodal analgesia that combines drug and non-drug measures, with safety checks for acetaminophen, NSAIDs and adjuvant analgesics.
5. Give opioids safely by monitoring sedation and breathing, and recognize and escalate opioid-induced respiratory depression.
6. Care for patients living with chronic pain or opioid use disorder, including those on opioid agonist treatment, without stigma.
7. Teach patients and families about pain plans and opioid safety at home.
8. Distinguish RN and RPN roles in pain care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 4	Clinician; Scholar	Foundations of Practice
2, 3, 6	Clinician; Advocate	Foundations of Practice; Ethical Practice
5, 8	Clinician; Leader	Foundations of Practice; Professional Practice
7	Educator; Communicator	Foundations of Practice; Collaborative Practice

Introduction

Pain is one of the most common reasons people come to hospital, and one of the most common sources of distress once they are there. On a medical-surgical unit, patients have pain from surgery, injuries, procedures and acute illness. Many also arrive with long-standing pain that started well before this admission.

Getting pain care right matters in both directions. Pain is more than a sensation: it can bring fear, anxiety, poor sleep, fatigue and low mood, and it can interfere with physical and mental functioning (Registered Nurses' Association of Ontario [RNAO], 2025). Too much medication, or the wrong combination, also causes harm: combining opioids with gabapentin, pregabalin, benzodiazepines or alcohol, for example, raises the risk of slowed breathing and overdose (Health Canada, 2019).

Nurses are with patients around the clock, so they assess pain often. They give analgesics, offer non-drug measures, watch for adverse effects and speak up when the plan is not working. This chapter covers how pain works (section 5.1), pain assessment (5.2), multimodal and non-opioid analgesia (5.3), safe opioid use in hospital (5.4) and pain care for people living with chronic pain or opioid use disorder (5.5). Perioperative pain care is covered in Chapter 7, cancer pain in Chapter 9, end-of-life symptom control in Chapter 10, and opioid toxicity and withdrawal in Chapter 11.

5.1 Understanding Pain

Defining Pain

In 2020, the International Association for the Study of Pain (IASP) revised its definition of **pain** for the first time since 1979. Pain is now described as an unpleasant sensory and emotional experience that is linked to, or resembles one linked to, actual or potential tissue damage (Raja et al., 2020). The word "resembling" matters: a person can have real pain even when no injury can be found.

The IASP added notes to the definition that shape nursing practice (IASP, n.d.-b; Raja et al., 2020):

- Pain is always a personal experience, shaped by biological, psychological and social factors.
- Pain is not the same as **nociception**, the nervous system's process of detecting and encoding harmful stimuli. Nerve activity alone cannot tell anyone how much a person hurts.
- People learn what pain means through their own life experiences.
- Each person's own account of their pain deserves respect.
- Pain usually protects the body, but it can also harm function and well-being.
- Words are only one way to express pain. A person who cannot speak or communicate may still be in pain.

For the nurse, these notes mean starting from belief, and finding other ways to recognize pain when a person cannot describe it (section 5.2).

How Pain Signals Travel

The path from injury to awareness of pain has four linked processes.

Transduction is the first step. Specialized nerve endings called **nociceptors** respond to strong heat, pressure or chemical stimuli and convert them into electrical signals (IASP, n.d.-b).

Transmission carries the signal inward. Sensory nerve fibres carry it to the dorsal horn of the spinal cord. There they connect with neurons whose fibres cross to the other side and rise in the spinothalamic tract to the thalamus and on to the brain (Ossipov et al., 2010).

Perception is the point at which the person becomes aware of pain. No single "pain centre" exists. Areas involved in sensation, emotion and thinking are activated together, which helps explain why fear, mood and memory change how pain feels (Ossipov et al., 2010).

Modulation is the nervous system's ability to turn pain signals up or down. Pathways that descend from the brainstem, including the periaqueductal grey and the rostral ventromedial medulla, can inhibit or enhance signals arriving at the spinal cord. These pathways use chemical messengers such as serotonin and noradrenaline. The body's own opioids, called **endogenous opioids**, are part of this system. Naloxone, an opioid blocker, reverses the pain relief produced by stimulating these brain areas (Ossipov et al., 2010). Modulation also explains why expectation matters: hope of relief can reduce pain, and fear and anxiety can increase it.

Pain signalling can also become more sensitive. In **peripheral sensitization**, nerve endings near damaged tissue fire more easily. In **central sensitization**, neurons in the spinal cord and brain respond more strongly than usual to normal or even weak input (IASP, n.d.-b). Two clinical signs follow. **Allodynia** is pain from a stimulus that normally does not hurt, such as light touch from bed linen. **Hyperalgesia** is more pain than expected from a stimulus that normally hurts (IASP, n.d.-b). Loss of descending inhibition, or too much descending facilitation, may help keep these changes going in some chronic pain conditions (Ossipov et al., 2010).

Types of Pain

The IASP describes three types of pain by mechanism (IASP, n.d.-b). Many patients have more than one type at the same time.

- **Nociceptive pain** comes from actual or threatened damage to tissue other than nerves, with a nervous system that works normally. **Somatic pain** arises in skin, muscle, bone or joints; it is often well localized and sharp or aching, as with a surgical incision or a fractured hip. **Visceral pain** arises in internal organs, such as with a bowel obstruction or a distended bladder; it is

often harder to pinpoint than somatic pain. Pain can also be felt in a body region away from the site of the harmful stimulus, which is called **referred pain** (Jin et al., 2023). Pain from the heart is a familiar example (see Chapter 17).

- **Neuropathic pain** results from damage to, or disease of, the nerves that carry sensation (IASP, n.d.-b). Patients often describe burning or electric shock-like pain, tingling, numbness or pain from light touch. Examples include painful diabetic neuropathy, pain after shingles (postherpetic neuralgia) and pain after an amputation (Colloca et al., 2017).
- **Nociplastic pain** arises from altered pain processing, without clear evidence of tissue damage or nerve disease to explain it (IASP, n.d.-b). It can occur together with nociceptive pain (IASP, n.d.-b).

Acute and Chronic Pain

Acute pain begins suddenly, usually after injury, illness, surgery or trauma, and acts as a warning. It usually settles as the cause heals (RNAO, 2025). **Chronic pain** is pain that lasts, or keeps returning, for longer than 3 months (Treede et al., 2019). In the IASP classification used in the World Health Organization's *International Classification of Diseases*, 11th revision (ICD-11), chronic pain falls into two groups. In **chronic primary pain**, the pain is a condition in its own right, as in fibromyalgia or nonspecific low back pain. In **chronic secondary pain**, the pain stems from another disease, such as cancer, nerve injury or arthritis (Treede et al., 2019).

Chronic postsurgical pain is pain that begins or worsens after surgery, outlasts normal healing and is still present at least 3 months later (Schug et al., 2019). It is under-recognized and under-treated (Schug et al., 2019). The sensitization processes described above may help explain how pain can outlast the injury that started it.

Pain in Canada

The Canadian Pain Task Force (2021) estimated that 7.6 million people in Canada, or about one in five people of all ages, have chronic pain, based on Health Canada's analysis of the 2019 Canadian Community Health Survey. About one in three people over 65 have chronic pain. Groups the Task Force named as disproportionately affected include older adults, women, Indigenous Peoples, Veterans, people with low incomes, people with mental health or substance use disorders, workers in the trades and transportation, some racialized and ethnic communities, sexually and gender diverse people, people with disabilities and survivors of trauma or violence (Canadian Pain Task Force, 2021). Its first report described older survey data in which Indigenous Peoples had the highest rates of chronic pain. It noted that many Indigenous people describe physical pain as secondary to emotional pain caused by racism, colonization, the early deaths of family members and dispossession, and that discrimination keeps people from getting the help they need (Canadian Pain Task Force, 2019).

Chronic pain is often invisible to others, and many people living with it report feeling disbelieved and stigmatized (Canadian Pain Task Force, 2021). Access to specialized care is uneven. The median wait for a multidisciplinary pain clinic was still about 5.5 months in 2017–2018, 91% of these clinics were in urban areas, and most non-drug treatments were paid for through private insurance or out of pocket (Canadian Pain Task Force, 2019).

CANADIAN CONTEXT

An Action Plan for Pain in Canada

Health Canada set up the Canadian Pain Task Force in 2019 to advise on better prevention and management of chronic pain. It released three reports, in 2019, 2020 and 2021. The final report, *An Action Plan for Pain in Canada*, set six goals (Canadian Pain Task Force, 2021):

- treat pain as a public health priority and coordinate action across jurisdictions;
- give people equitable, consistent access to timely, evidence-informed, person-centred pain care;
- build knowledge, skills and education about pain for people living with pain and for health professionals;
- strengthen pain research;
- use data to monitor pain and improve health system quality;
- improve equitable access for populations disproportionately affected by pain.

The plan calls for pain care that is equity-oriented, trauma- and violence-informed and biopsychosocial. It names legitimizing pain as essential to fighting stigma.

For nurses, the plan becomes concrete at the bedside: believing the patient's report, asking about goals as well as scores, offering non-drug options, and noticing when bias or cost blocks access to care. See Chapter 2 for cultural safety.

5.2 Pain Assessment

Self-Report Comes First

When a person can communicate, their own report is the reference standard for pain assessment (RNAO, 2025). Observers, including experienced nurses, cannot reliably judge from appearance how much someone hurts. A patient who is smiling, sleeping or talking on the phone may still have severe pain.

The **numeric rating scale (NRS)** is the default self-report tool in this book. The nurse asks the patient to rate pain from 0 (no pain) to 10 (the worst pain imaginable). A **verbal descriptor scale** asks the patient to choose a word, such as none, mild, moderate or severe; some people, including some older adults, find words easier than numbers. The **Faces Pain Scale–Revised (FPS-R)** shows six faces scored 0 to 10; the person chooses the face that matches how much they hurt (Hicks et al., 2001). It was developed for children (IASP, n.d.-a). In a study of older adults in acute care in the United States, most of whom were African American or Hispanic, nearly all participants could use the FPS-R, and those with cognitive impairment most often preferred it (Ware et al., 2006). The FPS-R is free for clinical use if it is not changed, but reproducing it in print requires permission (IASP, n.d.-a).

Whatever tool is chosen, the nurse uses the same one each time so that scores can be compared, and records which tool was used. Pain is assessed at rest and with activity, such as turning, coughing, deep breathing or walking. A patient may rate pain 2 out of 10 in bed but 8 out of 10 when trying to cough after abdominal surgery. The second number guides care.

A Complete Pain Assessment

Screening asks whether pain is present. A **comprehensive pain assessment** explores its nature in depth (RNAO, 2025). It is done on admission, when a new pain appears and when pain changes. RNAO (2025) suggests a structured mnemonic, such as OPQRSTUV, so that nothing is missed. A complete assessment covers:

- **Onset and timing:** when the pain began, whether it is constant or comes and goes, and how long episodes last.
- **Location:** where it hurts and whether it spreads; the patient can point or mark a body diagram.
- **Quality:** the patient's own words, such as aching, cramping, stabbing or burning.
- **Intensity:** the score at rest and with movement, now and at its best and worst.
- **Aggravating and relieving factors:** what makes it worse or better, including medications, positions and heat or cold.
- **Effects on function, sleep and mood:** what the pain stops the patient from doing.
- **The patient's goals and the meaning of the pain:** what they hope to be able to do, and what they fear the pain means.
- **Treatment history:** analgesics taken before admission and their effects, including over-the-counter drugs, prescribed opioids, opioid agonist treatment, cannabis, alcohol and other substances (section 5.5).

RNAO (2025) asks providers to consider biological, psychological, social and cultural factors, the person's preferences and input from family. Function-based goals are often more useful than a target number. "Able to walk to the bathroom with a walker," "able to cough and deep breathe every hour" or "able to sleep 4 hours" tell the team whether pain care is working in ways that matter for recovery.

The nurse also listens for features of neuropathic pain, such as burning or electric shock-like sensations, tingling, numbness, or pain from light touch (allodynia) (Colloca et al., 2017). The nurse reports these features to the prescriber, because neuropathic pain may need different medications (section 5.3).

Culture, Language and Trust

People express pain in different ways. Some speak about it freely; others stay quiet, minimize it or describe it in spiritual or emotional terms. The nurse asks rather than assumes, and avoids stereotypes about how any group "should" react to pain. When the patient's preferred language is not English, the nurse uses a professional interpreter rather than family members for assessment (see Chapter 1, section 1.7). RNAO (2025) states that organizations should give health providers access to reliable translation services.

Bias in pain care is documented in Canada. The *In Plain Sight* review in British Columbia found widespread Indigenous-specific racism in health care. It described Indigenous patients being presumed intoxicated, being presumed to have ulterior motives when they needed pain medication, and having pain minimized, ignored or left untreated, sometimes with staff openly invoking a stereotype of Indigenous people as drug-seeking (Turpel-Lafond, 2020). RNAO (2025) asks providers to reflect on their implicit and explicit biases toward Black, Indigenous and racialized people and other underserved groups, and to give care that is culturally safe and trauma- and violence-informed. Chapter 2 (sections 2.2 and 2.3) explains these approaches.

Sexually and gender diverse people and people with disabilities are among the groups more affected by chronic pain (Canadian Pain Task Force, 2021). Past experiences of dismissal can make a patient slow to report pain. Using the patient's chosen name and pronouns, asking about communication needs and adapting tools, such as a large-print scale, all build the trust that honest reporting depends on.

Adults Who Cannot Self-Report

Some adults cannot give a reliable self-report, including people living with advanced dementia, people who are critically ill, sedated or unconscious, people with acute brain injury or stroke, and people at the end of life (RNAO, 2025). For these patients, the nurse must rely on other ways of inferring pain (Herr et al., 2019). The nurse combines several sources of information:

- **Try for self-report first.** Even a yes or no, a head nod, a hand squeeze or an eye blink may work (RNAO, 2025).
- **Consider likely causes.** Recent surgery, fractures, wounds and procedures commonly cause pain, and a full bladder or constipation can cause distress.
- **Observe behaviour with a validated tool.** Observational tools are needed when self-report is not possible (RNAO, 2025).
- **Ask people who know the patient.** Family and caregivers can describe usual behaviour and changes. Their estimates may be too low or too high, so they add to, rather than replace, other information (RNAO, 2025).
- **Treat likely pain and watch the response.** When pain is likely, the nurse gives the prescribed analgesic and reassesses the behaviours afterward, as after any pain treatment (RNAO, 2025).

The **Pain Assessment in Advanced Dementia (PAINAD) scale** was developed for people living with advanced dementia (Warden et al., 2003). The nurse observes five items: breathing, negative vocalization, facial expression, body language and consolability. Each is scored 0 to 2, for a total of 0 to 10 (Resnick et al., 2021). In a study of nursing home residents with moderate to severe dementia, the scale worked the same way for Black and White residents (Resnick et al., 2021).

The **Critical-Care Pain Observation Tool (CPOT)** was first validated in Quebec in 105 adults after cardiac surgery (Gélinas et al., 2006). It scores four behaviours: facial expression, body movements, muscle tension, and either compliance with the ventilator (for intubated patients) or vocalization (for others). Each is scored 0 to 2, for a total of 0 to 8 (Afenigus, 2024). In a later study of intubated adults after cardiac surgery, a cutoff score above 2 during turning detected pain with a sensitivity of 86% and a specificity of 78% (Gélinas et al., 2009).

With either tool, observing during care, such as turning or washing, can reveal pain that is not seen at rest. In the CPOT validation study, scores were higher during turning than at rest (Gélinas et al., 2006).

Behavioural tools show whether pain is likely, not how severe it feels to the person. Vital signs on their own are not reliable indicators of pain. Heart rate and blood pressure may rise during painful procedures, but their value in pain assessment is questionable (Afenigus, 2024), and they also change with fever, fluid loss, anxiety and medications. RNAO (2025) advises minimizing reliance on changes in vital signs alone.

PAINAD and CPOT score behaviours, not skin colour. Colour changes such as flushing or pallor can be harder to see on darker skin (Mukwende et al., 2020), so the nurse relies on cues that are visible on every skin tone: grimacing, frowning, clenched jaw, tense or rigid posture, guarding a body part, rubbing a site, restlessness and resisting care.

Reassessment and Documentation

Pain is reassessed after every drug or non-drug intervention (RNAO, 2025), at the interval set by employer policy for the drug and route. RNAO (2025) also recommends screening at least once a shift for inpatients, after changes in condition, before and after

procedures and before discharge. When pain is not improving or is getting worse, the nurse tells the team and escalates (RNAO, 2025).

Documentation records the tool used, the score at rest and with activity, the patient's description and function, interventions and the response. When opioids are given, sedation level and breathing are recorded too (section 5.4). Documentation follows the College of Nurses of Ontario (CNO) documentation standard (Chapter 1). Table 5.1 compares the main assessment tools.

Table 5.1 Pain assessment tools for adults (Hicks et al., 2001; Warden et al., 2003; Gélinas et al., 2006, 2009; Ware et al., 2006; Resnick et al., 2021; Afenigus, 2024; RNAO, 2025)

Tool	Who it is for	What it measures	Score range	Nursing points
Numeric rating scale (NRS)	Adults who can understand and use numbers	Pain intensity by self-report	0 (no pain) to 10 (worst pain imaginable)	Default tool in this book; ask at rest and with movement; use the same tool each time
Verbal descriptor scale	Adults who prefer words to numbers, including some older adults	Pain intensity by self-report, chosen from a short list of words	Categories such as none, mild, moderate, severe	Record the word chosen, not a converted number; use the same scale each time
Faces Pain Scale–Revised (FPS-R)	Developed for children; usable by many older adults, including some with cognitive impairment	Pain intensity by pointing to one of six faces	0 to 10 in steps of 2	Ask how much it hurts, not how the face looks; free for clinical use unaltered; permission needed to reproduce
Pain Assessment in Advanced Dementia (PAINAD)	Adults living with advanced dementia who cannot self-report	Five behaviours: breathing, negative vocalization, facial expression, body language, consolability	0 to 10 (each item 0 to 2)	Observe during care such as turning; shows likely pain, not its severity; rule out other causes of distress
Critical-Care Pain Observation Tool (CPOT)	Critically ill adults who cannot self-report, intubated or not	Four behaviours: facial expression, body movements, muscle tension, ventilator compliance or vocalization	0 to 8 (each item 0 to 2)	Score above 2 suggests pain; assess at rest and during procedures; do not rely on vital signs

CLINICAL JUDGMENT

Pain in an Older Adult Living With Dementia

Names and details are fictional; this is a composite story.

An 86-year-old woman living with advanced dementia had surgical repair of a hip fracture yesterday. On the evening shift she is restless, calling out and pulling at her gown. She cannot use a number scale.

- **Recognize cues:** She grimaces and holds her breath when turned, pushes the nurse's hands away from her hip and cannot be settled by talking. Her daughter says she is usually calm in the evening. Her last dose of analgesic was 7 hours ago, and she has not voided since her urinary catheter was removed 6 hours ago.
- **Analyze cues:** Her PAINAD score during turning is 7 out of 10. Pain is likely, but agitation after surgery can also come from delirium, a full bladder, low oxygen or infection.
- **Prioritize hypotheses:** Unrelieved incision pain is the most likely cause. Urinary retention and early delirium must be ruled out at the same time.
- **Generate solutions:** Check vital signs and oxygen saturation, scan the bladder per policy, review analgesic orders and plan to reassess with the same tool.
- **Take action:** Oxygen saturation and temperature are normal. The bladder scan shows a large volume, so the nurse follows the retention protocol and reports to the prescriber. The nurse gives the prescribed analgesic, repositions her with a pillow between her knees and dims the lights. The nurse also reports the new agitation, because delirium screening is needed (Chapter 8).
- **Evaluate outcomes:** When the analgesic is expected to have taken effect, her PAINAD score during turning is 2. She is resting and holds her daughter's hand. The nurse documents the scores, actions and response and plans scheduled reassessment.

See Chapter 1, section 1.4, for the clinical judgment model.

5.3 Multimodal and Non-Opioid Analgesia

Why Multimodal

Multimodal analgesia combines different medications, procedures and non-drug measures that act on different parts of the pain pathway (Health Quality Ontario, 2018). Because each one works differently, the combination can relieve pain better than one drug alone. Ontario's quality standard on opioid prescribing for acute pain states that most acute pain, including pain after surgery, can be treated successfully with non-opioid medications combined with physical or psychological measures. Compared with an opioid-based approach, this combination gives better pain control with less opioid use and fewer adverse effects. Opioids are added only when appropriate (Health Quality Ontario, 2018).

The nurse's part is practical. When a non-opioid is ordered on a regular schedule, giving each dose on time keeps relief steady. When it is ordered as needed, the nurse offers it before pain becomes severe and before planned activities, such as physiotherapy or a dressing change. Table 5.2 summarizes the options and the safety checks for each.

Acetaminophen

Acetaminophen relieves mild to moderate pain and reduces fever (B. Braun of Canada, 2023). Acetaminophen, a **nonsteroidal anti-inflammatory drug (NSAID)** or both together are first-line choices for many types of acute pain in people without contraindications (Health Quality Ontario, 2018). Acetaminophen's main serious risk is liver injury.

The Canadian product monograph for intravenous acetaminophen sets the maximum for adults who weigh at least 50 kg and have no added risk of liver toxicity at 4,000 mg in 24 hours. Below 50 kg, dosing is based on weight. When liver function is impaired or other risk factors for liver toxicity are present, the monograph says a lower daily total of 3,000 mg may be appropriate (B. Braun of Canada, 2023). It names chronic alcohol use, malnutrition and dehydration among those risk factors.

The maximum includes acetaminophen from every source and every route: oral, rectal and intravenous (B. Braun of Canada, 2023). Most reported cases of liver injury involve doses above the daily limit, often from more than one acetaminophen-containing product (B. Braun of Canada, 2023). Acetaminophen is "hidden" in many combination products, including cold and flu remedies and some prescription opioid tablets. The nurse checks the medication administration record and the patient's own medications for every source, totals the daily dose, and teaches the patient to read labels at home.

NSAIDs and COX-2 Inhibitors

NSAIDs reduce pain and inflammation by blocking cyclooxygenase (COX) enzymes, which lowers prostaglandin production (GlaxoSmithKline Consumer Healthcare ULC, 2025). Examples include ibuprofen, naproxen and ketorolac. Celecoxib is a COX-2 inhibitor, an NSAID that acts mainly on one form of the enzyme. The Canadian celecoxib monograph describes risks that apply across the class (Nora Pharma, 2026):

- **Gastrointestinal ulcers and bleeding,** which can occur without warning. Risk is higher with a past ulcer or bleed, older age, long-term use, heavy alcohol use, smoking, and use with anticoagulants, antiplatelet drugs including low-dose acetylsalicylic acid (ASA), oral corticosteroids or selective serotonin reuptake inhibitors.
- **Kidney injury,** especially with existing kidney disease, dehydration, heart failure, liver disease, older age, and use with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs) or diuretics. NSAIDs can also raise potassium.
- **Cardiovascular events,** including heart attack and stroke, with risk rising with dose and duration. Sodium and fluid retention can raise blood pressure and worsen heart failure.
- **Bleeding with anticoagulants,** such as warfarin.

The celecoxib monograph's contraindications include severe kidney impairment, active gastrointestinal bleeding, severe uncontrolled heart failure, the period around coronary artery bypass graft surgery, the third trimester of pregnancy, and a history of asthma, hives or other allergic reactions after taking ASA or another NSAID (Nora Pharma, 2026). Before each dose, the nurse checks kidney function and urine output, signs of bleeding (black stools, vomiting blood, bruising), blood pressure, fluid status and the medication list. Kidney function and electrolytes are covered in Chapter 3.

Adjuvant Analgesics

An **adjuvant analgesic** is a drug whose main use is not pain relief but which relieves some types of pain, especially neuropathic pain. Ontario's acute pain standard lists the anticonvulsants gabapentin and pregabalin and the antidepressants amitriptyline, nortriptyline and duloxetine among non-opioid options (Health Quality Ontario, 2018). Patients may not expect an anticonvulsant or antidepressant to be ordered for pain, so the nurse explains why it is being used.

Gabapentin and pregabalin, called **gabapentinoids**, need special care. Health Canada (2019) warns that taking them with opioids raises the risk of opioid overdose; the combination can slow breathing and cause increased sleepiness, dizziness, fainting and death. Benzodiazepines and alcohol can also raise the risk. When a patient receives a gabapentinoid with an opioid, the nurse monitors sedation and breathing as closely as for an opioid alone (section 5.4).

Local and Regional Anesthesia

Local anesthetics block nerve signals where they are applied. A surgeon may infiltrate the wound at the end of surgery. An anesthesiologist may inject near a nerve or group of nerves (a nerve block), sometimes leaving a catheter for a continuous infusion, or give medication into the epidural space for chest, abdominal or lower limb surgery. These interventional techniques are one part of multimodal analgesia (Health Quality Ontario, 2018). They also bring specific risks, such as numbness, weakness and low blood pressure. Monitoring is described in section 5.4.

Non-Drug Measures

Non-drug measures are part of the plan, not an afterthought. Ontario's quality standard lists self-management measures (heat, ice, massage, stretching and rest), professional measures (positioning, splints, bracing, physiotherapy and transcutaneous electrical nerve stimulation) and psychological measures (relaxation, guided imagery and cognitive behavioural therapy) (Health Quality Ontario, 2018). RNAO (2025) names physiotherapy, massage, relaxation and education among strategies to help prevent pain after surgery. It calls for an integrated approach that combines drug and non-drug strategies to fit each person and family; this good practice statement was not based on a formal evidence review.

On a medical-surgical unit, the nurse can:

- position the patient with pillows to support painful areas and change position regularly;
- teach the patient to splint an abdominal or chest incision with a pillow when coughing;
- help with early, planned movement, timed after an analgesic dose;
- apply heat or cold as ordered, with a cloth barrier, for a limited time, checking the skin, and avoiding them where sensation or circulation is reduced;
- coach slow breathing and relaxation, and offer distraction, such as music or conversation;
- protect sleep by clustering care and reducing noise and light at night;
- explain what to expect, which reduces fear and builds the patient's sense of control.

Table 5.2 Multimodal analgesia: options and nursing safety checks (Health Quality Ontario, 2018; Health Canada, 2019; B. Braun of Canada, 2023; Nora Pharma, 2026)

Approach	Examples	How it helps	Nursing safety checks
Acetaminophen	Acetaminophen by mouth, rectally or intravenously	Relieves mild to moderate pain and fever; first-line for many types of acute pain	Total daily dose from all products and routes; lower limit with liver disease or risk factors; check combination products
NSAIDs and COX-2 inhibitors	Ibuprofen, naproxen, ketorolac, celecoxib	Reduce pain and inflammation	Kidney function and urine output; bleeding; blood pressure and fluid status; anticoagulants, ACE inhibitors, ARBs, diuretics
Gabapentinoids	Gabapentin, pregabalin	Non-opioid options, especially for neuropathic pain	Sedation, dizziness, slowed breathing, especially with opioids; fall risk

Approach	Examples	How it helps	Nursing safety checks
Antidepressants for neuropathic pain	Duloxetine, amitriptyline, nortriptyline	Non-opioid options, especially for neuropathic pain	Drowsiness, dizziness, falls; explain why an antidepressant is used for pain
Local and regional anesthesia	Wound infiltration, nerve blocks, epidural analgesia	Block pain signals at the site or nerve	Sensation, movement, blood pressure, catheter site; see section 5.4
Opioids	See section 5.4	Relieve moderate to severe pain when other measures are not enough	Sedation and respiratory monitoring; see section 5.4
Non-drug measures	Positioning, splinting, early movement, heat, cold, relaxation, distraction, sleep, education	Reduce pain, fear and muscle tension; support function	Skin checks with heat and cold; avoid where sensation is reduced; match to patient preference

LIFESPAN CONSIDERATIONS

Older Adults and Pain

About one in three people over 65 in Canada live with chronic pain (Canadian Pain Task Force, 2021). About half of people living with dementia have pain, which often goes unrecognized and untreated (Resnick et al., 2021). The nurse asks every older adult about pain directly, offers a verbal descriptor scale if numbers are hard, and uses PAINAD when self-report is not possible. Family members who know the person's usual behaviour add valuable information (RNAO, 2025).

Older adults are more sensitive to medication harms:

- NSAIDs: older adults tolerate ulcers and bleeding less well, and most fatal gastrointestinal events reported with celecoxib occurred in older adults. Older age also raises the risk of kidney injury. The monograph advises considering a lower starting dose with close supervision (Nora Pharma, 2026).
- Gabapentinoids with opioids: the sleepiness, dizziness and fainting that Health Canada (2019) warns about can lead to a fall.

The nurse reviews kidney function, watches for new confusion, constipation and unsteadiness, and reports them promptly. Chapter 8 covers delirium and falls.

5.4 Opioids: Safe Use in Hospital

Opioids remain essential for moderate to severe acute pain when non-opioid and non-drug measures (section 5.3) are not enough. They are also among the drugs most often involved in serious medication incidents. This section explains how opioids work and how the nurse keeps patients who receive them safe.

How Opioids Work

An **opioid** is a drug that acts on the body's opioid receptors to relieve pain. The receptor that matters most for pain relief is the **mu-opioid receptor**. Mu receptors are concentrated in the parts of the brain and spinal cord that modulate pain, and morphine and similar drugs act mainly there (BGP Pharma, 2015). When an opioid binds to these receptors, fewer pain signals pass upward through the spinal cord, and the brain responds less strongly to the signals that do arrive.

The same receptors explain the adverse effects. Opioids cause drowsiness and, at higher levels, slow and shallow breathing. Mu receptors in the wall of the gut slow bowel movement, which is why constipation is so common; drugs that block only these gut receptors are an option when laxatives have not worked (Crockett et al., 2019). Nausea, itching and difficulty passing urine are also common. Morphine can release histamine from cells, which adds to itching and flushing (Fresenius Kabi Canada, 2019).

Morphine, hydromorphone, oxycodone and fentanyl are **full agonists**: they switch the mu receptor fully on, and their effects keep increasing as the dose rises. Buprenorphine, used mainly to treat opioid use disorder (section 5.5), is a **partial agonist**: it activates the mu receptor, but less fully (Indivior UK, 2025).

Opioids Used in Canadian Hospitals

Table 5.3 lists the opioids nurses most often give for pain in Canadian hospitals, with their routes and key safety points. Routes include oral, intravenous (IV), subcutaneous, intramuscular and transdermal; patient-controlled and epidural routes are described in the Going Deeper box.

A few points deserve emphasis. Codeine has little effect until the liver enzyme CYP2D6 converts it to morphine. Some people, called ultra-rapid metabolizers, make this conversion faster and more completely than others, so a usual dose can produce an unexpected morphine overdose (Health Canada, 2013). Tramadol carries a similar warning: ultra-rapid metabolizers form its stronger active metabolite quickly, which can cause life-threatening respiratory depression (Health Canada, 2017). Because no one can tell from the bedside how a patient metabolizes these drugs, the nurse watches every patient for oversedation.

Morphine is broken down into metabolites that the kidneys excrete. One of them, morphine-6-glucuronide, is itself active and builds up in people with kidney disease (BGP Pharma, 2015). The nurse reviews kidney function (Chapter 3) and reports rising creatinine. Hydromorphone and oxycodone also need caution in kidney or liver impairment (Purdue Pharma, 2023; Sandoz Canada, 2025).

Fentanyl patches release the drug slowly over days. They are meant only for patients who already take a substantial daily amount of opioid for long-term pain. They are contraindicated for acute or perioperative pain and in **opioid-naive** patients, those not already taking opioids regularly, at any strength (Teva Canada, 2022).

Table 5.3 Opioids commonly used for pain in Canadian hospitals (Health Canada product monographs)

Opioid	Common routes	Points for nursing safety
Morphine	Oral (immediate- and sustained-release); IV, subcutaneous and intramuscular injection	An active metabolite builds up in kidney impairment, so sedation can increase over days; may release histamine, causing itching or flushing
Hydromorphone	Oral tablets; IV, subcutaneous and intramuscular injection; PCA	High-alert drug often confused with morphine; written HYDROmorphone in tall man lettering; several injectable concentrations exist; caution in kidney or liver impairment
Oxycodone	Oral	Tablets are swallowed whole, never cut, crushed or chewed; caution in kidney or liver impairment
Fentanyl	Transdermal patch; injection, mainly in critical care, anesthesia and procedures	Patch only for opioid-tolerant patients with long-term pain; contraindicated for acute or perioperative pain and in opioid-naive patients; heat and fever increase absorption; used patches folded sticky sides together and returned to a pharmacy
Codeine	Oral, including products combined with acetaminophen	Converted to morphine by CYP2D6; ultra-rapid metabolizers may form enough morphine to overdose; Health Canada advises alternatives in children under 12
Tramadol	Oral	Converted by CYP2D6 to a stronger metabolite; ultra-rapid metabolizers are at risk of life-threatening respiratory depression
Tapentadol	Oral	Acts on mu receptors and blocks norepinephrine reuptake; risk of serotonin syndrome with other serotonergic drugs and of seizures; not used within 14 days of a monoamine oxidase inhibitor

Opioid-Induced Respiratory Depression

Opioid-induced respiratory depression (OIRD) is a reduced drive and effort to breathe caused by an opioid. Breathing becomes slower, shallower or irregular, carbon dioxide builds up, and untreated OIRD can progress to respiratory arrest and death. The Institute for Safe Medication Practices Canada (ISMP Canada) and coroners' and medical examiners' offices in four provinces reviewed deaths from 2007 to 2012. Of the 115 deaths in which a medication incident may have contributed to or caused the death, opioids were involved in 54 (47%), more than any other drug class (ISMP Canada, 2014).

Respiratory depression is generally preceded by sedation (The Joint Commission, 2012). As the opioid level in the brain rises, the patient becomes drowsier before breathing slows to a dangerous degree. Increasing sleepiness is therefore the nurse's earliest warning, and the time to act.

Every hospitalized patient who receives opioids for acute pain carries some risk, so every patient's risk is assessed and reassessed (Jungquist et al., 2020). The risk is higher with the following (Chincholkar, 2020; ISMP Canada, 2014; Purdue Pharma, 2023; The Joint Commission, 2012):

- **Patient factors:** no recent opioid use; older age, with risk rising in each decade after 60; obstructive sleep apnea, other sleep disorders or snoring; obesity; lung or heart disease; and kidney or liver impairment, which slow drug clearance.
- **Treatment factors:** recent surgery, especially upper abdominal or chest surgery; longer general anesthesia; dose increases or a switch to another opioid; use of other drugs that cause drowsiness, for example benzodiazepines, gabapentinoids or sedating antihistamines; and more than one opioid order left active at the same time.
- **Environment of care:** the setting and how often the patient can be watched also affect risk (Jungquist et al., 2020).

Older adults need special attention, because these factors often occur together (Chapter 8).

Monitoring Sedation and Breathing

The nurse assesses sedation and breathing before giving an opioid, again at the intervals the order set or policy sets, and more often after a dose increase or a change of opioid (Jungquist et al., 2020; The Joint Commission, 2012). The assessment includes:

- **Sedation level:** how awake the patient is and how easily they rouse.
- **Breathing:** respiratory rate counted carefully, depth, regularity, pauses, and snoring or noisy breathing.
- **Oxygen saturation (SpO2):** with supplemental oxygen, SpO2 can stay normal while carbon dioxide builds up, so a normal reading can be falsely reassuring (The Joint Commission, 2012).
- **Colour:** a bluish or greyish tinge is a late sign and may be harder to see on darker skin, so the nurse also looks at the lips, tongue, gums and inside of the mouth.

For higher-risk patients, policy may call for continuous pulse oximetry or **capnography**, which measures exhaled carbon dioxide and detects hypoventilation directly (The Joint Commission, 2012).

A **sedation scale** gives nurses a shared language for drowsiness. The Pasero Opioid-induced Sedation Scale (POSS) is widely used outside critical care (Pasero, 2009). In summary, the scale sorts patients into two groups. Patients who are fully awake, sleeping but easy to wake, or a little sleepy yet quick to rouse are at a safe level. Patients who keep nodding off, even while talking, or who can barely be roused are not, and the nurse acts at once. Intensive care units use the Richmond Agitation-Sedation Scale (RASS) instead.

When sedation increases, the nurse holds further opioid doses, wakes the patient, coaches deep breathing, reassesses and notifies the prescriber or RN. If the patient responds minimally or breathing is inadequate, the nurse calls for help at once, supports the airway and gives naloxone according to the order, medical directive and policy (Table 5.4). Rapid response is covered in Chapter 6, and naloxone and opioid toxicity in Chapter 11.

Table 5.4 Recognizing and responding to opioid-induced sedation and respiratory depression (based on Pasero, 2009; Jungquist et al., 2020; The Joint Commission, 2012)

What the nurse sees	What it may mean	Nursing actions
Fully awake, or sleeping but opens eyes to a normal voice and stays awake	Safe level of sedation	Continue the pain plan; give opioid as ordered when needed; reassess at the intervals policy sets
A little sleepy, but wakes with a word and joins in the conversation	Still safe; watch for a downward trend	Continue the plan; reassess sooner after each opioid dose or dose increase
Keeps nodding off, even while talking, but can be woken	Too sedated; respiratory depression may follow	Hold opioid doses (including PCA doses, per policy); rouse and coach deep breaths; check breathing and SpO2; notify the prescriber or RN; stay close and recheck often; use non-opioid analgesia as ordered
Hard to wake; little or no reaction to voice or a firm touch	Dangerously sedated; breathing may stop	Stop all opioids; call for help (rapid response per policy); stay; stimulate; open and support the airway and breathing; give naloxone per order or medical directive

What the nurse sees	What it may mean	Nursing actions
Slow, shallow or irregular breathing, pauses or snoring; SpO2 falling or exhaled carbon dioxide rising	Respiratory depression (hypoventilation)	Act as for a patient who is hard to wake: stop opioids, call for help, support breathing, give naloxone per order; do not rely on raising oxygen alone

CLINICAL SAFETY

When the Patient Is Too Sleepy

Increasing sleepiness is the first and most important cue of opioid-induced respiratory depression. Breathing usually slows only after the patient has become hard to keep awake (The Joint Commission, 2012).

- If a patient keeps drifting off while talking with the nurse, hold the next opioid dose, wake them fully, coach deep breaths, check breathing and SpO2, and notify the prescriber or RN.
- If the patient barely responds, call for help immediately, stay, support breathing and give naloxone according to the order or medical directive.
- Do not wake a sleeping patient only to offer an as-needed (PRN) opioid. Do wake the patient to assess sedation and breathing when the plan or policy calls for it.
- Be wary of the phrase "sleeping comfortably." A patient who is truly asleep wakes easily and stays awake. A patient who cannot stay awake may be oversedated.
- Remember that SpO2 can look normal on supplemental oxygen while carbon dioxide rises.
- Tell the next nurse at handover about any increase in sedation, even if it has settled.

High-Alert Medication Safety

Opioids are **high-alert medications**: errors with them are more likely to cause serious harm (ISMP Canada, n.d.; Chapter 1, section 1.6). In ISMP Canada's (2014) analysis of opioid-related deaths linked to medication incidents, hydromorphone figured in over a third of the incidents reviewed. Patterns included morphine and hydromorphone mix-ups caused by similar names and doses, and small doses drawn from high-concentration vials; in one case, 4 mg was given instead of 0.4 mg (ISMP Canada, 2013). Others were an old opioid order left active alongside a new one, pump programming errors, crushed long-acting tablets, and PRN doses given routinely (ISMP Canada, 2014; Figure 5.1).

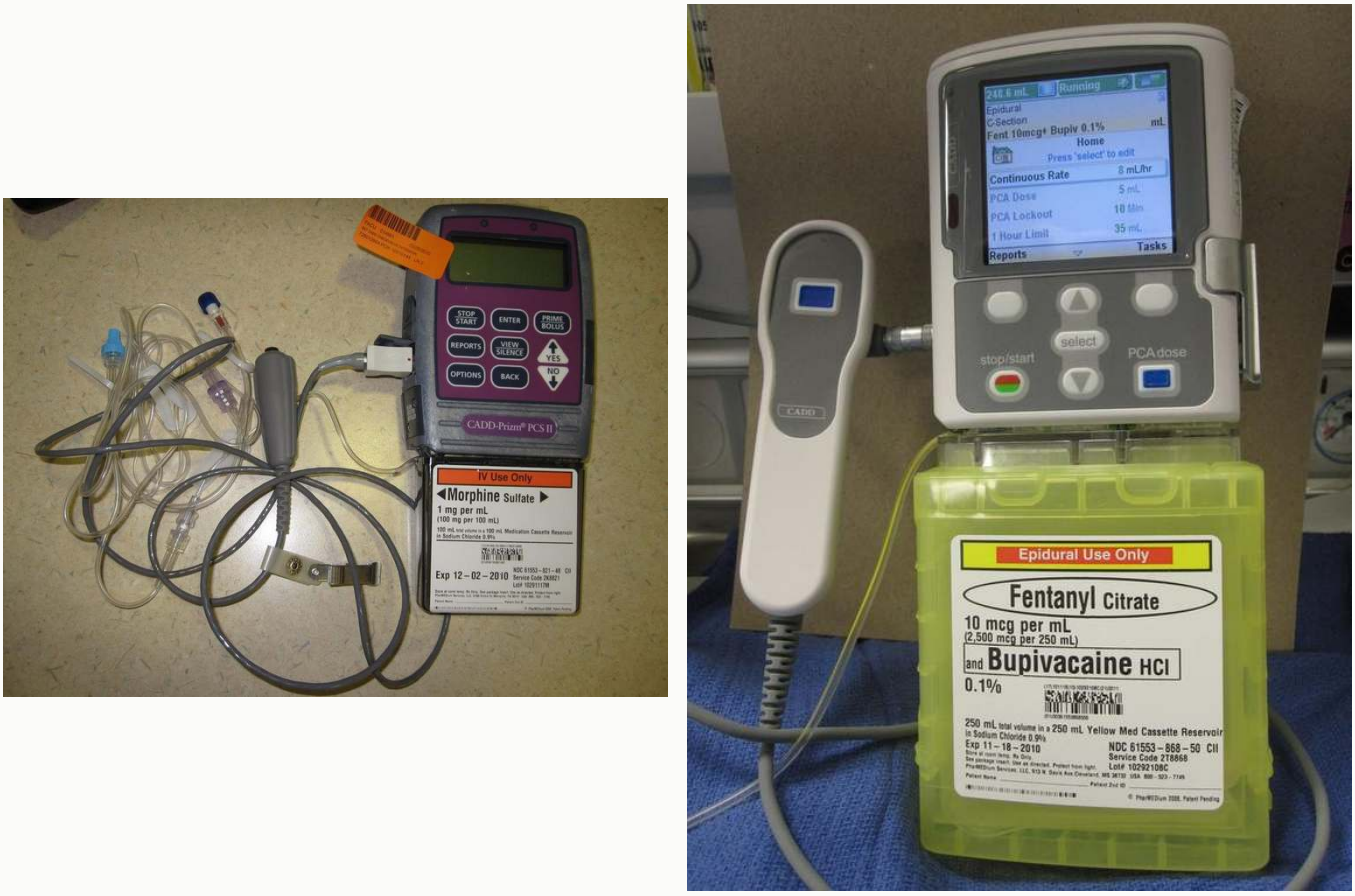

Figure 5.1 (a) A patient-controlled analgesia (PCA) pump with a morphine cassette for intravenous use. (b) A pump set up for an epidural infusion of fentanyl with bupivacaine; the label reads “Epidural Use Only.” These labels are from the United States; Canadian products are labelled differently. (credit: (a) “PCA-02” and (b) “PCA-01” by DiverDave/Wikimedia Commons, CC BY-SA 3.0)

Safeguards work at several levels:

- Tall man lettering (HYDROmorphone) and separate storage for morphine and hydromorphone.
- Limiting high-concentration products on units, and supplying dosage forms that match the doses usually ordered (ISMP Canada, 2013, 2014).
- Order sets that set monitoring parameters and when to act.
- **Independent double checks** of dose calculations, pump programming and administration, as policy requires (ISMP Canada, 2014, 2016).
- **Smart pumps** with dose-error reduction software (The Joint Commission, 2012).

SCOPE IN PRACTICE

Opioids, PCA and Epidural Analgesia

CNO's Scope of Practice standard explains nursing roles through authority, competence and context (College of Nurses of Ontario, 2025; Chapter 1, section 1.3).

- **Authority:** Both RNs and RPNs give controlled substances, including opioids, when there is an order or a medical directive that applies. Nurses do not initiate opioids in a public hospital.
- **Competence:** Before giving an opioid, the nurse needs the knowledge and skill to assess pain, sedation and breathing, and to recognize and respond to oversedation.
- **Context:** Managing patient-controlled analgesia (PCA) or epidural analgesia depends on employer policy, the nurse's education and the patient's needs. Some hospitals limit these to RNs with added education; others prepare RPNs for parts of the care. When a patient's condition changes or becomes less predictable, the RPN consults the RN.

- **Every nurse escalates:** Any nurse who notices increasing sedation or slow breathing acts at once and calls for help, whoever is assigned to the patient.

Employer policy and the province or territory matter. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (College of Nurses of Ontario, 2026).

GOING DEEPER

PCA, Epidural Analgesia and Morphine Milligram Equivalents

Required for RN students; optional for PN students.

Patient-controlled analgesia (PCA) uses a programmable pump. The patient presses a button to receive a set **demand dose**. A **lockout interval** blocks further doses until the last one has had time to act, and the pump may also cap the total over a set period. PCA has a built-in safety check: a patient who becomes too drowsy stops pressing the button. A continuous **basal infusion** removes that check, because the drug keeps flowing even when the patient is sleepy, so a patient with a basal infusion needs especially close monitoring of sedation and breathing.

PCA by proxy happens when someone other than the patient, such as a family member or a staff member, presses the button. It bypasses the safety check and has caused serious harm (The Joint Commission, 2004). The nurse teaches the patient and visitors that only the patient presses the button.

Epidural analgesia delivers local anesthetic, often with an opioid, through a catheter into the epidural space. As policy directs, the nurse monitors pain, sedation and breathing; sensory and motor block in the legs; blood pressure; and the catheter site. Anticoagulant doses, such as enoxaparin, are timed around catheter insertion and removal. New back pain, numbness or weakness in the legs, or new bowel or bladder problems can signal a spinal or epidural hematoma. This bleeding around the spinal cord can cause lasting or permanent paralysis and needs urgent diagnosis and treatment, so the nurse reports these signs immediately (sanofi-aventis Canada, 2021).

Morphine milligram equivalents (MME) express different opioids as an equivalent amount of oral morphine. This makes it possible to compare total opioid exposure. For example, fentanyl patches are only for patients already taking at least 60 mg of morphine equivalents a day (Teva Canada, 2022). The 2017 Canadian guideline for chronic non-cancer pain recommends keeping new prescriptions below 90 mg morphine equivalents daily and suggests below 50 mg (Busse et al., 2017). Conversions between opioids are the work of prescribers and pharmacists, not nurses.

Constipation and Other Effects

Constipation affects nearly all patients who take opioids regularly (Fresenius Kabi Canada, 2019). Traditional laxatives are first-line treatment for opioid-induced constipation (Crockett et al., 2019). For this reason, a **bowel regimen** is usually ordered as soon as regular opioids begin. This is a scheduled plan, often a stimulant laxative, an osmotic laxative or both. The nurse assesses the usual bowel pattern, last bowel movement, distension and fluid intake, encourages movement, and reports no bowel movement despite the regimen.

Nausea is managed with antiemetics as ordered and by reducing opioid needs through multimodal analgesia (section 5.3). Itching is common, especially with morphine; the nurse reports it rather than assuming it is an allergy. Opioids can cause urinary retention (Fresenius Kabi Canada, 2019). The nurse monitors voiding and assesses the bladder as policy directs, especially after surgery. Drowsiness and dizziness also raise the risk of falls, particularly in older adults (Chapter 8).

Tolerance, Physical Dependence and Opioid Use Disorder

Three terms are often confused, and the confusion harms patients.

- **Tolerance:** the need for more of a drug to get the same effect, or a smaller effect from the same dose, after repeated use.
- **Physical dependence:** the body's adaptation to a drug, so that stopping it suddenly or cutting the dose quickly causes withdrawal symptoms.
- **Opioid use disorder (OUD):** a problematic pattern of opioid use that causes significant problems or distress. Under the criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), it is diagnosed when at least 2 of 11 criteria are present within a year, such as craving, unsuccessful attempts to cut down, and continued use despite harm. Severity is mild (2 to 3 criteria), moderate (4 to 5) or severe (6 or more) (Centers for Disease Control and Prevention [CDC], 2024).

Tolerance and physical dependence are expected after regular opioid use. Under the diagnostic criteria, they do not count toward OUD in a person who takes opioids only as medically supervised (CDC, 2024). A patient who needs a higher dose, or feels unwell when a dose is late, is not showing addiction. Tapering is gradual, because fast reductions can increase pain and cause withdrawal (Busse et al., 2017).

Words matter. Health Canada (2022) advises person-first, medically accurate language, such as "person with opioid use disorder," instead of "addict," "abuser" or "clean," because stigmatizing words drive people away from care and contribute to poorer care. "Drug-seeking" is a similar label that assumes a motive. The nurse documents what was observed instead: "requested analgesia 40 minutes before due; rates pain 8 out of 10 when walking."

Figure 5.2 A take-home naloxone kit as distributed in British Columbia. (credit: "NaloxoneKit" by James Heilman, MD/Wikimedia Commons, CC BY-SA 4.0)

Opioids at Discharge

Ontario's quality standard *Opioid Prescribing for Acute Pain*, for people 15 years and older, calls for prescribing the weakest immediate-release opioid that works, at the lowest dose that relieves the pain (Health Quality Ontario, 2018). Three days or less is often enough, and more than 7 days is rarely needed. Methadone, fentanyl patches and extended-release opioids are not recommended for acute pain. Patients and families should receive information about benefits and harms, safe storage and safe disposal, and a plan for tapering and stopping (Figure 5.2).

Since October 23, 2018, pharmacies and prescribers who dispense prescription opioids must provide a warning sticker and a patient information handout; opioids given under supervision in hospital are exempt (Health Canada, 2018). The sticker warns of dependence, addiction and overdose, and the handout describes signs of overdose and safe storage.

The nurse reconciles medications (Chapter 1, section 1.7), teaches the patient to return unused opioids to a pharmacy, and tells patients about free take-home naloxone kits. In Ontario, pharmacies in the Ontario Naloxone Program for Pharmacies supply them at no cost to people at risk of overdose and to their family and friends, without a health card (Ontario Ministry of Health, 2025). Naloxone is covered in Chapter 11.

PATIENT EDUCATION

Opioids at Home

The nurse teaches the patient and family to:

- Take the opioid only as prescribed and only while pain needs it. Use acetaminophen, an anti-inflammatory if allowed, ice, rest and movement first.
- Follow the tapering plan, and never take extra doses or doses closer together.
- Report severe drowsiness, confusion, slow or shallow breathing, or trouble staying awake. Family should call 9-1-1 if they cannot wake the person.
- Prevent constipation with the prescribed laxative, fluids and activity.
- Avoid alcohol, sleeping pills, cannabis and other sedating drugs unless the prescriber approves.
- Not drive or operate machinery while drowsy or after a dose increase.
- Store opioids locked and out of sight, away from children, teens, visitors and pets, and never share them.
- Return unused opioids and used patches to a pharmacy; do not flush them or put them in the garbage.
- Get a free naloxone kit from a pharmacy and show family where it is kept.
- Call the prescriber or pharmacist with questions about pain, side effects or stopping.

5.5 Patients Living With Chronic Pain or Opioid Use Disorder

Many adults admitted to hospital already live with chronic pain, take long-term opioids, or have opioid use disorder. Their pain is real, and it is often harder, not easier, to treat. This section explains how the nurse adapts pain care for these patients and builds the trust that care depends on.

Chronic Pain in Hospital

A patient who takes medications for chronic pain at home usually continues them in hospital unless there is a clear reason to stop, such as oversedation, a new kidney problem or surgery that prevents swallowing. The nurse confirms the home regimen through medication reconciliation (Chapter 1, section 1.7), including the drug, dose, timing and last dose taken. Stopping a long-term opioid abruptly can cause withdrawal and worse pain; when a dose must be reduced, it is done gradually (Busse et al., 2017).

Acute pain from surgery or injury comes on top of the chronic pain. A patient who regularly takes opioids has tolerance, so usual doses may give little relief. Ontario's quality standard calls for these patients to receive care from clinicians with pain expertise. Any short-term increase in opioids should come with a plan to return to the previous dose (Health Quality Ontario, 2018). Multimodal analgesia (section 5.3) is especially valuable here.

The nurse asks about the patient's own pain plan: what usually works, what goals matter, and which activities they want to manage. Function, such as walking to the bathroom, doing breathing exercises or sleeping, is often a more useful goal than a pain score of zero. The 2017 Canadian guideline on opioids for chronic non-cancer pain remains the national reference (Busse et al., 2017). At discharge, the nurse makes sure the patient's usual prescriber learns of any change to the regimen, so that the plan to return to the previous dose is carried out in the community.

Opioid Agonist Treatment and Acute Pain

Opioid agonist treatment (OAT) treats opioid use disorder with a long-acting opioid that prevents withdrawal and cravings. Canada's 2024 national guideline recommends **buprenorphine** and **methadone** as preferred first-line options. Slow-release oral morphine is a second-line option (Yakovenko et al., 2024). Buprenorphine is often given as buprenorphine-naloxone, dissolved under the tongue. It is also available as Sublocade, an extended-release injection under the skin given only by a health care professional. Its monograph advises non-opioid analgesia whenever possible for acute pain, and this advice extends to anyone who has received it within the past 6 months (Indivior UK, 2025).

A patient on OAT usually continues it in hospital. Ontario's quality standard states that people taking methadone or buprenorphine-naloxone continue it during acute pain (Health Quality Ontario, 2018). Before giving the first hospital dose, the team confirms the current dose and whether today's dose was already taken, by calling the community pharmacy or prescriber (College of Physicians & Surgeons of Manitoba [CPSM], 2023). This step prevents a double dose or a dangerous gap. Methadone stays in the body a long time, so a patient who receives too much needs prolonged monitoring (ISMP Canada, 2014).

The daily OAT dose is the baseline that prevents withdrawal; it does not provide significant relief of acute pain (CPSM, 2023). Patients on OAT therefore usually need additional analgesia for acute pain. Multimodal measures come first. When opioids are needed, they are added to the OAT, and because of tolerance, higher doses may be required (CPSM, 2023; Indivior UK, 2025). Undertreating acute pain in patients on OAT is poor care, and it rests partly on misconceptions that can be corrected (Alford et al., 2006). The nurse advocates for an addiction medicine or acute pain service consultation when one is available. The nurse also keeps monitoring sedation and breathing, because tolerance does not remove risk.

Stigma, Trust and Harm Reduction

In a Vancouver study, people who use drugs and had left hospital against medical advice described stigma, feeling neglected, and poorly managed pain and withdrawal in the emergency department. Some said these experiences made them less willing to come back for care (Mayer et al., 2023). Stigma also works through policies and routines, not only through individual attitudes (Health Canada, 2022).

The nurse counters this with trauma-informed, non-judgmental care (Chapter 2). Many patients who use drugs have past experiences of being dismissed or mistreated in health care, and First Nations, Inuit and Métis patients may also have faced Indigenous-specific

racism (Chapter 2, sections 2.2 and 2.3). The nurse believes and assesses the patient's report of pain and asks about withdrawal symptoms. The nurse explains the plan, including when the next dose is due and why, and follows through on what was promised. Small, reliable actions rebuild trust. Person-first language in conversation, handover and documentation shows respect and shapes how colleagues see the patient.

Harm reduction means practical steps that reduce the harms of substance use without requiring a person to stop using. In hospital, it can include treating withdrawal promptly, offering naloxone and teaching, and connecting the patient with community services. The nurse involves addiction medicine, social work, or an Indigenous patient navigator or liaison when the patient wants this. These partners can bridge gaps in trust that the unit cannot bridge alone. Canada's 2024 guideline states that evidence-based harm reduction belongs across the continuum of care (Yakovenko et al., 2024).

When a Patient Wants to Leave

When a patient who uses drugs says they want to leave before treatment is finished, the nurse treats this as a cue, not a confrontation. The nurse asks why. Poorly managed pain or withdrawal and feeling judged or dismissed are among the experiences people describe before leaving (Mayer et al., 2023). Many of these can be fixed. The nurse reassesses pain and withdrawal, tells the RN or most responsible practitioner right away, and asks the team to review the plan.

If the patient still chooses to leave, the nurse respects a capable person's decision (consent and capacity are covered in Chapter 1, section 1.5). The nurse also works to make leaving safer. Steps, according to policy, include:

- Offering a naloxone kit and teaching.
- Offering harm reduction supplies.
- Arranging prescriptions and a follow-up plan with the patient's OAT provider or primary care.
- Telling the patient they are welcome to return.

For a patient on OAT, the team communicates directly with the community prescriber and pharmacy, so the patient's next dose is not missed. Any opioid prescription for acute pain is kept short, to match the patient's follow-up at the OAT clinic (CPSM, 2023). The nurse documents the discussion and the patient's own words. Withdrawal management and starting OAT are covered in Chapter 11.

> **PRACTICE STORY**
>
> **"Nobody Believes I'm Hurting"**
>
> *Names and details are fictional; this is a composite story.*
>
> Nurse: Renata Kowalczyk, RPN. Years in practice: 6. Setting: surgical unit, community hospital, Ontario.
>
> Mr. Desmond Ferris was 41 and two days out from a repair of a fractured ankle. At handover I heard, "He's on methadone, so he's probably just looking for more." When I walked in, he was sitting rigid on the edge of the bed, his foot elevated, his jaw tight.
>
> "Nobody believes I'm hurting," he said. "They act like I'm here to get high."
>
> I sat down and asked him to tell me about the pain. He rated it 9 out of 10, worse on movement, and he hadn't been able to get to the bathroom without help. His chart showed his methadone had been given each morning since admission, but nobody had documented confirming his community dose. I called his pharmacy, which confirmed that the dose matched and that his last dose there was the morning he was injured. That was one less worry.
>
> Then I went to my RN, Joel, with what I had: his pain score, his function, his vital signs and his sedation level: wide awake, with no sign of drowsiness. I explained that his methadone was holding off withdrawal, not treating his surgical pain. Joel agreed the plan wasn't working. Together we called the surgical resident and asked about scheduled acetaminophen and an anti-inflammatory, ice and elevation, a review of his opioid order, and an addiction medicine consult.
>
> The consult team came that afternoon. By evening, Mr. Ferris was walking to the bathroom with a walker. Before I left, he said, "Thanks for not treating me like a junkie." I told him he shouldn't have had to thank anyone for that.
>
> The next morning, I raised the handover comment with our manager. I didn't want to blame anyone; I wanted us to talk about how we hand over patients on OAT.
>
> Reflect: Which parts of Mr. Ferris's care were within Renata's scope as an RPN, and when was consulting the RN the right step? How could the unit change its handover language for patients on OAT?

Chapter 5 Summary

Introduction

- Pain is a common reason for admission and a major source of distress; both under-treatment and over-treatment cause harm.
- Nurses assess pain, give analgesics and non-drug measures, monitor for adverse effects and escalate when the plan is not working.

5.1 Understanding Pain

- The IASP (2020) defines pain as an unpleasant sensory and emotional experience; each person's report of pain deserves respect, and inability to communicate does not rule out pain.
- Pain signals involve transduction, transmission, perception and modulation; descending pathways and endogenous opioids can turn signals down or up.
- Peripheral and central sensitization make the nervous system more responsive, producing allodynia and hyperalgesia.
- Pain is nociceptive (somatic or visceral), neuropathic or nociplastic; chronic pain lasts or keeps returning for longer than 3 months.
- About one in five people in Canada live with chronic pain, and some groups are disproportionately affected; stigma and uneven access are common.

5.2 Pain Assessment

- Self-report is the reference standard; the 0–10 numeric rating scale is the default, with verbal descriptor and faces scales as alternatives.
- A comprehensive assessment covers pain's features, its effect on function, sleep and mood, the patient's goals and all analgesics and substances used.
- Bias in pain care is documented in Canada; nurses use interpreters, reflect on their own biases and give culturally safe care.
- For adults who cannot self-report, nurses attempt self-report, look for causes, use PAINAD (advanced dementia) or CPOT (critical illness), involve family and reassess after treatment; vital signs alone are not reliable indicators.
- Pain is reassessed after each intervention and documented with the tool, score, function and, with opioids, sedation and breathing.

5.3 Multimodal and Non-Opioid Analgesia

- Multimodal analgesia combines non-opioid drugs and non-drug measures, adding opioids only when needed, to improve relief and reduce opioid harms.
- The Canadian intravenous acetaminophen monograph sets an adult maximum of 4,000 mg in 24 hours for adults of at least 50 kg (3,000 mg may be appropriate with liver risk factors), counting every product and route.
- NSAIDs carry risks of gastrointestinal bleeding, kidney injury, cardiovascular events and bleeding with anticoagulants; the nurse checks kidney function, bleeding and the medication list.
- Gabapentinoids help neuropathic pain but increase the risk of slowed breathing and overdose with opioids.
- Positioning, splinting, early movement, heat and cold, relaxation, distraction, sleep and education are part of every plan.

5.4 Opioids: Safe Use in Hospital

- Opioids relieve pain mainly through mu-opioid receptors in the brain and spinal cord; the same receptors cause sedation, respiratory depression and constipation.
- Key drug points: codeine and tramadol depend on CYP2D6 metabolism, morphine metabolites build up in kidney impairment, and fentanyl patches are never used for acute pain or in opioid-naive patients.
- Increasing sedation usually comes before respiratory depression. The nurse assesses sedation, breathing and SpO2, remembering that SpO2 can look normal on supplemental oxygen.

- At unacceptable sedation, the nurse holds opioids, rouses the patient, escalates, and calls for help and gives naloxone per order when the patient barely responds.
- Opioids are high-alert medications; safeguards include tall man lettering, standard concentrations, independent double checks and smart pumps.
- Tolerance and physical dependence are expected with regular use and are not opioid use disorder; discharge teaching covers short courses, tapering, safe storage, disposal and naloxone.

5.5 Patients Living With Chronic Pain or Opioid Use Disorder

- Patients with chronic pain usually continue their home regimen; long-term opioids are never stopped abruptly, and function-based goals guide care.
- Patients on methadone or buprenorphine continue OAT after the dose is confirmed with the community pharmacy or prescriber.
- OAT prevents withdrawal but does not treat acute pain through the day, so additional multimodal analgesia, and opioids when needed, are usually required.
- Stigma leads to undertreated pain and early departure from hospital; trauma-informed care, person-first language and harm reduction build trust.
- When a patient wants to leave, the nurse explores reasons, escalates, and offers naloxone, harm reduction supplies and follow-up.

Key Terms (55)

acute pain: pain of recent onset, usually from injury, illness, surgery or trauma, that settles as the cause heals

adjuvant analgesic: a drug whose main use is not pain relief but which relieves some types of pain, especially neuropathic pain

allodynia: pain from a stimulus that does not normally cause pain, such as light touch

bowel regimen: a scheduled laxative plan started with regular opioids to prevent constipation.

buprenorphine: a partial mu-opioid agonist used as a first-line opioid agonist treatment, often combined with naloxone or given as an extended-release injection.

capnography: continuous measurement of exhaled carbon dioxide, which detects hypoventilation directly.

central sensitization: increased responsiveness of pain neurons in the spinal cord and brain to normal or weak input

chronic pain: pain that lasts, or keeps returning, for longer than 3 months

chronic postsurgical pain: pain that begins or worsens after surgery and persists beyond healing, at least 3 months after surgery

comprehensive pain assessment: an in-depth assessment of pain's onset, location, quality, intensity, timing, aggravating and relieving factors, effects on function, the person's goals and treatment history

COX-2 inhibitor: an NSAID that acts mainly on the COX-2 form of the enzyme, such as celecoxib

Critical-Care Pain Observation Tool (CPOT): an observational tool scoring four behaviours from 0 to 8 for critically ill adults who cannot self-report

endogenous opioids: the body's own opioid substances, which help reduce pain signals

epidural analgesia: delivery of a local anesthetic, often with an opioid, through a catheter into the epidural space.

Faces Pain Scale–Revised (FPS-R): a self-report scale of six faces scored 0 to 10, developed for children

full agonist: an opioid that fully activates the mu receptor, with effects that keep increasing as the dose rises.

gabapentinoid: gabapentin or pregabalin, anticonvulsants used for neuropathic pain that raise the risk of opioid overdose and slowed breathing when combined with opioids

harm reduction: practical measures that reduce the harms of substance use without requiring the person to stop using.

high-alert medication: a drug that is more likely to cause serious harm when an error occurs, such as an opioid or insulin.

hyperalgesia: more pain than expected from a stimulus that normally causes pain

independent double check: a check in which a second practitioner separately verifies a drug, dose, calculation or pump setting before administration.

methadone: a long-acting full opioid agonist used as a first-line opioid agonist treatment; its long duration of action calls for prolonged monitoring after excess doses.

modulation: the nervous system's ability to increase or decrease pain signals, largely through pathways descending from the brainstem

morphine milligram equivalent (MME): a way of expressing different opioids as an equivalent amount of oral morphine, so that total opioid exposure can be compared.

mu-opioid receptor: the opioid receptor most responsible for pain relief, found in pain-modulating areas of the brain and spinal cord and in the gut wall.

multimodal analgesia: the combined use of medications, procedures and non-drug measures that act on different parts of the pain pathway

naloxone: an opioid antagonist that reverses opioid effects, including respiratory depression.

neuropathic pain: pain resulting from damage to, or disease of, the nerves that carry sensation

nociception: the nervous system's process of detecting and encoding harmful stimuli; it is not the same as pain

nociceptive pain: pain from actual or threatened damage to tissue other than nerves, with a normally working nervous system

nociceptor: a sensory nerve ending that responds to strong heat, pressure or chemical stimuli and converts them into nerve signals

nociplastic pain: pain from altered pain processing without clear tissue damage or nerve disease to explain it

nonsteroidal anti-inflammatory drug (NSAID): a drug that reduces pain and inflammation by blocking cyclooxygenase enzymes

numeric rating scale (NRS): a self-report scale on which the patient rates pain from 0 (no pain) to 10 (worst pain imaginable)

opioid: a drug that acts on the body's opioid receptors to relieve pain; adverse effects include sedation, respiratory depression and constipation.

opioid agonist treatment (OAT): treatment of opioid use disorder with a long-acting opioid, such as methadone or buprenorphine, that prevents withdrawal and cravings.

opioid use disorder (OUD): a problematic pattern of opioid use causing significant problems or distress, diagnosed when at least 2 of 11 criteria occur within a year.

opioid-induced respiratory depression (OIRD): reduced drive and effort to breathe caused by an opioid, leading to carbon dioxide build-up and possibly respiratory arrest; usually preceded by increasing sedation.

opioid-naive: describes a patient who has not been taking opioids regularly.

pain: an unpleasant sensory and emotional experience linked to, or resembling one linked to, actual or potential tissue damage (IASP definition, 2020)

Pain Assessment in Advanced Dementia (PAINAD) scale: an observational tool scoring five behaviours from 0 to 10 for people living with advanced dementia who cannot self-report

partial agonist: a drug, such as buprenorphine, that activates the mu receptor less fully than a full agonist.

patient-controlled analgesia (PCA): a programmable pump that lets a patient give themselves set doses of analgesic, limited by a lockout interval.

PCA by proxy: unauthorized pressing of a PCA button by someone other than the patient, which bypasses the pump's safety check.

perception: the point at which a person becomes aware of pain, involving areas of the brain for sensation, emotion and thinking

peripheral sensitization: increased responsiveness of nerve endings near damaged tissue, so they fire more easily

physical dependence: the body's adaptation to a drug, so that stopping suddenly or reducing the dose quickly causes withdrawal.

referred pain: pain felt in a body region away from the site of the harmful stimulus, such as pain from an internal organ felt elsewhere

sedation scale: a structured tool for rating how drowsy a patient is, such as the Pasero Opioid-induced Sedation Scale outside critical care or the Richmond Agitation-Sedation Scale in intensive care.

somatic pain: nociceptive pain arising in skin, muscle, bone or joints, often well localized

tolerance: the need for more of a drug to produce the same effect after repeated use.

transduction: the conversion of a harmful stimulus into an electrical signal by nociceptors

transmission: the movement of pain signals from the periphery through the spinal cord to the brain

verbal descriptor scale: a self-report scale on which the patient chooses a word, such as mild, moderate or severe, to describe pain intensity

visceral pain: nociceptive pain arising in internal organs, often harder to locate than somatic pain

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mr. Ernest Pelletier (Questions 1–4): Mr. Ernest Pelletier, 84, lives with advanced dementia and has osteoarthritis of both knees. He was admitted to a medical unit in an Ontario hospital 2 days ago with pneumonia. He speaks only a few words and cannot use a number scale. An RPN is caring for him on the day shift.

1. [CORE] The RPN wants to assess Mr. Pelletier for pain. Which approach is most appropriate?

a. Ask him to rate his pain from 0 to 10 and record the number he says

b. Use the Pain Assessment in Advanced Dementia (PAINAD) scale while helping him turn and wash

c. Use the Critical-Care Pain Observation Tool (CPOT) while he rests quietly in bed between care activities

d. Record his heart rate and blood pressure as the main indicators of pain

Answer: b — PAINAD is designed for people living with advanced dementia who cannot self-report, and observing during care such as turning reveals more than observing at rest (section 5.2). Option a is wrong because he cannot reliably use a number scale; a number given without understanding is not a valid self-report. Option c is wrong because the CPOT is for critically ill adults, and observing only at rest can miss pain. Option d is wrong because vital signs change for many reasons and are not reliable indicators of pain.

2. [CORE] Which finding most strongly suggests that Mr. Pelletier is in pain?

a. He sleeps for 2 hours after lunch

b. His face looks flushed compared with yesterday

c. His heart rate is 92 beats per minute and his temperature is 38.1 °C

d. He grimaces and guards his knees when his legs are moved

Answer: d — Grimacing and guarding a painful area when it is moved are behavioural cues of pain that can be seen on any skin tone (section 5.2). Option a is wrong because sleep does not rule out pain. Option b is wrong because colour changes are unreliable, can be hard to see on darker skin and may reflect fever. Option c is wrong because a raised heart rate and temperature may be explained by his pneumonia, and vital signs alone are not reliable signs of pain.

3. [CORE] Mr. Pelletier's PAINAD score is 6 during morning care. The RPN gives his prescribed analgesic. What should the RPN do next?

a. Repeat PAINAD during movement once the drug should be working, and document the result

b. Reassess at the end of the shift using a 0 to 10 numeric rating scale

c. Document the dose given and reassess only if his family reports that he seems uncomfortable

d. Wait until the next scheduled dose and then repeat the PAINAD score

Answer: a — Pain is reassessed after each intervention, at the interval set by policy, with the same tool and during the activity that caused pain, and the result is documented (section 5.2). Option b is wrong because the timing is too late and he cannot use a numeric scale. Option c is wrong because reassessment is the nurse's responsibility; family input adds to it but does not replace it. Option d is wrong because waiting until the next dose leaves the effect of this dose unknown.

4. [CORE] The next afternoon, Mr. Pelletier's PAINAD score rises from 2 to 8. He is newly unable to bear weight on his right leg after being found sitting on the floor beside his bed. What is the RPN's priority action?

a. Give an extra dose of the as-needed analgesic now and recheck his PAINAD score at the end of the shift

b. Reassure him and his daughter that his arthritis often flares in hospital

c. Keep him in bed, assess the leg and promptly consult the RN and the prescriber

d. Record the score and ask the next shift to repeat the PAINAD assessment

Answer: c — A sudden rise in pain score, inability to bear weight and a possible fall suggest a new injury, such as a fracture, that needs urgent assessment. An RPN who notices a change like this acts at once, consults the RN as the patient's needs change, and informs the prescriber (section 5.2; Chapter 1, section 1.3). Option a is wrong because treating the score without finding the cause could hide a serious injury. Option b is wrong because it assumes a cause without assessment. Option d is wrong because it delays escalation.

5. [CORE] A nurse is reviewing the medication list of a 72-year-old patient before giving a prescribed dose of naproxen. Which factors increase this patient's risk of harm from an NSAID? Select all that apply.

a. History of a bleeding stomach ulcer

b. Daily use of a diuretic and an ACE inhibitor

c. Taking warfarin

d. Daily acetaminophen use within the recommended limit

e. Vomiting and poor fluid intake for 2 days

f. Normal kidney function on recent blood work

Answer: a, b, c, e — A past ulcer or bleed raises the risk of gastrointestinal bleeding; a diuretic and an ACE inhibitor, and dehydration, raise the risk of kidney injury; and anticoagulants such as warfarin raise the risk of serious bleeding (section 5.3). Option d is wrong because acetaminophen within the daily limit does not add to NSAID risks. Option f is wrong because normal kidney function lowers, rather than raises, the risk of kidney injury.

6. [CORE] A patient who weighs 70 kg receives scheduled acetaminophen after surgery. At home he takes a cold and flu medicine and a prescription tablet that combines an opioid with acetaminophen. Which teaching is most important?

a. Acetaminophen is safe at any dose because it is sold without a prescription

b. Acetaminophen should be taken only on an empty stomach

c. The daily maximum counts acetaminophen from every product, so he should check all labels

d. Combination products contain too little acetaminophen to add meaningfully to his daily total

Answer: c — The maximum daily dose includes acetaminophen from all products and routes, and most liver injury involves exceeding that limit, often with more than one product (section 5.3). Option a is wrong because acetaminophen can cause serious liver injury. Option b is wrong because no such rule applies; the key risk is total dose. Option d is wrong because combination products can add substantially to the total.

7. [CORE] A patient with diabetes describes burning, electric pain in both feet that is worse at night and says the bed sheets hurt to touch. Which type of pain is this most likely to be?

a. Neuropathic pain
b. Visceral pain
c. Referred pain
d. Somatic nociceptive pain

Answer: a — Burning, electric pain and pain from light touch (allodynia) are typical of neuropathic pain, which results from disease of the nerves carrying sensation, as in diabetic neuropathy (section 5.1). Option b is wrong because visceral pain comes from internal organs, not from nerve disease. Option c is wrong because referred pain is pain felt away from its source, such as pain from an internal organ felt elsewhere in the body. Option d is wrong because somatic pain arises from damage to skin, muscle, bone or joints, not from nerve disease.

8. [CORE] An RPN is caring for a patient on day 2 after bowel surgery whose pain has been well controlled. The patient now reports new, severe abdominal pain rated 9 out of 10 that is not relieved by the prescribed analgesic, and the abdomen is distended. Which action is most appropriate for the RPN?

a. Give a second dose of the as-needed analgesic earlier than ordered
b. Apply a heating pad to the abdomen and reassess in 2 hours
c. Encourage the patient to walk in the hallway to relieve gas pain
d. Stay with the patient, complete a focused assessment, and consult the RN and prescriber promptly

Answer: d — New, severe, unrelieved pain with abdominal distension after surgery is a change in condition that may signal a complication. Every nurse who notices deterioration acts and escalates; the RPN consults the RN as the patient's needs change and informs the prescriber, following employer policy (section 5.2; Chapter 1, section 1.3). Option a is wrong because giving a dose outside the order is not within the nurse's authority and could hide a complication. Option b is wrong because heat delays assessment of a possible complication. Option c is wrong because it assumes a minor cause without assessment.

9. [CORE] A patient says, "My pain is 8 out of 10," but is laughing with visitors. Which response by the nurse is best?

a. Record a lower score that matches the patient's behaviour
b. Accept the rating, ask what the pain stops them doing, and offer treatment
c. Tell the patient that the pain must be lower than 8 because they are laughing
d. Ask the visitors to estimate how much pain the patient seems to be having

Answer: b — The patient's self-report is the reference standard and deserves respect; people cope with pain in different ways, and function-based questions guide treatment (sections 5.1 and 5.2). Option a is wrong because the nurse records the patient's report, not the nurse's impression. Option c is wrong because it dismisses the report and damages trust. Option d is wrong because proxy reports are used only when a patient cannot self-report.

Case: Mr. Lionel Gagnon (Questions 10–15): Mr. Lionel Gagnon, 68, had an open bowel resection under general anesthesia yesterday afternoon. He has obstructive sleep apnea and uses CPAP at home, but his machine is still at home. His weight is 112 kg, with a body mass index of 38. He receives hydromorphone by PCA with no basal infusion, and gabapentin was started this morning. He did not take opioids before admission. At 2200 he was fully awake, with a respiratory rate of 18, SpO2 96% on 2 L/min of oxygen by nasal cannula, and pain 4 out of 10. At 0200 the nurse finds him drifting off in the middle of answering questions. His respiratory rate is 10 and shallow, with loud snoring and brief pauses. SpO2 is 94% on 2 L/min. His temperature is 37.4 °C, heart rate 84 and blood pressure 128/74 mm Hg. The PCA history shows he pressed the button 14 times in the past 4 hours. His abdominal dressing is dry, and he rates his pain 3 out of 10 when roused.

10. [CORE] The nurse reviews Mr. Gagnon's 0200 findings. Which findings need immediate follow-up? Select all that apply.

a. Drifts off in the middle of answering questions
b. Respiratory rate of 10 and shallow
c. Temperature 37.4 °C
d. Loud snoring with brief pauses in breathing
e. Dry abdominal dressing
f. Pain 3 out of 10 when roused

Answer: a, b, d — Falling asleep mid-conversation is advancing sedation, the earliest sign of opioid-induced respiratory depression (a). A slow, shallow respiratory rate (b) and snoring with pauses (d) suggest hypoventilation and airway obstruction (section 5.4, Table 5.4). A temperature of 37.4 °C (c) is not a fever and is common the day after surgery. A dry dressing (e) is expected. Pain of 3 out of 10 (f) shows the pain is controlled; it is not a concern in itself.

11. [CORE] The nurse analyzes the cues. Which combination of factors best explains Mr. Gagnon's risk of opioid-induced respiratory depression?

a. A normal blood pressure, a normal heart rate and a pain score of only 3 out of 10 when roused
b. Use of PCA without a basal infusion, together with a dry and intact abdominal surgical dressing
c. Supplemental oxygen at 2 L/min by nasal cannula and a temperature of 37.4 °C overnight
d. Untreated sleep apnea, obesity, age, abdominal surgery, no prior opioids and added gabapentin

Answer: d — Sleep apnea, obesity, older age, recent abdominal surgery, being opioid-naive and a gabapentinoid added to an opioid are all recognized risk factors, and they add together (d) (section 5.4). Normal blood pressure and heart rate do not raise risk (a). PCA without a basal infusion is the safer setup, and the dressing is unrelated (b). Oxygen does not cause respiratory depression, though it can mask it, and the temperature is unrelated (c).

12. [CORE] Which problem is the priority for Mr. Gagnon at 0200?

a. Acute postoperative pain that is not controlled by the current PCA settings
b. Postoperative infection at the surgical site
c. Advancing opioid-induced sedation with hypoventilation
d. Fluid volume deficit after bowel surgery

Answer: c — Advancing sedation, slow shallow breathing and pauses point to opioid-induced sedation and respiratory depression, which can progress to respiratory arrest (c) (section 5.4). His pain is controlled at 3 out of 10 (a). There is no fever, and the dressing is dry (b). His heart rate and blood pressure are normal, and nothing suggests hypovolemia (d).

13. [CORE] Which actions should the nurse plan for Mr. Gagnon now? Select all that apply.

a. Pause PCA doses according to policy and remove the button from his reach
b. Rouse him fully and coach him to take deep breaths
c. Increase oxygen to 6 L/min and reassess in 1 hour
d. Notify the RN or prescriber immediately with the findings
e. Ask his daughter to press the PCA button if he seems uncomfortable while asleep
f. Begin continuous SpO2 monitoring, or capnography where available, as policy allows
g. Give a PRN dose of lorazepam to help him sleep

Answer: a, b, d, f — Holding further opioid (a), waking him and coaching deep breaths (b), escalating at once (d) and closer monitoring (f) match the actions for unacceptable sedation (section 5.4, Table 5.4). Raising oxygen and waiting an hour (c) can mask rising carbon dioxide while the patient deteriorates. Having a family member press the button (e) is PCA by proxy and bypasses the safety check. A benzodiazepine (g) would deepen sedation and respiratory depression.

14. [CORE] At 0215, Mr. Gagnon responds only to a firm shake and his respiratory rate is 6. What should the nurse do first?

a. Stay with him, call for help and stimulate him while supporting his airway
b. Leave the room to find the prescriber and ask for a naloxone order
c. Remove his oxygen to see what his SpO2 is on room air
d. Document the findings in detail, then recheck his sedation and breathing in 15 minutes

Answer: a — Minimal response with a respiratory rate of 6 is an emergency. The nurse stays, calls for help (rapid response per policy), stimulates and supports the airway and breathing, then gives naloxone per order or medical directive (a) (section 5.4). Leaving the patient alone (b) delays help. Removing oxygen (c) worsens hypoxemia. Waiting 15 minutes (d) risks respiratory arrest.

15. [CORE] Naloxone is given according to the medical directive, and the PCA remains paused. Which findings 30 minutes later show that the interventions have been effective? Select all that apply.

a. He is awake and speaks in full sentences
b. Respiratory rate 15, regular and of normal depth
c. He falls asleep while the nurse is asking a question
d. SpO2 96% on 2 L/min, with no snoring or pauses
e. He rates his pain 9 out of 10 and is restless
f. He wakes easily to voice and stays awake

Answer: a, b, d, f — Being awake and conversing (a), a normal respiratory rate and depth (b), good SpO2 without obstructed breathing (d), and waking easily and staying awake (f) show that sedation and breathing have improved (section 5.4, Table 5.4). Falling asleep mid-question (c) means sedation persists and needs further action. Severe pain and restlessness (e) suggest the naloxone also reversed his analgesia; this needs reassessment and a new plan, likely with more non-opioid analgesia, not a return to the old plan.

16. [CORE] An RPN is caring for a postoperative patient whose hydromorphone PCA is managed by an RN, as hospital policy requires. The RPN finds the patient dozing off mid-sentence, with a respiratory rate of 10. What is the RPN's best action?

a. Document the findings and mention them to the RN at the next break

b. Wake the patient, check breathing and SpO2, and notify the RN immediately

c. Wait for the RN to complete the next scheduled PCA assessment and report then

d. Increase the PCA lockout interval on the pump

Answer: b — Every nurse who notices deterioration acts at once and escalates. The RPN wakes the patient, assesses breathing and oxygenation, and consults the RN right away (b) (section 5.4, Scope in Practice box). Delaying the report (a, c) risks progression to respiratory arrest. Changing pump settings (d) is outside this RPN's role under the policy and requires an order.

17. [CORE] A new graduate RPN asks about RPN practice with opioids in an Ontario hospital. Which response is accurate?

a. "Only RNs may give controlled substances; RPNs give non-opioid analgesics."

b. "CNO requires that RPNs care only for patients who are stable and predictable."

c. "RPNs give opioids on an order or medical directive. Whether they manage PCA or epidurals depends on employer policy, their education and the patient's needs."

d. "RPNs may start an opioid on their own judgment if the patient's pain is severe."

Answer: c — Authority, competence and context determine practice. RPNs give opioids on an order or medical directive, and employer policy, education and patient needs shape PCA and epidural care (c) (section 5.4, Scope in Practice box). RPNs are not barred from giving controlled substances (a). Assigning by stability is a common employer practice, not a CNO rule (b). Nurses do not initiate opioids in a public hospital (d).

18. [CORE] A patient started regular oxycodone yesterday after a hip fracture repair. Which order should the nurse expect to accompany it?

a. A scheduled stimulant laxative, osmotic laxative or both

b. A fluid restriction of 1 L per day to prevent urinary retention

c. A fibre supplement alone, given only if no bowel movement for 5 days

d. An antidiarrheal to be given as needed for any loose stools

Answer: a — Nearly everyone on regular opioids becomes constipated, and laxatives are first-line, so a scheduled bowel regimen usually starts with regular opioids (a) (section 5.4). Fluid restriction (b) would worsen constipation and does not prevent urinary retention. Waiting 5 days and relying on fibre alone (c) lets constipation become established, and fibre without enough fluid can make it worse in a less mobile patient. An antidiarrheal (d) would worsen opioid-induced constipation.

19. [CORE] A patient has taken hydromorphone for 3 weeks after major trauma. He now needs a slightly higher dose for the same relief, and he becomes sweaty and achy when a dose is late. He has no craving and takes the drug only as prescribed. How should the nurse interpret these findings?

a. Opioid use disorder, because he now needs more of the drug

b. An allergic reaction to hydromorphone that causes sweating

c. Drug-seeking behaviour that should be reported to the prescriber

d. Tolerance and physical dependence, both expected with regular use

Answer: d — Needing more drug for the same effect is tolerance, and withdrawal symptoms when a dose is late reflect physical dependence. Both are expected with regular use (d) (section 5.4). Under the diagnostic criteria, needing more of the drug (tolerance) and withdrawal do not count toward OUD when opioids are taken only as medically supervised, and he shows no other criteria (a). Sweating and aching are withdrawal symptoms, not allergy (b). "Drug-seeking" is a stigmatizing label, and his behaviour does not warrant it (c).

20. [CORE] A patient is being discharged after an appendectomy with a 3-day supply of an immediate-release opioid. Which statements by the patient show understanding of the teaching? Select all that apply.

a. "I'll take acetaminophen regularly and use the opioid only if I still need it."

b. "I'll keep the pills in my kitchen drawer so they're easy to find."

c. "I'll bring any leftover pills back to the pharmacy."

d. "A glass of wine at night will help me sleep while I'm taking these."

e. "My wife will call 9-1-1 if she can't wake me."

f. "If the pain gets worse, I'll take two pills at a time."

Answer: a, c, e — Using non-opioid analgesia first (a), returning unused opioids to a pharmacy (c) and knowing that unrousable sleepiness is an emergency (e) are correct (section 5.4, Patient Education box). Opioids should be locked and out of sight, not easy to find (b). Alcohol adds to sedation and respiratory depression (d). Doubling doses (f) is unsafe; worsening pain needs a call to the prescriber.

21. [CORE] A patient on methadone for opioid use disorder is admitted with a fractured femur. Which plan is most appropriate?

a. Confirm the dose with the pharmacy, continue methadone, and add analgesics, including opioids

b. Stop the methadone, because the opioids ordered for the fracture pain will prevent withdrawal

c. Continue the methadone and manage the fracture pain only with ice, splinting and positioning

d. Double the methadone dose to treat the pain, and avoid giving any other opioid in hospital

Answer: a — OAT continues in hospital once the dose is confirmed. It prevents withdrawal but does not treat acute pain through the day, so additional analgesia, including opioids when needed, is usually required (a) (section 5.5). Stopping methadone (b) causes withdrawal and destabilizes recovery. Non-drug measures alone (c) undertreat a fracture. The prescriber, not a fixed rule, sets methadone doses, and doubling them (d) risks dangerous accumulation.

22. [CORE] Which handover statement about the patient in bed 4 uses non-stigmatizing language?

a. "She's an addict, but she has been clean for a year now."

b. "She's a drug seeker; she keeps asking for her PRN early."

c. "She's a heroin abuser who is now on methadone."

d. "She has opioid use disorder and takes methadone; she asked for her PRN 30 minutes early with pain at 8 out of 10."

Answer: d — Person-first, medically accurate language and objective description of behaviour (d) avoid stigma (section 5.4). "Addict" and "clean" (a), "drug seeker" (b) and "abuser" (c) are labels that Health Canada advises against, because they contribute to poorer care and lead people to avoid seeking it.

23. [CORE] A prescriber's order reads "fentanyl patch for postoperative pain" for an opioid-naive patient after knee surgery. What should the nurse do?

a. Apply the patch and monitor sedation every 4 hours

b. Apply the patch and cover it with a heating pad to speed absorption

c. Hold the patch and clarify the order with the prescriber

d. Cut the patch in half to reduce the dose

Answer: c — Fentanyl patches are contraindicated for acute or perioperative pain and in opioid-naive patients at any strength, so the nurse clarifies the order (c) (section 5.4, Table 5.3). Applying it (a) risks serious respiratory depression. Heat increases fentanyl absorption and is dangerous (b). Patches are not cut (d).

24. [CORE] Why does the nurse watch a patient who receives codeine for oversedation, even when the patient takes a usual dose?

a. Codeine is converted to morphine only in people who have kidney disease

b. Some people convert codeine to morphine unusually fast and completely

c. Codeine causes oversedation only when it is combined with acetaminophen

d. Codeine has no effect on breathing, so sedation is the only risk

Answer: b — Codeine works after the liver enzyme CYP2D6 converts it to morphine, and ultra-rapid metabolizers can form enough morphine to overdose on usual doses (b) (section 5.4). This conversion happens in everyone, not only in people with kidney disease (a). The overdose risk comes from the morphine formed, with or without acetaminophen (c). Like all opioids, codeine can slow breathing (d).

25. [CORE] A patient receiving regular morphine has a creatinine that has doubled since admission. On day 3 the patient is increasingly drowsy, although the dose has not changed. What is the most likely explanation?

a. Tolerance has developed, so the same dose now has a stronger effect

b. Opioid use disorder has developed after three days of regular use

c. An allergic reaction to morphine is developing and is causing the drowsiness

d. An active morphine metabolite is building up as kidney function falls

Answer: d — Morphine-6-glucuronide is active and is excreted by the kidneys; it builds up when kidney function falls, increasing sedation over days (d) (section 5.4). Tolerance (a) reduces, not increases, the effect of the same dose. Increasing sedation on an unchanged dose is not a sign of OUD (b). Drowsiness is not an allergic reaction (c).

26. [CORE] A patient receiving IV hydromorphone is on 4 L/min of oxygen by nasal cannula. SpO2 is 98%, but the patient is hard to rouse and breathes 8 times a minute. Which statement best explains the nurse's concern?

a. Oxygen can keep SpO2 normal while carbon dioxide builds up from slow breathing

b. An SpO2 of 98% on oxygen confirms that the patient's breathing is adequate

c. The pulse oximeter is probably malfunctioning and should be replaced before anything else

d. The oxygen flow is suppressing the drive to breathe and should be stopped

Answer: a — With supplemental oxygen, SpO2 can stay normal while hypoventilation lets carbon dioxide build up, so sedation and respiratory rate are the key cues and capnography can detect the problem directly (a) (section 5.4). A normal SpO2 does not prove adequate ventilation (b). Replacing the probe (c) delays action on a clear clinical problem. The opioid, not the oxygen, is causing the slow breathing, and stopping oxygen would worsen hypoxemia (d).

27. [RN] A patient on hydromorphone PCA is pressing the button often, and the pump records many attempts but fewer doses delivered. What explains this?

a. The pump is malfunctioning and is not delivering the programmed demand doses at all

b. A basal infusion is running and is replacing the demand doses he requests

c. The lockout interval blocks doses until the previous dose has had time to act

d. The patient is receiving doses each time the button is pressed

Answer: c — The lockout interval prevents another demand dose until the last one has had time to work, so attempts can exceed delivered doses (c) (section 5.4, Going Deeper box). The pattern is expected and does not mean the pump is faulty (a). A basal infusion runs continuously and does not replace demand doses (b). If every press delivered a dose (d), attempts would equal doses. Many attempts can signal uncontrolled pain, and the nurse reassesses.

28. [RN] A patient has a thoracic epidural infusion and received enoxaparin as ordered. Four hours after the catheter is removed, the patient reports new numbness and weakness in both legs. What is the nurse's priority?

a. Report the findings immediately as a possible spinal or epidural hematoma

b. Reposition the patient, elevate the legs and reassess sensation and strength in 2 hours

c. Apply warm packs to the legs

d. Give the next dose of enoxaparin as scheduled

Answer: a — New numbness or weakness after epidural catheter use in a patient receiving an anticoagulant suggests a spinal or epidural hematoma, which can cause permanent paralysis and needs urgent diagnosis and treatment (a) (section 5.4, Going Deeper box). Waiting (b) delays treatment. Warm packs (c) do not address the cause. Another anticoagulant dose (d) could worsen bleeding and should be held pending urgent review.

29. [RN] A nursing student asks what morphine milligram equivalents (MME) are used for. Which answer is accurate?

a. They let nurses convert a patient from one opioid to another at the bedside

b. They state each opioid as an equivalent amount of oral morphine, to compare total exposure

c. They measure how sedated a patient is

d. They set one maximum safe daily dose for each opioid that applies to every adult patient

Answer: b — MME express different opioids in morphine terms so that total opioid exposure can be compared, for example against guideline thresholds (b) (section 5.4, Going Deeper box). Conversions are done by prescribers and pharmacists, not nurses at the bedside (a). Sedation is measured with a sedation scale (c). Thresholds guide prescribing but do not set a safe maximum for every patient (d).

30. [RN] A visitor tells the nurse, "When Dad moans in his sleep, I press his pain button so he doesn't wake up hurting." What is the nurse's best response?

a. "That's helpful; it keeps his pain under control."

b. "Only your dad should press the button. When he is too sleepy to press it, that is a safety signal that he has had enough medicine."

c. "Please press it no more than once an hour, so he doesn't get too much medicine."

d. "It's fine to press it, as long as his breathing seems normal and he isn't snoring."

Answer: b — PCA by proxy bypasses the safety check that a drowsy patient stops pressing the button, and it has caused serious harm. Only the patient presses the button (b) (section 5.4, Going Deeper box). Praising the practice (a) or limiting how often it is done (c) still allows proxy dosing. Family members cannot reliably judge breathing or sedation (d), and the nurse reassesses the patient's pain and sedation.

06 Recognizing Deterioration and Shock

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Recognize early cues of clinical deterioration, including trends, changes in mental status, and the concerns of patients and families.
2. Explain how early warning scores support, but do not replace, nursing judgment.
3. Escalate concerns promptly and clearly using SBAR, rapid response teams and the hospital's escalation pathway.
4. Explain how shock harms the body, its stages, and the four types: hypovolemic, cardiogenic, distributive and obstructive.
5. Recognize and give first care for hypovolemic, cardiogenic, anaphylactic and obstructive shock, as ordered and per hospital policy.
6. Give first care for anaphylaxis, including intramuscular epinephrine, and teach the patient before discharge.
7. Distinguish RN and RPN roles in caring for patients who are deteriorating or in shock, using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4	Clinician; Scholar	Foundations of Practice
3, 7	Communicator; Coordinator; Leader	Collaborative Practice; Professional Practice
5, 6	Clinician; Educator	Foundations of Practice

Introduction

In a large United States registry of in-hospital cardiac arrests on general wards and telemetry or step-down units, 59.4% of patients had at least one abnormal heart rate, respiratory rate or systolic blood pressure in the 1 to 4 hours before the arrest, and the risk of death rose with each additional abnormal sign (Andersen et al., 2016). A review of respiratory rate monitoring described earlier research in which a rate above 24 breaths per minute was often recorded as long as 24 hours before a serious adverse event (Cretikos et al., 2008). Those hours are a window for rescue.

The nurse, at the bedside more than anyone else on the team, is often first to notice a change. This chapter shows how to recognize **clinical deterioration** (a worsening of the patient's physiological condition that can lead to serious harm or death if untreated) and how to act on it. Section 6.1 covers early cues, 6.2 early warning scores and escalation, and 6.3 how shock develops; sections 6.4 to 6.6 cover the types of shock and nursing care.

Sepsis is covered in Chapter 4, pulse oximetry across skin tones in Chapter 12, pulmonary embolism in Chapter 15, acute coronary syndromes and heart failure in Chapters 17 and 18, transfusion in Chapter 20, and neurogenic shock in Chapter 32.

6.1 Recognizing Clinical Deterioration

Failure to Rescue

In 1992, Silber and colleagues studied deaths after surgery. They separated two questions: how often patients developed a complication, and how often patients who developed one then died. They called the second measure **failure to rescue**: death after a complication (Silber et al., 1992). Complication rates were linked mainly to characteristics of the patients, while failure to rescue was linked more strongly to characteristics of the hospital and depended less on how sick patients were on admission (Silber et al.,

1992). In other words, some complications will happen, but whether a patient survives one depends a great deal on the care around them, including how quickly the team notices the problem and responds.

Cues are missed for many reasons. A finding that has been slightly off all shift can start to seem normal for that patient. A heavy assignment leaves less time to look closely. Vital sign sets may be incomplete: the respiratory rate, in particular, is the sign most often left out of the record, even in patients whose main problem is respiratory (Cretikos et al., 2008). Night shifts carry their own risks, discussed later in this section. Finally, a nurse may hesitate to call a busy physician or to question a plan that a senior colleague made. Each of these is a system problem as well as a personal one, and Chapter 1, section 1.6 describes the safety culture that helps teams address them.

Early Cues

Deterioration usually shows first as small changes in breathing, thinking, perfusion or urine output rather than as a falling blood pressure.

- **Respiratory rate and effort:** An abnormal respiratory rate helps predict serious events such as cardiac arrest (Cretikos et al., 2008). An adult breathing more than 20 times a minute is probably unwell, and one breathing more than 24 times a minute may be critically ill (Cretikos et al., 2008). The nurse also notes effort: use of neck and shoulder muscles, speaking in short phrases, or a patient who must sit upright to breathe. Oxygen saturation measured by pulse oximetry (SpO2) does not replace counting the respiratory rate, because the two give different information (Cretikos et al., 2008).
- **Mental status:** New confusion, restlessness, agitation or unusual drowsiness can signal poor oxygen delivery to the brain. When it is unclear whether confusion is new, it is treated as new until proven otherwise (Royal College of Physicians [RCP], 2017). Chapter 8 describes delirium in older adults.
- **Urine output:** Output below 0.5 mL/kg/h is one of the body's "windows" on poor perfusion (Vincent & De Backer, 2013).
- **Skin:** Skin that is cool, clammy or mottled, with slow capillary refill, suggests that blood is being diverted away from the skin (Cecconi et al., 2014).
- **Heart rate:** A rising heart rate is often an early compensating response.
- **Blood pressure:** A fall in blood pressure is frequently a late sign, because the body works hard to hold it steady (see section 6.3).

Colour changes look different on different skin tones, and visual assessment alone is unreliable (Pusey-Reid et al., 2023). On dark skin, cyanosis may make the lips, tongue and the skin around the mouth look grey or whitish, and a bluish tint may show in the nail beds, conjunctivae, palms and soles. Pallor may appear as ash-grey mucous membranes, or the conjunctivae and the lining of the mouth may look pale (Pusey-Reid et al., 2023). The nurse checks these sites in natural or halogen light rather than fluorescent light, compares with an unaffected area and with the patient's own baseline, and pairs what is seen with what is felt: skin temperature, moisture and capillary refill. Chapter 12 explains how skin pigmentation can affect pulse oximeter readings.

Table 6.1 groups common cues with what they may mean and the nurse's first actions (Table 6.1).

Table 6.1 Cues of deterioration, what they may mean and first nursing actions (Cretikos et al., 2008; Vincent & De Backer, 2013; Cecconi et al., 2014; RCP, 2017)

Cue	What it may mean	First nursing actions
Respiratory rate above 20 per minute, or rising; more effort to breathe	Hypoxemia, acidosis, sepsis, pain, fluid overload or a developing lung problem	Count for a full minute; check SpO2 and effort; sit the patient up; complete a full set of vital signs; escalate if above 24 or rising
Falling SpO2 or a new or increased need for oxygen	Worsening gas exchange or ventilation	Check probe and waveform; assess breathing and colour; apply or adjust oxygen per order or policy; escalate
Heart rate rising or above 100 per minute	Pain, fever, fluid or blood loss, sepsis, dysrhythmia or early compensation for shock	Check rhythm and blood pressure; look for bleeding and fluid losses; review trends; escalate if sustained or rising
Systolic blood pressure falling, or well below the patient's usual value	Compensation is failing; possible shock	Repeat the reading manually; check perfusion and level of consciousness; escalate urgently

Cue	What it may mean	First nursing actions
New confusion, agitation or drowsiness	Poor brain perfusion or oxygenation, low glucose, sepsis, drug effect or delirium	Assess level of consciousness and glucose; keep the patient safe; treat as new until proven otherwise; escalate
Cool, clammy, mottled or grey skin; slow capillary refill	Blood diverted from the skin to vital organs	Compare with baseline and other sites; check temperature of limbs; escalate with other findings
Urine output below 0.5 mL/kg/h	Poor kidney perfusion, low volume or urinary retention	Check catheter or bladder; total intake and output; escalate if it continues
New fever, an unusually low temperature or new rigors	Infection or sepsis; low temperature can be a sign of severe illness	Complete a full set of vital signs; use sepsis screening (Chapter 4, section 4.6); escalate
New or worse pain, or a new symptom such as chest pain	A new complication such as bleeding, ischemia or a leak	Assess the pain fully; check vital signs; do not attribute it to the known diagnosis without review; escalate

Trends Matter More Than Single Readings

A single reading tells the nurse where the patient is; a trend tells the nurse where the patient is heading. A heart rate of 98 beats per minute may be reassuring in one patient, but it is a warning in a patient whose rate was 70 at the start of the shift. The nurse compares each set of vital signs with the previous ones and with the patient's usual values, such as a blood pressure that normally runs high (Figure 6.1).

Figure 6.1 (a) A bedside monitor showing heart rate, oxygen saturation and blood pressure for a simulated patient. (b) A pulse oximeter with a finger sensor. Monitors show single readings; the nurse looks at the trend over time. (credit: (b) "Pulse oximeter" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Several mildly abnormal signs together can matter more than one very abnormal sign. In the registry study described in the introduction, each additional abnormal vital sign before a cardiac arrest was linked with a higher risk of death (Andersen et al., 2016). An adult on a general ward with a respiratory rate above 24 per minute needs close monitoring and review even when every other sign is normal (Cretikos et al., 2008).

Incomplete sets hide trends. A missing respiratory rate removes one of the most useful predictors of serious events (Cretikos et al., 2008). The rate is best counted while the patient is resting and unaware of being counted, over a full minute, because breathing often speeds up once a patient knows it is being watched (Gandevia & McKenzie, 2008). A guessed or rounded number defeats the purpose.

Listening to Patients and Families

Nurses' worry is a real cue. A systematic review of 18 studies found that nurses' worry or concern was triggered by signs such as changes in breathing, circulation or mentation, agitation, new pain, a recovery that is not following the expected path, and patients saying they feel unwell, and that it sometimes appeared before vital signs changed (Douw et al., 2015). Some nurses in the included studies were simply convinced that something was wrong without being able to say why. That feeling is a reason to look harder and

to ask for help, not a reason for embarrassment. The authors noted that some rapid response systems allow worry alone as a calling criterion (Douw et al., 2015).

Patients and families also notice change. A family member who says "this isn't like her" is reporting a change from baseline that no chart contains. Some hospitals give patients and families a direct way to call for help when they feel their concern is not being heard. At St. Paul's Hospital in Vancouver, Providence Health Care's Code H let patients and families phone a clinical resource nurse who was not part of their care team; in a survey, 85% of the patients and families who responded said they felt safer knowing Code H existed (Parsons et al., 2015). In the United States, the Condition Help model asks patients and families to call when there is an emergency and staff can't be reached, when they see a change the care team is not recognizing, or when care breaks down or the plan is unclear (Eden et al., 2017). Language barriers, past experiences of racism and distrust of hospitals can all make a patient or family slower to speak up. Culturally safe care, described in Chapter 2, helps make it safe to raise a concern.

Vital Sign Frequency and Night Shifts

How often vital signs are measured depends on orders, hospital policy and the patient's condition. Policy sets a minimum, not a maximum: when a patient's condition changes, the nurse measures more often. Early warning scores also set monitoring frequency (section 6.2).

Nights need extra care. In a large English hospital study, fewer vital sign sets were recorded overnight, and many patients with high early warning scores in the late evening had no further observations recorded for the next 6 hours (Hands et al., 2013). Sicker patients were checked again sooner, but not as soon as the hospital's own protocol required (Hands et al., 2013). Fewer staff, sleeping patients and reluctance to wake a physician can all delay action. A patient who is hard to rouse at 0300 is not necessarily "just sleeping."

CLINICAL JUDGMENT

A Quiet Change Overnight

Names and details are fictional; this is a composite story.

Mr. Tomas Kowalski, 72, is on day 2 after a bowel resection for colon cancer. At 2200 his vital signs are near his baseline. At 0200 the registered nurse (RN), Grace, finds him picking at his blankets and asking to go home.

- **Recognize cues:** His respiratory rate is 26 per minute (18 at 2200), heart rate 112 (88), blood pressure 104/62 mm Hg (128/76), temperature 38.3 °C. He is newly confused. His urine output has been 80 mL over the past 4 hours.
- **Analyze cues:** The cues fit together: faster breathing, rising heart rate, falling blood pressure, fever and new confusion. They are not explained by pain alone.
- **Prioritize hypotheses:** Grace considers sepsis from a leak at the bowel join, pneumonia, a blood clot in the lung and delirium. Sepsis is the most dangerous possibility that fits.
- **Generate solutions:** She needs urgent medical review. His early warning score has reached the hospital's threshold for urgent review, and new confusion alone triggers one.
- **Take action:** She stays with him, sits him up and checks his oxygen saturation. She asks a colleague to watch him while she calls the surgical resident using SBAR (Situation, Background, Assessment, Recommendation; Table 6.2), reads back the orders, and calls the rapid response team as the hospital's protocol requires.
- **Evaluate outcomes:** Within the hour, the team draws a lactate and blood cultures and starts fluids and antibiotics. Grace rechecks his vital signs every 15 minutes and documents the times of each call. By 0400 his respiratory rate is 22 and his blood pressure is 118/70 mm Hg. A computed tomography (CT) scan later confirms a leak, and he returns to the operating room.

6.2 Early Warning Scores and Escalation

How Early Warning Scores Work

An **early warning score** turns routine vital signs into a single number that reflects how sick a patient is. It is the core of a **track-and-trigger system**: the nurse tracks the score over time, and preset scores trigger a defined response, such as more frequent monitoring or a call for urgent review.

A widely used example is the **National Early Warning Score 2 (NEWS2)**, published by the Royal College of Physicians of London in 2017 and endorsed in England as the standard system for acutely ill adults (RCP, 2017). NEWS2 scores seven items: respiratory rate, oxygen saturation, whether the patient is receiving supplemental oxygen, systolic blood pressure, pulse rate, level of consciousness and temperature. Each measured parameter earns more points the further it moves from normal, and receiving oxygen adds points of its own (RCP, 2017).

Two features deserve attention. First, oxygen saturation has a second scale for patients whose blood gases have confirmed hypercapnic respiratory failure (a build-up of carbon dioxide), usually from chronic obstructive pulmonary disease (COPD), and whose prescribed saturation target is 88% to 92%. A competent clinical decision maker chooses this scale and records the decision (RCP, 2017). Second, consciousness is scored with ACVPU: alert, new confusion, responds to voice, responds to pain, unresponsive. NEWS2 added new confusion to the consciousness scale because a new change in mental state can signal serious illness (RCP, 2017).

The score triggers a response in two ways. The aggregate score is sorted into low, medium and high bands, and each band calls for a faster and more senior response, from assessment by a competent registered nurse at the low end to emergency assessment by a team with critical care skills at the high end. In addition, a single parameter that earns the top score of 3 triggers urgent review even when the total is low (RCP, 2017). The score also sets minimum monitoring frequency, which rises to continuous monitoring for the highest scores (RCP, 2017). The official charts, which may be used only unaltered and with acknowledgement, are available from the Royal College of Physicians website (RCP, 2017); nurses follow the version and thresholds their hospital has adopted.

Canada has its own score. The **Hamilton Early Warning Score (HEWS)** was developed through a quality improvement process at hospitals affiliated with Hamilton Health Sciences in Ontario (Skitch et al., 2018). It scores vital signs and level of consciousness and adds a delirium screen and graded points for the amount of supplemental oxygen (Skitch et al., 2018; Xu et al., 2015). Among 5,491 patients seen by a rapid response team at two Canadian hospitals, HEWS predicted in-hospital death about as well as NEWS2 (Fernando et al., 2019).

What Scores Cannot Do

An early warning score supports clinical judgment; it does not replace it. The NEWS2 report is clear that clinical concern about a patient warrants urgent review, whatever the score (RCP, 2017). Scores have known limits:

- **Chronic abnormal values:** A patient with long-standing lung disease may always score points for low saturation, which can blunt the score's meaning (RCP, 2017).
- **Medications:** A beta-blocker limits the rise in heart rate that normally signals trouble. In a laboratory model of blood loss, blocking this response reduced people's tolerance of the loss (Schiller et al., 2017).
- **Groups excluded:** NEWS2 is not intended for people under 16 or for pregnant people, and it may be unreliable after spinal cord injury (RCP, 2017).
- **Missed patients:** No score catches everyone. In a study of 5,491 patients seen by a rapid response team, a NEWS2 of 5 or more had a sensitivity of 84.5% for in-hospital death: it flagged most, but not all, of the patients who went on to die (Fernando et al., 2019).

A low score with a worried nurse is still a reason to escalate.

Rapid Response and Critical Care Outreach

A **rapid response team (RRT)** brings critical care skills to a patient on a general unit before a cardiac arrest occurs. Teams often include a critical care nurse, a respiratory therapist and a physician (Tran et al., 2020). In Ontario, many hospitals call them **Critical Care Response Teams (CCRTs)**. They were introduced as part of the province's Critical Care Strategy after the 2003 outbreak of severe acute respiratory syndrome (SARS), starting at four sites and growing quickly. Each team was led by an intensivist, with intensive care unit (ICU) nurses or respiratory therapists as responders (Salenieks & Reynolds, 2008). Critical Care Services Ontario, the provincial body that supports critical care planning, is now part of Ontario Health (Critical Care Services Ontario, n.d.).

Each hospital sets its own calling criteria. Criteria commonly include abnormal vital signs or early warning scores, and some systems also accept a nurse's worry alone as a reason to call (Douw et al., 2015). Many policies allow any staff member to call, and

some allow patients and families to call (section 6.1). In Ontario's early rollout, teams also followed up patients after discharge from the ICU (Salenieks & Reynolds, 2008).

Escalation Pathways

Escalation means moving a concern to a person or team who can act on it, quickly enough to matter. Every hospital has a pathway, and the nurse learns it on the first day on a unit. A typical pathway runs from the charge nurse, to the most responsible provider (the physician or nurse practitioner (NP) in charge of the patient's care), to the rapid response team. A patient who is not breathing, has no pulse or is about to arrest needs the hospital's emergency code (often "code blue") at once; the nurse does not work through the other steps first.

When a concern is not addressed, the nurse continues up the chain of command: call again, call the charge nurse, call the next most senior physician, or call the rapid response team directly. Policies exist to protect patients, and the nurse is accountable for following through until the patient receives the care needed.

Communicating Concern

SBAR stands for Situation, Background, Assessment and Recommendation. It gives the caller and the listener a shared, predictable structure, which helps both stay aware of the patient's situation (Haig et al., 2006). SBAR was first adapted for acute care by clinicians at Kaiser Permanente, and its spread drew on work with the Institute for Healthcare Improvement (Toronto Rehabilitation Institute, 2010). A systematic review found moderate evidence that SBAR improves patient safety, strongest for telephone calls between nurses and physicians, though high-quality studies are lacking (Müller et al., 2018). SBAR is this book's standard tool for both escalation and handover (Table 6.2):

- **Situation:** who is calling, about which patient, and the problem in one sentence.
- **Background:** the facts the listener needs to understand the problem.
- **Assessment:** what the nurse found and what the nurse thinks is happening.
- **Recommendation:** what the nurse is asking for, and by when.

Before calling, the nurse has the chart, recent vital signs, medications and laboratory results at hand (Toronto Rehabilitation Institute, 2010). When the listener does not seem to grasp the urgency, plain critical language helps: "I'm concerned," "I'm uncomfortable," "This is unsafe" (Toronto Rehabilitation Institute, 2010). Some teams teach these three phrases by their first letters, CUS. Other structured tools, such as I-PASS for shift handover, are used in some hospitals.

Closed-loop communication means the receiver repeats back the message and the sender confirms it, so both know it was understood. For telephone orders, the nurse writes the order directly into the record as it is given and reads the entire order back, spelling out drug names, and calls back if anything is unclear (Koczmara et al., 2006). The nurse then documents the escalation: the time of each call, who was called, what was reported, the response and the patient's condition afterward (see Chapter 1, section 1.5).

Table 6.2 SBAR: parts and a worked example (original)

Part	What to include	Example (Mr. Kowalski, section 6.1)
Situation	Your name, role and unit; the patient's name and room; the problem in one sentence	"This is Grace, RN on 5 West. I'm calling about Tomas Kowalski in room 12. I'm concerned he may be developing sepsis."
Background	Age, admitting problem or surgery and date; relevant history; recent changes	"He is 72, day 2 after a bowel resection. He has hypertension. His vital signs were stable at 2200."
Assessment	Current vital signs and trends; key findings; what you think is happening	"His respiratory rate is 26, up from 18. Heart rate 112, blood pressure 104/62, temperature 38.3. He is newly confused and his urine output is low. His early warning score has reached the urgent review threshold. I am worried this is sepsis, possibly from a leak."
Recommendation	What you need, how soon, and what you will do meanwhile; confirm the plan	"I need you to see him now. Should I draw a lactate and blood cultures? I will recheck vital signs every 15 minutes. Can you be here within 15 minutes? If not, I will call the rapid response team."

SCOPE IN PRACTICE

Every Nurse Escalates

Recognizing and escalating deterioration is every nurse's responsibility. Using the College of Nurses of Ontario (CNO) framework of authority, competence and context (Chapter 1, section 1.3):

- **Authority:** No order is needed to assess a patient, stay with them, call for help or call the rapid response team when policy allows. Every nurse who notices deterioration acts at once and escalates.
- **Competence:** RNs and registered practical nurses (RPNs) both learn to recognize cues and report them clearly. As a patient's needs change, the RPN consults the RN, who may take on more of the care. The RPN does not wait for that consultation to escalate an emergency; many policies allow the RPN to call the rapid response team directly.
- **Context:** Employer policy sets who may call the team, the escalation pathway and how care is reassigned. Some employers assign patients by stability, but this is a common employer practice, not a CNO rule. Rules also differ by province or territory, where practical nurses may be called licensed practical nurses (LPNs).

The question is never "Is this my patient?" but "Who needs to know, right now?"

6.3 Shock: How It Develops

What Shock Is

Shock is a life-threatening failure of the circulation in which cells cannot get or use enough oxygen (Cecconi et al., 2014; Vincent & De Backer, 2013). Every type of shock creates a gap between the oxygen the tissues need and the oxygen they receive (Standl et al., 2018). Without enough oxygen, cells switch to anaerobic metabolism, which produces far less energy and generates lactate. A rising blood lactate is therefore a marker of tissue hypoperfusion (Vincent & De Backer, 2013). Chapter 3, section 3.7 explains lactic acidosis, and Chapter 4, section 4.6 explains how lactate is used in sepsis.

Low blood pressure is common in shock but is not required to diagnose it (Cecconi et al., 2014). Instead, clinicians look through three "windows" on perfusion: the skin (cold, clammy, mottled), the kidneys (urine output below 0.5 mL/kg/h) and the brain (confusion, disorientation or reduced alertness) (Cecconi et al., 2014; Vincent & De Backer, 2013).

When blood pressure is low in adults with shock, the systolic pressure is typically below 90 mm Hg or the mean arterial pressure (MAP, explained below) below 70 mm Hg, usually with a fast heart rate (Vincent & De Backer, 2013). Lactate is normally about 1 mmol/L; a level above 1.5 mmol/L suggests acute circulatory failure, and levels in shock are typically above 2 mmol/L (Cecconi et al., 2014; Vincent & De Backer, 2013). A single value is less useful than the direction of repeated values, so lactate is measured more than once (Cecconi et al., 2014). Reference ranges vary by laboratory.

Mean arterial pressure (MAP) is the average pressure in the arteries over one cardiac cycle, and it reflects the pressure driving blood into the organs (Meaney et al., 2000). Because the heart spends longer in diastole than in systole, MAP is closer to the diastolic pressure than to the systolic. A common estimate is the diastolic pressure plus one third of the pulse pressure (the difference between systolic and diastolic) (Meaney et al., 2000). For a blood pressure of 120/60 mm Hg, the pulse pressure is 60, one third of that is 20, and the estimated MAP is 80 mm Hg. Most monitors calculate MAP automatically. For adults with septic shock, the Surviving Sepsis Campaign recommends starting with a MAP goal of 65 mm Hg rather than aiming higher (Prescott et al., 2026).

The Body's Compensation

When circulation falters, the body defends blood pressure. Pressure sensors in the large arteries (baroreceptors) detect the drop and increase sympathetic nervous system activity (Schiller et al., 2017). The heart rate rises, and blood vessels in the skin, gut and kidneys constrict, which is why the skin becomes cool and pale. Hormones add to this response. The renin–angiotensin–aldosterone system and antidiuretic hormone (ADH, also called vasopressin) constrict vessels and help the kidneys hold onto sodium and water (Schiller et al., 2017). Chapter 3 explains these hormones.

These responses work well enough that blood pressure can stay near normal while the patient loses a large amount of blood or while perfusion fails. In laboratory studies of simulated blood loss, a fast heart rate was one of the main reasons people tolerated the loss (Schiller et al., 2017). This is why a normal blood pressure does not rule out shock and why a rising heart rate, a falling urine output

and new restlessness deserve attention. In a patient with long-standing high blood pressure, a reading that looks normal may already be low for that person (Vincent & De Backer, 2013).

Compensation has limits. A patient taking a beta-blocker cannot raise the heart rate normally, so one of the earliest cues may be missing and tolerance of blood loss may be lower (Schiller et al., 2017). When compensation finally fails, blood pressure can fall suddenly. In the same laboratory studies, the final collapse came with a sharp slowing of the heart rate (Schiller et al., 2017). A heart rate that drops in a patient who has been tachycardic and hypotensive is therefore not a sign of improvement until proven otherwise; the nurse calls for help at once.

Stages

Nursing and medical education often describe shock as passing through three overlapping stages. The stages are a teaching framework rather than a formal classification, and they blur in real patients, but they help explain why early action matters. The physiology behind them is the compensation, and its failure, described above (Schiller et al., 2017; Vincent & De Backer, 2013).

- **Compensated shock:** Compensating mechanisms keep blood pressure near normal. The patient may have a fast heart rate, faster breathing, cool skin, anxiety or restlessness and a falling urine output. Treating the cause at this stage gives the best chance of full recovery.
- **Progressive (decompensated) shock:** Compensation can no longer keep up. Blood pressure falls, and signs of organ hypoperfusion become clear: confusion, very low urine output, mottled skin and a rising lactate (Cecconi et al., 2014). In laboratory studies, the change from compensation to decompensation can be sudden (Schiller et al., 2017).
- **Refractory (irreversible) shock:** Shock persists despite fluids and vasopressors, and damage to cells and organs may be permanent. Survival becomes unlikely.

For the nurse, the lesson is that the best time to act is the compensated stage, when the signs are subtle and blood pressure is still reassuring. The longer hypoperfusion lasts, the more organs it can injure.

Four Types of Shock

Shock has four main mechanisms, and a patient can have more than one at the same time (Vincent & De Backer, 2013). Among 1,600 patients with shock enrolled in one large treatment trial, 62% had septic shock, 16% cardiogenic, 16% hypovolemic, 4% other distributive and 2% obstructive (Vincent & De Backer, 2013). Table 6.3 compares the four types (Table 6.3), and sections 6.4 and 6.5 give the details.

Hypovolemic shock occurs when the volume of blood or fluid in the vessels is too low to fill the heart. Losses may be external, such as bleeding after trauma or surgery, or internal, such as bleeding into the abdomen or large fluid shifts after burns (Standl et al., 2018; Vincent & De Backer, 2013).

Cardiogenic shock occurs when the heart itself fails as a pump. The usual cause is a large myocardial infarction; others include end-stage cardiomyopathy, severe valve disease, myocarditis and dysrhythmias (Vincent & De Backer, 2013). Chapters 17 and 18 cover these conditions.

Distributive shock occurs when blood vessels lose their tone and dilate, so the existing blood volume no longer fills the circulation. Sepsis is by far the most common cause; anaphylaxis and neurogenic shock after spinal cord injury are others (Standl et al., 2018). Cardiac output is usually high in distributive shock, but it can fall if severe illness also depresses the heart muscle, so one patient can have features of two types at once (Vincent & De Backer, 2013). Chapter 4 covers septic shock.

Obstructive shock occurs when something physically blocks blood flow into or out of the heart. Causes include a large pulmonary embolism, cardiac tamponade (fluid compressing the heart) and tension pneumothorax (Vincent & De Backer, 2013). It can look like cardiogenic shock at the bedside, but it needs different treatment aimed at removing the obstruction (Standl et al., 2018).

Table 6.3 The four types of shock compared (Vincent & De Backer, 2013; Cecconi et al., 2014; Standl et al., 2018)

Type	Main problem	Common causes	Typical skin and key cues

Type	Main problem	Common causes	Typical skin and key cues
Hypovolemic	Too little volume in the vessels to fill the heart	Bleeding from trauma, surgery or the gastrointestinal tract; vomiting and diarrhea; burns	Cool, pale or grey, clammy skin; fast heart rate; low urine output; visible or hidden blood or fluid loss
Cardiogenic	The heart cannot pump enough blood	Myocardial infarction, cardiomyopathy, severe valve disease, myocarditis, dysrhythmias	Cool, clammy skin; chest pain or a known heart condition; breathlessness and signs of fluid backing up into the lungs
Distributive	Blood vessels dilate and lose tone	Sepsis (most common), anaphylaxis, spinal cord injury (neurogenic)	Skin may be warm early, then cool and mottled; fever or low temperature in sepsis; hives and airway swelling in anaphylaxis; slow heart rate in neurogenic shock
Obstructive	Blood flow into or out of the heart is blocked	Pulmonary embolism, cardiac tamponade, tension pneumothorax	Cool, clammy skin; sudden breathlessness or chest pain; findings of the underlying cause; needs the obstruction removed

CANADIAN CONTEXT

Triage in Canadian Emergency Departments

Many patients admitted to medical and surgical units arrive through the emergency department, where nurses sort them with the **Canadian Triage and Acuity Scale (CTAS)**. CTAS has five levels: 1, resuscitation; 2, emergent; 3, urgent; 4, less urgent; and 5, non-urgent (Murray et al., 2004). A national advisory committee of the Canadian Association of Emergency Physicians (CAEP) and the National Emergency Nurses Association (NENA) maintains the scale. In 2025 the committee completed a multi-year update of the scale's guidelines and teaching materials (Canadian Association of Emergency Physicians [CAEP], 2026).

A CTAS level describes how sick a patient appeared on arrival. It does not predict how the patient will be hours later. The nurse who receives a patient from the emergency department reviews the trend of vital signs since triage, completes a full set on arrival, and escalates any change, even if the patient was triaged as less urgent. Triage itself requires separate training.

6.4 Hypovolemic and Cardiogenic Shock

This section applies the types of shock from section 6.3 to two that often develop on medical and surgical units: loss of volume and failure of the heart as a pump.

Hypovolemic Shock

Hypovolemic shock develops when so much fluid leaves the circulation that too little blood returns to the heart. With less blood filling the ventricles, stroke volume and cardiac output fall (Cecconi et al., 2014). **Hemorrhagic shock** is hypovolemic shock caused by bleeding. Bleeding may follow surgery or a procedure, come from the gastrointestinal (GI) tract, or follow trauma such as a fall. Non-hemorrhagic causes include vomiting, diarrhea, large drain or ostomy losses, excessive diuresis, and fluid shifts in burns, pancreatitis or bowel obstruction (Chapter 3, section 3.2).

As volume falls, the sympathetic nervous system speeds the heart and narrows the blood vessels of the skin, gut and kidneys, helped by hormones such as angiotensin and vasopressin (Schiller et al., 2017). These responses can keep blood pressure near normal while bleeding continues. Tolerance varies widely between people, and when compensation fails, blood pressure can drop suddenly (Schiller et al., 2017). The nurse therefore acts on early cues and never waits for hypotension.

The cues tend to appear in this order, although every patient is different:

- **Rising heart rate.** Sympathetic tachycardia is one of the body's main defences against blood loss (Schiller et al., 2017). The trend matters more than any single value (section 6.1).
- **Narrowing pulse pressure. Pulse pressure** is the difference between the systolic and diastolic pressures. As stroke volume falls and the vessels tighten, the gap shrinks (for example, from 130/80 to 112/90 mm Hg). A narrow pulse pressure is a recognized sign of poor perfusion (Chioncel et al., 2020).

- **Cool, pale, clammy or mottled skin and slow capillary refill** (Cecconi et al., 2014). Pallor is harder to see on darker skin, so the nurse checks the conjunctivae, palms and oral mucous membranes and compares them with the patient's usual colour (Chapter 2).
- **Anxiety, restlessness, then confusion,** as blood flow to the brain falls (Cecconi et al., 2014).
- **Falling urine output.** Output below 0.5 mL/kg/h is a sign that the kidneys are underperfused (Cecconi et al., 2014).
- **Hypotension,** a late sign that compensation is failing (Schiller et al., 2017).

A lactate above 2 mmol/L supports tissue hypoperfusion (Cecconi et al., 2014; Chapter 3, section 3.7).

Bleeding is not always visible. The nurse checks the dressing and the sheets under the patient, measures drain output, and looks for swelling around a surgical or puncture site, vomited blood, black stools or a growing abdomen. A dry dressing does not rule out bleeding into the abdomen, bowel or tissues.

When hypovolemic shock is suspected, the nurse calls for help at once through the RRT or the most responsible provider, as policy directs, and reports with SBAR (section 6.2). The nurse then carries out ordered actions and those allowed by medical directives:

- **Airway, breathing and oxygen.** Oxygen is given if saturation is low (Chapter 12).
- **Intravenous (IV) access.** Large-bore access lets fluid and blood run quickly.
- **Blood work.** In major bleeding, the group and screen sample comes first, so blood can be crossmatched. Other tests include a complete blood count (hemoglobin and platelets), the international normalized ratio (INR), fibrinogen, electrolytes, ionized calcium, a blood gas and lactate, repeated at least hourly (Callum et al., 2019).
- **Fluids and blood.** Crystalloid boluses are given as ordered (Chapter 3, section 3.3). For major bleeding, hospitals use a **massive hemorrhage protocol** that rapidly delivers blood components. An Ontario regional protocol template calls for uncrossmatched red cells at the bedside within 10 minutes of activation, warmed IV fluids and blood components, and temperature checks with measures to keep the patient at 36 °C or warmer; ordered tranexamic acid is given as soon as IV access allows, within 3 hours of injury or of protocol activation (Callum et al., 2019). Transfusion is taught in Chapter 20.
- **Position.** The patient lies flat. Teams may raise the legs briefly (passive leg raising) to test whether more fluid would help (Cecconi et al., 2014).
- **Monitoring.** Vital signs and level of consciousness are checked often, and urine output hourly, with a catheter if ordered.
- **Stopping the source.** Fluids and blood buy time until surgery, endoscopy or interventional radiology controls the bleeding (Callum et al., 2019). The nurse prepares the patient and records when the protocol starts and ends.

The team sets the blood pressure target; in uncontrolled bleeding without head injury, a lower pressure may be accepted until bleeding stops (Cecconi et al., 2014).

Cardiogenic Shock

Cardiogenic shock is shock caused by a primary heart problem: the heart cannot pump enough blood to meet the body's needs, so tissues are underperfused and lactate rises (Chioncel et al., 2020). Acute myocardial infarction (MI) is the classic cause, although its share is falling: a European position statement reports that acute coronary syndromes caused about 81% of cases a decade earlier but about one third in a recent cardiac intensive care dataset (Chioncel et al., 2020). Other causes include myocarditis, cardiomyopathy and dysrhythmias (Cecconi et al., 2014).

When the pump fails, blood backs up while too little moves forward. Most patients with MI-related cardiogenic shock are "cold and wet": poorly perfused and congested (van Diepen et al., 2017). The cues include:

- low blood pressure, often a systolic pressure below 90 mm Hg for more than 30 minutes or a need for drugs to support it; perfusion can be poor even before the pressure falls (Chioncel et al., 2020; van Diepen et al., 2017);
- cool, clammy extremities, a narrow pulse pressure, dizziness, confusion and reduced urine output (Chioncel et al., 2020);
- signs of congestion in the lungs, such as worsening shortness of breath and falling oxygen saturation; a chest X-ray helps assess congestion (Chioncel et al., 2020);
- chest pain and electrocardiogram (ECG) changes when MI is the cause (Chapter 17), and dysrhythmias (Chapter 16).

Fluids need caution. A small fluid challenge is tried only when there are no signs of congestion (Chioncel et al., 2020), because extra volume can flood the lungs when the heart cannot move it forward. Before and after any ordered fluid, the nurse listens to the lungs, checks oxygen saturation and reports any worsening at once.

Cardiogenic shock needs urgent escalation: in-hospital mortality is roughly 30% to 60%, and nearly half of these deaths occur within 24 hours (Chioncel et al., 2020). A 12-lead ECG is done at once, followed by continuous cardiac monitoring, urgent echocardiography, troponin and lactate (Chioncel et al., 2020). Shock from an acute coronary syndrome calls for early opening of the blocked artery (van Diepen et al., 2017). The patient moves quickly to an ICU or coronary care unit, often at a centre with a round-the-clock cardiac catheterization laboratory (Chioncel et al., 2020), where drugs to support the circulation are started (section 6.6). The team also discusses goals of care and palliative care with the patient and family (van Diepen et al., 2017; Chapter 10). Acute coronary syndromes and heart failure are covered in Chapters 17 and 18.

6.5 Distributive and Obstructive Shock

In distributive shock, blood vessels lose their tone and widen, so the circulating blood no longer fills the enlarged space. Blood pressure falls even though the heart's output is usually normal or high (Cecconi et al., 2014). Its three main causes are sepsis, anaphylaxis and spinal cord injury. Obstructive shock, discussed at the end of this section, has a different cause: something physically blocks blood flow into or out of the heart.

Septic Shock

Sepsis is life-threatening organ dysfunction that results from a dysregulated host response to infection. **Septic shock** is the subset of sepsis in which circulatory and metabolic changes are severe enough to raise the risk of death substantially. Clinically, the patient needs a vasopressor to keep the MAP at 65 mm Hg or higher and has a serum lactate above 2 mmol/L, even after adequate fluid resuscitation. In this group, hospital mortality is above 40% (Singer et al., 2016). Septic shock is a form of distributive shock, in which infection leads to loss of vascular tone (Cecconi et al., 2014). Screening, the first hour of care and fluid resuscitation are taught in Chapter 4, section 4.6; vasopressors are covered in section 6.6.

Anaphylaxis

Anaphylaxis is a severe, potentially life-threatening allergic reaction, the most serious form of acute systemic allergic reaction (Cardona et al., 2020). Its signs start suddenly and progress over minutes, usually in two or more body systems (Public Health Agency of Canada [PHAC], 2023a). Mediators released from immune cells widen blood vessels and make capillaries leak, so fluid leaves the circulation and blood pressure falls; airway smooth muscle also contracts (Mylan Specialty, 2024). The immune basis of allergy is explained in Chapter 21.

The World Allergy Organization (WAO) considers anaphylaxis highly likely when either of two criteria is met (Cardona et al., 2020):

- a sudden illness, developing over minutes to several hours, that involves the skin, mucous membranes or both (for example, widespread hives, itching or flushing, or swollen lips, tongue or uvula), together with significant symptoms in at least one other body system, such as the breathing or circulatory system; or
- sudden low blood pressure, bronchospasm or throat (laryngeal) involvement after contact with an allergen that is known, or highly likely, to affect that patient, even without skin signs.

Drugs are among the most frequent triggers of anaphylaxis, and many are given in hospital. Antibiotics, contrast media used for imaging, analgesics, biologic drugs and chemotherapy can all cause anaphylaxis, as can latex and antiseptic skin preparations (Cardona et al., 2020). In a national audit of anaphylaxis during anesthesia in the United Kingdom, the culprits identified most often were antibiotics, neuromuscular blocking agents, chlorhexidine and a blue dye used in surgery. Reactions to antibiotics and neuromuscular blockers began quickly, while reactions to chlorhexidine and the dye were delayed (Harper et al., 2018). Any first dose of an IV drug therefore calls for close watching in the first minutes.

The cues can involve every system (Association des allergologues et immunologues du Québec [AAIQ], 2020; PHAC, 2023a):

- **Skin and mucosa:** hives, itching, flushing, warmth, and swelling of the face, eyelids, lips or tongue (Figure 6.2).

- **Airway and breathing:** throat tightness, a hoarse voice, trouble swallowing, cough, wheeze and shortness of breath.
- **Circulation:** dizziness, fainting, a weak and fast pulse, pale or bluish skin and low blood pressure.
- **GI:** nausea, cramping, vomiting and diarrhea.
- **Other:** anxiety, a sense of doom and a metallic taste.

Skin signs are common but not universal. They are present in about 80% to 90% of reactions (PHAC, 2023a) and absent in 10% to 20%, which can delay recognition (Cardona et al., 2020). During anesthesia, low blood pressure was the most common first sign (Harper et al., 2018). On darker skin, redness may not look red, so flushing and hives are easy to miss (Wounds International, 2023). The nurse looks and feels for raised welts and swelling, compares areas of skin, and asks the patient about itching and throat tightness.

Figure 6.2 Raised red welts on light skin during a skin reaction, similar to hives. On darker skin, redness can be harder to see. (credit: "Rash" by Enochlau/Wikimedia Commons, CC BY-SA 3.0)

Speed saves lives. Epinephrine given intramuscularly (IM) is the first-line treatment (Cardona et al., 2020; Li et al., 2021), and there is no absolute contraindication to it in anaphylaxis (Cardona et al., 2020). The first actions happen together, not one after another (PHAC, 2023a), and they are summarized in Table 6.4. The standard adult dose is described in the Medications box.

Table 6.4 First actions in anaphylaxis (original summary of AAIQ, 2020; Cardona et al., 2020; PHAC, 2023a, 2023b)

Step	Nursing action	Why
Remove the trigger	Stop the infusion at once and disconnect the tubing that holds the drug; keep the IV access	Less of the allergen reaches the patient
Call for help	Use the call bell or emergency call; activate the rapid response or code team as policy directs	Several people are needed for drugs, monitoring and the airway
Give epinephrine	Give IM epinephrine into the mid-anterolateral thigh without delay, per order, medical directive or protocol; record the time	Reverses vasodilation, capillary leak and bronchospasm
Position	Lay the patient flat with legs raised; sit them up if breathing is hard; turn them onto their side if vomiting; never stand or sit them up suddenly	Keeps blood returning to the heart; sudden upright posture can cause collapse
Support breathing	Give oxygen; watch the airway for swelling, hoarseness or noisy breathing	Airway swelling can progress within minutes
Support circulation	Give IV fluid boluses as ordered for low blood pressure	Replaces fluid that has leaked out of the vessels
Monitor and repeat	Check blood pressure, heart rate and rhythm, breathing and oxygen saturation continuously; repeat epinephrine as ordered if symptoms persist	Most patients improve after one or two doses
Observe and record	Document the reaction, every drug and time, and the response; flag the allergy	Symptoms can return, and the trigger must never be given again

Antihistamines may ease itching and hives, and corticosteroids are often ordered too (Cardona et al., 2020). Antihistamines have no role in treating breathing or circulation problems in anaphylaxis, and an antihistamine must never be used in place of epinephrine or delay it (PHAC, 2023a).

After the first reaction settles, symptoms can come back without new exposure. This **biphasic reaction** occurs in up to 23% of patients (PHAC, 2023a). There is no agreed length of observation (Cardona et al., 2020); a Canadian emergency plan advises

observation in hospital, generally for about 4 to 6 hours, as the emergency physician decides (AAIQ, 2020). On a medical unit, the nurse continues frequent assessments and teaches the patient to report any returning itching, throat tightness or breathing difficulty at once.

The nurse documents the reaction, the suspected trigger and the treatment (Chapter 1, section 1.5), updates the allergy record and allergy band as hospital policy directs, and reports the event through the hospital's reporting system. Only about half of patients who have anaphylaxis are referred to an allergist, although referral helps identify the cause and plan prevention (Cardona et al., 2020). The nurse advocates for referral. Epinephrine autoinjectors are indicated for people at increased risk of anaphylaxis, including those who have had it before (Mylan Specialty, 2024), so the prescriber decides whether the patient needs one at discharge. As of October 2026, the Health Canada Drug Product Database lists EpiPen and EpiPen Jr autoinjectors and an epinephrine nasal spray (neffy) as marketed, while other autoinjectors sold in earlier years, such as Allerject and Emerade, are no longer marketed (Health Canada, n.d.). Teaching is described in the Patient Education box in section 6.6.

MEDICATIONS

Epinephrine for Anaphylaxis

Epinephrine acts on alpha-adrenergic receptors to tighten blood vessels, which counters vasodilation and capillary leak and raises blood pressure. Its beta-adrenergic effects relax airway smooth muscle, easing wheeze and shortness of breath (Mylan Specialty, 2024).

- **Route and site:** IM, into the mid-anterolateral thigh (vastus lateralis), through clothing if needed with an autoinjector (Figure 6.3). The deltoid is not recommended (PHAC, 2023a). Never inject into the buttock, fingers, hands or feet (Mylan Specialty, 2024).
- **Standard adult dose:** Canadian guidance gives 0.01 mg/kg of the 1 mg/mL solution, to a maximum of 0.5 mg. For people older than 12 years who weigh 46 kg or more, the dose is 0.5 mg, which is 0.5 mL of the 1 mg/mL solution (PHAC, 2023a, 2023b; Li et al., 2021). Autoinjectors deliver a fixed dose.
- **Repeat:** as ordered if symptoms persist or worsen. PHAC advises repeating every 5 minutes if symptoms persist, and the EpiPen monograph allows a repeat every 5 to 15 minutes (Mylan Specialty, 2024; PHAC, 2023a).
- **Expected effects:** fast heart rate, palpitations, pallor, anxiety, headache, nausea and vomiting (Mylan Specialty, 2024).
- **Safety:** Check the concentration: only the 1 mg/mL solution is used for IM injection. Never give the IM dose intravenously; an accidental IV dose can cause a sharp rise in blood pressure and bleeding in the brain (Mylan Specialty, 2024). Record the time of every dose (PHAC, 2023a).

Neurogenic Shock

Neurogenic shock is low blood pressure with a slow heart rate, without another cause, after a spinal cord injury. It follows cervical or high-thoracic cord injuries, which suddenly cut the sympathetic nerve output that keeps vessels toned and the heart rate up, leaving parasympathetic activity, which slows the heart, unopposed (SCIRE Professional, 2022). In one study it was present at first emergency department presentation in about 19% of people with cervical cord injuries (SCIRE Professional, 2022). The slow heart rate helps the nurse tell it apart from hypovolemic shock. Spinal cord injury and its care are covered in Chapter 32.

Obstructive Shock

In obstructive shock, the heart muscle and blood volume may be normal, but something blocks the filling or emptying of the heart, so cardiac output falls (Cecconi et al., 2014). The three main causes can progress quickly and need urgent treatment by a physician or other authorized provider.

Tension pneumothorax is air trapped in the pleural space under rising pressure. It collapses the lung and squeezes the great veins and heart. Compared with patients breathing on their own, patients receiving assisted ventilation more often develop low oxygen levels, low blood pressure and cardiac arrest, often within minutes (Roberts et al., 2015). Cues include sudden, worsening shortness of breath, falling oxygen saturation, a fast heart rate and falling blood pressure. Many signs taught as "classic" may be absent (Leigh-Smith & Davies, 2003), so the nurse acts on the pattern and never waits for a full set of signs.

Cardiac tamponade is fluid or blood in the pericardial sac that presses on the heart and stops it from filling. Causes include bleeding after cardiac surgery or procedures, pericarditis, cancer and trauma. Beck's triad describes three classic findings: low blood

Figure 6.3 An epinephrine autoinjector held in the fist, with the blue safety release at the top and the orange tip pointing down toward the outer thigh. (credit: “Adrenalina autoinyector9” by AngelHM/Wikimedia Commons, CC BY-SA 4.0)

pressure, distended neck veins and muffled heart sounds. A fast heart rate, shortness of breath and cool extremities are also common. Echocardiography is the key test, and fluids or drugs to support the heart must not replace or delay drainage of the fluid by pericardiocentesis or surgery (Jensen et al., 2017).

A **massive pulmonary embolism** blocks blood flow through the lungs and strains the right side of the heart (Cecconi et al., 2014). It is covered in Chapter 15.

The nurse's role in all three is to recognize the pattern, call the rapid response or code team at once, give oxygen, keep the patient continuously monitored, bring the equipment the team will need, such as a chest tube or pericardiocentesis tray and the ultrasound machine, and report with SBAR. Definitive treatment is done by physicians or other authorized providers.

6.6 Nursing Care of the Patient in Shock

Whatever the type of shock, the nurse's actions follow the same pattern: find poor perfusion early, call for help, support the airway, breathing and circulation, and watch closely to see whether treatment is working.

Priorities

The Clinical Judgment Measurement Model (CJMM; Chapter 1, section 1.4) gives these actions a clear shape.

- **Recognize cues.** The nurse looks through three "windows" on perfusion: the skin (cold, clammy, mottled or slow to refill), the kidneys (urine output below 0.5 mL/kg/h) and the brain (new anxiety, confusion or drowsiness). Shock can be present before blood pressure falls (Cecconi et al., 2014). Trends in early warning scores matter more than single values (section 6.2).
- **Analyze cues.** The nurse asks which type of shock fits: a fast heart rate after surgery suggests bleeding; signs of congestion after an MI suggest pump failure; hives after a new drug suggest anaphylaxis; a slow heart rate after a neck injury suggests neurogenic shock (section 6.3).
- **Prioritize hypotheses.** Airway and breathing come first, then circulation.
- **Generate solutions and take action.** The nurse calls for help early, through the RRT or the most responsible provider as policy directs. While help comes, the nurse gives oxygen (Figure 6.4), secures IV access and gives fluids or blood as ordered (Chapter 3, section 3.3; Chapter 20). Continuous ECG and oxygen saturation monitoring begins, with frequent blood pressure checks. The nurse measures urine output hourly, inserting a urinary catheter if ordered, and checks a point-of-care glucose, because a low or high glucose can also change mental status (Chapter 22). Ordered tests often include lactate, a complete blood count, electrolytes, creatinine, clotting tests and a blood gas (Chapter 3, section 3.7). Lactate is repeated, because its trend shows whether perfusion is improving (Cecconi et al., 2014).
- **Evaluate outcomes.** Improvement shows as clearer thinking, warmer skin, a slower heart rate, better urine output and a falling lactate. After each fluid bolus, the nurse listens for crackles and watches oxygen saturation, because too much fluid can cause lung congestion (Chapter 4, section 4.6).

Vasopressors and the Nurse's Role

A **vasopressor** is a drug that tightens blood vessels to raise blood pressure. Vasopressors are used when fluids alone do not restore an adequate MAP (Cecconi et al., 2014). For septic shock, the 2026 Surviving Sepsis Campaign guideline recommends norepinephrine as the first-line vasopressor (strong recommendation) and a starting MAP target of 65 mm Hg rather than a higher one (strong recommendation, moderate certainty). It suggests a starting range of 60 to 65 mm Hg for adults aged 65 and older (conditional recommendation, low certainty), and it suggests starting vasopressors peripherally to restore the MAP rather than delaying until central venous access is secured (conditional recommendation, very low certainty) (Prescott et al., 2026). Norepinephrine may also be preferred in cardiogenic shock because it causes fewer dysrhythmias (van Diepen et al., 2017).

Figure 6.4 A non-rebreather mask with its reservoir bag, used to give high-concentration oxygen as ordered. (credit: "Non re-breather mask" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

A central venous catheter is preferred for vasopressor infusions, and patients whose shock needs vasopressors usually have an arterial line for continuous blood pressure monitoring in the ICU (Cecconi et al., 2014). The nurse's responsibilities include:

- **Infusion site.** A peripheral infusion runs through a large vein, preferably at the inner elbow (antecubital vein). The nurse inspects the site often for free flow and for swelling or blanching along the vein. **Extravasation** (leakage of the drug into the tissues) can cause tissue injury, so the nurse stops the infusion into that site and follows hospital policy, which may include an ordered antidote injected into the area (Juno Pharmaceuticals, 2023).
- **Blood pressure.** The norepinephrine prescribing information advises checking blood pressure every 2 minutes from the start until the target is reached, then every 5 minutes while the infusion continues (Juno Pharmaceuticals, 2023).
- **Line safety.** The infusion runs on a pump through a labelled line that the nurse traces from bag to patient at every handover. The nurse never flushes a vasopressor line or pushes other drugs through it, because anything pushed through the line also pushes the drug left in the tubing into the patient faster than intended (Institute for Safe Medication Practices Canada [ISMP Canada], 2014).
- **Never stop suddenly.** The infusion is reduced gradually, as ordered (Juno Pharmaceuticals, 2023).

Vasopressor infusions are usually managed in critical care by nurses with added education. Who may care for them depends on authority, competence and context, and on employer policy and the province or territory (Chapter 1, section 1.3).

Supporting the Patient and Family

Shock is frightening. Patients in anaphylaxis may describe a sense of doom (AAIQ, 2020), and patients in any type of shock may be anxious, short of breath or confused. The nurse speaks calmly, explains each step in plain words, and stays at the bedside or makes sure someone else does. Families are told what is happening and where to wait, and someone is named to update them. When the patient or family speaks a language other than the nurse's, the nurse uses a professional interpreter rather than a family member for clinical information (Chapter 2). Many patients in shock are moved to the ICU. The nurse prepares them and their family for the move, hands over with SBAR (section 6.2), and documents the events, the times and the patient's response (Chapter 1, section 1.5).

GOING DEEPER

Hemodynamics and Titrating Vasopressors

Required for RN students; optional for PN students.

Cardiac output is the volume of blood the heart pumps each minute: heart rate × **stroke volume** (the volume ejected with each beat). Stroke volume depends on three factors:

- **Preload:** how much the ventricle is filled and stretched before it contracts.
- **Afterload:** the resistance the ventricle must pump against.
- **Contractility:** the strength of the contraction itself.

Blood pressure depends on cardiac output and on **systemic vascular resistance** (SVR), the resistance to flow created by the tone of the small arteries. When cardiac output falls, the body raises SVR by vasoconstriction, which is why the skin turns cool.

Each type of shock has a typical pattern (Cecconi et al., 2014; van Diepen et al., 2017):

- **Hypovolemic:** low preload and low cardiac output; SVR rises.
- **Cardiogenic:** low cardiac output with high filling pressures, because blood backs up; SVR is usually high, but it varies.
- **Distributive:** low SVR from vasodilation; cardiac output is usually normal or high.
- **Obstructive:** low cardiac output from blocked filling or emptying; pressures on the right side rise in pulmonary embolism.

Vasopressors raise SVR. Drugs that strengthen contraction (inotropes) are added only when cardiac output stays low and perfusion stays poor after filling has been optimized (Cecconi et al., 2014). Titration is an ICU skill:

- The prescriber orders a MAP target and the limits for titration; the nurse adjusts within the order and hospital policy.
- Changes are small and stepwise, with blood pressure rechecked often, every few minutes after each change (Juno Pharmaceuticals, 2023), usually from an arterial line.
- Perfusion is judged on several measures together, never on one number (Cecconi et al., 2014).
- Infusions are weaned gradually, never stopped abruptly (Juno Pharmaceuticals, 2023).
- Extravasation is managed at once according to policy.

LIFESPAN CONSIDERATIONS

Older Adults in Shock

Shock can hide in older adults.

- **Blunted heart rate.** Beta-blockers weaken the sympathetic rise in heart rate that helps people tolerate blood loss (Schiller et al., 2017), so a heart rate of 84 does not rule out shock. In a national audit of anaphylaxis during anesthesia, taking a beta-blocker or angiotensin-converting enzyme inhibitor was linked to worse outcomes (Harper et al., 2018).
- **"Normal" blood pressure may be low.** In a large study of injured adults over 65, those with a systolic pressure of 90 to 109 mm Hg had odds of death similar to those below 90 mm Hg (Brown et al., 2015). The nurse compares each value with the patient's usual pressure, especially in long-standing hypertension. Targets are individualized: a higher MAP may suit some people with chronic hypertension (Cecconi et al., 2014), while lower targets are suggested for adults 65 and older in septic shock (Prescott et al., 2026).
- **Confusion as the first sign.** New confusion may be the earliest sign of poor brain perfusion and needs urgent assessment (Cecconi et al., 2014; Chapter 8).
- **Vein choice.** Leg and hand veins are avoided for norepinephrine infusions in older adults (Juno Pharmaceuticals, 2023).

PATIENT EDUCATION

Living With an Epinephrine Autoinjector

The nurse teaches the patient, and family if the patient wishes, using a trainer device if available:

- **Use it early.** Give epinephrine as soon as a reaction starts, whether anaphylaxis is known or only suspected. If you have asthma and trouble breathing, use the epinephrine before your inhaler (AAIQ, 2020).
- **Where.** Inject into the outer thigh, through clothing if needed. Never inject into the buttock, hands or feet (Mylan Specialty, 2024).
- **Call 9-1-1** and tell the dispatcher it is a life-threatening allergic reaction. If symptoms have not improved, a second dose may be given as soon as 5 minutes after the first (AAIQ, 2020). Ask your prescriber how many devices to carry.

- **Go to hospital, ideally by ambulance,** even when symptoms are mild or seem to be gone, because they can return (AAIQ, 2020).
- **Care of the device.** Keep it at room temperature, protected from light, and do not refrigerate it, following your device's instructions (Mylan Specialty, 2024). Check the expiry date regularly. Take a used device to a pharmacist or physician for disposal and replacement (AAIQ, 2020).
- **Prevent the next reaction.** Know your trigger, tell every health care provider, and see your allergist (Cardona et al., 2020).

PRACTICE STORY

"Her Lips Were Swelling"

Names and details are fictional; this is a composite story.

Nurse: Luc Vaillancourt, RN. Years in practice: 5. Setting: medical unit, community hospital, Ontario.

Mrs. Teresa Lindqvist was 62 and had been admitted with pneumonia. I hung her first dose of an IV antibiotic at 1500, checked her allergy band (no known allergies), and stayed for the first few minutes, as I always do with a first dose. At about 1506 she rubbed her neck and said her throat felt "scratchy." When I looked closer, her lips were swelling and her voice had gone hoarse.

I clamped the line, disconnected the tubing and pressed the emergency call button. Amira Haddad, an RPN on our team, was in the room within seconds. I asked her to call the rapid response team and bring the anaphylaxis kit. Mrs. Lindqvist's blood pressure was 86/50 mm Hg, her heart rate 128, and she was wheezing. Our hospital has an anaphylaxis medical directive, so I drew up epinephrine from a 1 mg/mL ampoule, checked the concentration aloud with Amira, and gave it into her outer thigh. Amira noted the time.

Mrs. Lindqvist said she couldn't breathe lying down, so we raised the head of the bed and kept her legs up. Amira put her on oxygen and, as the directive allowed, started a fresh bag of saline through the IV. Five minutes later her wheeze was no better, so I gave a second dose. The team arrived, and within 20 minutes her pressure was 118/72 and her voice was clearer.

What stays with me is how fast it moved: under two minutes from her first words to the first dose. We could only do that because Amira and I divided the work without discussing it. Afterward I documented every time and drug, updated her allergy record and band, and filed an incident report. I also asked the physician about an allergist referral and an autoinjector for discharge.

Reflect: Under the same medical directive, could Amira have given the epinephrine herself? What would authority, competence and context require? What made the teamwork in this story fast?

Chapter 6 Summary

Introduction

- In a large registry, most patients had at least one abnormal vital sign in the 1 to 4 hours before an in-hospital cardiac arrest, which gives the team a window to act.
- The nurse is often first to notice a change and is central to rescue.

6.1 Recognizing Clinical Deterioration

- Failure to rescue is death after a complication; it is linked more to the hospital than to the patient, so how quickly the team recognizes and responds matters.
- Early cues include a rising respiratory rate, new confusion, falling urine output, cool or mottled skin and a rising heart rate; falling blood pressure is often late.
- Colour changes look different on different skin tones; check lips, mucous membranes, conjunctivae and nail beds and compare with baseline.
- Trends matter more than single readings; count the respiratory rate for a full minute.
- Nurses' worry and patients' and families' concerns are valid cues, and night shifts need extra vigilance.

6.2 Early Warning Scores and Escalation

- Early warning scores such as NEWS2 and the Canadian HEWS turn vital signs into a score that triggers a defined response.
- Scores support but never replace judgment; escalate any concern, even with a low score.

- Rapid response teams (in Ontario, Critical Care Response Teams) bring critical care skills to the bedside.
- Follow the escalation pathway and the chain of command until the patient gets the care needed.
- Use SBAR, critical language, closed-loop communication and read-back, and document every escalation.

6.3 Shock: How It Develops

- Shock is circulatory failure in which cells cannot get or use enough oxygen; lactate rises as cells switch to anaerobic metabolism.
- MAP reflects organ perfusion pressure; the initial target in septic shock is 65 mm Hg.
- Sympathetic and hormonal compensation can keep blood pressure normal early, so a normal pressure does not rule out shock.
- Shock is often taught as three overlapping stages (compensated, progressive and refractory), a teaching framework rather than a formal classification.
- The four types are hypovolemic, cardiogenic, distributive and obstructive.

6.4 Hypovolemic and Cardiogenic Shock

- Hypovolemic shock follows loss of blood (hemorrhagic shock) or other body fluid; compensation can hold blood pressure near normal while losses continue.
- Cues usually appear as a rising heart rate, narrowing pulse pressure, cool skin, anxiety or confusion and falling urine output; hypotension is late.
- The nurse calls for help early, secures IV access, sends group and screen and other blood work, gives fluids and blood as ordered, and prepares for bleeding control.
- Cardiogenic shock is pump failure, classically after an acute MI; patients are often cool and congested.
- Fluids are given cautiously in cardiogenic shock; escalation, a 12-lead ECG, echocardiography and transfer to a specialized unit are urgent.

6.5 Distributive and Obstructive Shock

- In distributive shock, vessels lose tone; causes are sepsis, anaphylaxis and spinal cord injury.
- Septic shock requires a vasopressor to keep the MAP at 65 mm Hg or higher and a lactate above 2 mmol/L despite adequate fluids (Chapter 4).
- Anaphylaxis is treated first with IM epinephrine into the mid-anterolateral thigh; the standard adult dose (older than 12 years, 46 kg or more) is 0.5 mg (0.5 mL of 1 mg/mL). Antihistamines never replace it.
- Skin signs are absent in some reactions and redness is harder to see on darker skin; symptoms can return in a biphasic reaction.
- Neurogenic shock causes hypotension with a slow heart rate after a cervical or high-thoracic cord injury.
- Tension pneumothorax, cardiac tamponade and massive pulmonary embolism cause obstructive shock; the nurse recognizes the pattern and escalates at once.

6.6 Nursing Care of the Patient in Shock

- The CJMM guides care: look for poor perfusion in the skin, kidneys and brain, prioritize the airway, breathing and circulation, and call for help early.
- Urine output below 0.5 mL/kg/h and a rising lactate signal poor perfusion; repeated lactate shows the trend.
- Norepinephrine is the first-line vasopressor in septic shock, with an initial MAP target of 65 mm Hg.
- The nurse monitors vasopressor sites for extravasation, checks blood pressure often, never flushes the line and never stops the infusion abruptly.
- Calm explanations, presence, professional interpreters and a clear SBAR handover support patients and families.

Key Terms (37)

afterload: the resistance the ventricle must pump against to eject blood.

anaphylaxis: a severe, potentially life-threatening allergic reaction with sudden onset, usually involving two or more body systems.

biphasic reaction: a return of anaphylaxis symptoms after the first reaction has settled, without new exposure to the trigger.

Canadian Triage and Acuity Scale (CTAS): Canada's five-level emergency department triage scale, maintained by a national committee of CAEP and NENA.

cardiac output: the volume of blood the heart pumps each minute; heart rate × stroke volume.

cardiac tamponade: fluid or blood in the pericardial sac that compresses the heart and prevents it from filling.

cardiogenic shock: Shock caused by failure of the heart as a pump.

clinical deterioration: A worsening of a patient's physiological condition that can lead to serious harm or death if it is not recognized and treated.

closed-loop communication: An exchange in which the receiver repeats back the message and the sender confirms it, so both know it was understood.

compensated shock: An early stage of shock in which the body's responses keep blood pressure near normal while signs such as a fast heart rate and cool skin appear.

distributive shock: Shock caused by loss of blood vessel tone and widespread vasodilation, as in sepsis, anaphylaxis or spinal cord injury.

early warning score: A number calculated from routine vital signs that reflects how sick a patient is and how urgently a response is needed.

epinephrine autoinjector: a prefilled, spring-loaded device that injects a fixed dose of epinephrine into the thigh muscle for emergency treatment of anaphylaxis.

escalation: Moving a concern about a patient to a person or team who can act on it, quickly enough to make a difference.

extravasation: leakage of an infused drug out of the vein into the surrounding tissues.

failure to rescue: Death of a patient after a complication that develops in hospital; used as a measure of how well a hospital recognizes and treats complications.

Hamilton Early Warning Score (HEWS): A Canadian early warning score developed at hospitals affiliated with Hamilton Health Sciences that adds a delirium screen and graded oxygen scoring to vital signs and level of consciousness.

hemorrhagic shock: hypovolemic shock caused by bleeding.

hypovolemic shock: Shock caused by too little blood or fluid volume in the vessels.

massive hemorrhage protocol: a hospital protocol that rapidly delivers blood components to a patient with life-threatening bleeding until the bleeding is controlled.

mean arterial pressure (MAP): The average arterial pressure over one cardiac cycle, reflecting the pressure that drives blood into the organs; commonly estimated as diastolic pressure plus one third of the pulse pressure.

neurogenic shock: low blood pressure with a slow heart rate after a cervical or high-thoracic spinal cord injury, caused by loss of sympathetic tone.

NEWS2: The National Early Warning Score 2 (Royal College of Physicians, 2017), which scores respiratory rate, oxygen saturation, supplemental oxygen, systolic blood pressure, pulse, level of consciousness (including new confusion) and temperature.

obstructive shock: Shock caused by a physical blockage of blood flow into or out of the heart, as in pulmonary embolism, cardiac tamponade or tension pneumothorax.

preload: how much the ventricle is filled and stretched before it contracts.

progressive (decompensated) shock: The stage of shock in which compensation fails, blood pressure falls and organ hypoperfusion becomes evident.

pulse pressure: the difference between the systolic and diastolic blood pressures.

rapid response team: A team with critical care skills that assesses and treats deteriorating patients on general units before cardiac arrest; in Ontario, often called a Critical Care Response Team (CCRT).

refractory (irreversible) shock: Shock that persists despite fluids and vasopressors, with cell and organ damage that may be permanent.

SBAR: A structured communication tool: Situation, Background, Assessment, Recommendation.

septic shock: a subset of sepsis in which a vasopressor is needed to keep the MAP at 65 mm Hg or higher and the lactate is above 2 mmol/L despite adequate fluids.

shock: A life-threatening failure of the circulation in which cells cannot get or use enough oxygen.

stroke volume: the volume of blood the ventricle ejects with each beat.

systemic vascular resistance: the resistance to blood flow created by the tone of the small arteries.

tension pneumothorax: air trapped in the pleural space under rising pressure, which collapses the lung and impairs blood return to the heart.

track-and-trigger system: A system in which nurses track a patient's early warning score over time and preset scores trigger a defined response, such as more frequent monitoring or urgent review.

vasopressor: a drug that constricts blood vessels to raise blood pressure.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Asha Mensah (Questions 1–4): Asha Mensah, 66, was admitted to a medical unit yesterday with a kidney infection and is receiving intravenous (IV) antibiotics. At 0400, the registered practical nurse (RPN) caring for her finds her restless and trying to climb out of bed. At 2300 her vital signs were: respiratory rate 18, heart rate 92, blood pressure 132/78 mm Hg, temperature 37.9 °C, SpO2 96% on room air. Now they are: respiratory rate 28, heart rate 118, blood pressure 108/64 mm Hg, temperature 38.7 °C, SpO2 93% on room air. Her daughter, who is staying overnight, says, "She's not making sense. This isn't like her."

1. [CORE] Which finding is the most important early cue that Ms. Mensah is deteriorating?

a. Temperature of 38.7 °C, because fever confirms that the infection is not responding to antibiotics

b. Respiratory rate of 28 per minute together with new confusion

c. Blood pressure of 108/64 mm Hg, because it is below her usual value

d. Oxygen saturation of 93% on room air

Answer: b — An adult with a respiratory rate above 24 per minute may be critically ill, and new confusion signals poor brain perfusion or oxygenation; together they point to serious deterioration (section 6.1). Option a: fever is a cue, but it does not by itself show deterioration or confirm antibiotic failure. Option c: the fall in blood pressure matters, but blood pressure often falls late, and 108/64 is not yet the most telling sign. Option d: a saturation of 93% is a cue to act on, but the respiratory rate and new confusion change earlier and more sharply here.

2. [CORE] What should the RPN do first?

a. Give acetaminophen for the fever as ordered and reassess in 1 hour

b. Document the findings and report them to the RN at the 0700 handover

c. Ask the daughter to stay with her mother while the RPN looks up her laboratory results

d. Stay with Ms. Mensah, keep her safe and have the RN and physician notified now

Answer: d — Every nurse who notices deterioration acts at once and escalates; the RPN keeps the patient safe and consults the RN as her needs change (section 6.2, Scope in Practice box). Option a: treating the fever does not address the deterioration and delays escalation. Option b: waiting 3 hours could allow shock to progress. Option c: reviewing results is useful but should not delay escalation, and the family should not be left responsible for a deteriorating patient.

3. [CORE] The RPN prepares an SBAR report. Which statement belongs in the Assessment part?

a. "Her breathing and heart rate have risen sharply since 2300, she is newly confused, and I am worried she may be developing sepsis."

b. "I am calling about Asha Mensah in room 8 on the medical unit, who has become restless and newly confused tonight."

c. "She is 66, was admitted yesterday with a kidney infection, and is receiving IV antibiotics; her vital signs at 2300 were near normal."

d. "Please come and assess her within 15 minutes, and tell me whether you want a lactate and blood cultures drawn."

Answer: a — The Assessment states what the nurse found, including trends, and what the nurse thinks is happening (section 6.2, Table 6.2). Option b is the Situation: who is calling, about whom, and the problem. Option c is Background. Option d is a Recommendation.

4. [CORE] The RPN reports to the RN, who is caring for a patient in another room and says she will come "in a few minutes." Twenty minutes later, Ms. Mensah's blood pressure is 96/58 mm Hg and her respiratory rate is 30. What should the RPN do?

a. Wait for the RN, because the RN is responsible for deciding whether to call for help

b. Recheck the vital signs in 1 hour, because the RN has already been informed

c. Call the rapid response team as hospital policy allows and inform the RN and charge nurse

d. Ask the daughter whether she would like to call the patient's family physician

Answer: c — When a concern is not addressed and the patient keeps deteriorating, the nurse continues up the escalation pathway; many policies let any staff member, including the RPN, call the rapid response team directly (section 6.2). Option a: the RPN's duty to escalate does not depend on the RN's response. Option b: waiting an hour while the blood pressure falls is unsafe. Option d: a family physician outside the hospital cannot provide urgent care, and escalation is the nurse's responsibility.

5. [CORE] Which findings are early cues that a hospitalized adult may be deteriorating? Select all that apply.

a. A respiratory rate that has risen from 16 to 24 per minute over 4 hours

b. New restlessness in a patient who was calm earlier in the shift

c. Urine output of 15 mL/h for 3 hours in a 70-kg patient

d. A blood pressure that is stable at the patient's usual value

e. Cool, clammy hands with slow capillary refill

f. A patient who reports sleeping well and eating breakfast

Answer: a, b, c, e — A rising respiratory rate, new restlessness, urine output below 0.5 mL/kg/h (35 mL/h for a 70-kg adult) and cool, clammy skin with slow capillary refill are all early cues (section 6.1, Table 6.1). Option d: a blood pressure at the patient's usual value is not a cue, although a normal pressure does not rule out early shock. Option f: sleeping well and eating are reassuring findings.

6. [CORE] A patient's early warning score is 2, which is in the lowest band. The nurse is worried because the patient "looks different" and says he feels something is wrong. What should the nurse do?

a. Reassure the patient, because his score does not meet the threshold for review

b. Repeat the score in 4 to 6 hours as the monitoring schedule suggests

c. Ask the patient to call if he feels worse

d. Complete a full assessment and escalate the concern despite the low score

Answer: d — Early warning scores support but do not replace clinical judgment; concern about a patient should prompt review whatever the score, and nurses' worry and patients' reports of feeling unwell are recognized cues (sections 6.1 and 6.2). Option a: a low score does not rule out deterioration. Option b: the monitoring schedule is a minimum, not a reason to wait when the nurse is concerned. Option c: this shifts responsibility to the patient and delays assessment.

7. [CORE] A patient is bleeding slowly after surgery. Her heart rate has risen from 80 to 115 per minute, her skin is cool and pale, and she is anxious. Her blood pressure is 124/76 mm Hg, close to her baseline. Which stage of shock do these findings best fit?

a. No shock, because her blood pressure is normal

b. Compensated shock

c. Progressive (decompensated) shock

d. Refractory (irreversible) shock

Answer: b — In compensated shock, sympathetic and hormonal responses keep blood pressure near normal while heart rate rises and the skin becomes cool and pale (section 6.3). Option a: a normal blood pressure does not rule out shock. Option c: progressive shock involves falling blood pressure and clear signs of organ hypoperfusion. Option d: refractory shock persists despite fluids and vasopressors.

8. [CORE] A patient's son tells the nurse, "Dad's not himself. He's usually sharp, and today he keeps losing his train of thought." The vital signs taken 1 hour ago were within normal limits. What is the best response?

a. "Thank you for telling me. I'll assess him now and compare with how he was earlier."

b. "His vital signs were normal an hour ago, so there's no need to worry."

c. "Older people often get a bit confused in hospital. It should settle."

d. "I'll make a note of it and the doctor can look at it on rounds tomorrow."

Answer: a — A family member's report of change from baseline is a valid cue, and confusion that may be new is treated as new until proven otherwise (section 6.1). Option b: normal readings an hour ago do not rule out a change now. Option c: confusion should never be assumed to be "normal" for age; it may be delirium or a sign of deterioration. Option d: delaying assessment until the next day could miss serious illness.

9. [CORE] A registered practical nurse (RPN) on an Ontario surgical unit finds a patient who is suddenly breathless and hypotensive. Which statement about the RPN's role is correct?

a. The RPN must transfer the patient's care to an RN before taking any action.

b. Because CNO rules limit RPNs to stable patients, the RPN may not care for this patient.

c. The RPN acts at once, escalates according to policy, and consults the RN as the patient's needs change.

d. The RPN should wait for the patient's most responsible provider to arrive before calling anyone else.

Answer: c — Every nurse who notices deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change, within employer policy (section 6.2, Scope in Practice box). Option a: immediate action and escalation come first. Option b: assigning patients by stability is a common employer practice, not a CNO rule. Option d: waiting delays care; escalation pathways allow calls to the rapid response team.

Case: Ms. Grace Okonkwo (Questions 10–15): Ms. Grace Okonkwo, 46, was admitted to a medical unit this morning with cellulitis of her left lower leg. She weighs 70 kg and reported no known drug allergies. At 1330 her vital signs were temperature 37.8 °C, heart rate 88, respiratory rate 18, blood pressure 128/78 mm Hg and oxygen saturation 97% on room air. At 1400 the nurse starts the first dose of an IV antibiotic. At 1408 Ms. Okonkwo calls the nurse and says, "My throat feels tight and I'm itchy all over. Something terrible is happening." Assessment: heart rate 124, respiratory rate 28, blood pressure 84/46 mm Hg, oxygen saturation 91% on room air, wheezes in both lungs and a hoarse voice. Her lips and eyelids are swollen. On her dark brown skin, raised welts on her chest and arms are easier to feel than to see. She is nauseated. Her left leg is red-brown, warm and swollen, as it was this morning.

10. [CORE] Which findings at 1408 require immediate follow-up? Select all that apply.

a. Hoarse voice and a tight throat

b. Blood pressure 84/46 mm Hg

c. Warm, swollen left lower leg

d. Swollen lips and eyelids

e. Temperature 37.8 °C at 1330

f. No known drug allergies on admission

g. Oxygen saturation 91% with wheezes

Answer: a, b, d, g — A hoarse voice and tight throat (a) suggest airway swelling. A blood pressure of 84/46 mm Hg (b) is a sharp fall from her baseline and shows poor perfusion. Swelling of the lips and eyelids (d) is angioedema of the skin and mucosa. Low oxygen saturation with wheezes (g) shows bronchospasm. All are new since 1330 (section 6.5). The warm, swollen leg (c) and mild temperature (e) are unchanged findings of her cellulitis. Having no known allergies (f) does not rule out a first reaction and needs no action in itself.

11. [CORE] The nurse analyzes the cues. Which explanation best fits Ms. Okonkwo's findings?

a. Sepsis from cellulitis that is causing low blood pressure and fast breathing

b. A panic attack triggered by worry about her hospital admission

c. Anaphylaxis to the IV antibiotic started 8 minutes earlier

d. A vasovagal reaction caused by the insertion of her IV catheter

Answer: c — Sudden skin and mucosal signs together with breathing difficulty and low blood pressure within minutes of a new IV drug meet the WAO criteria for anaphylaxis (c) (section 6.5). Sepsis (a) does not cause hives, lip swelling and wheeze within minutes of a drug. A panic attack (b) does not cause hypotension, welts or swelling. A vasovagal reaction (d) causes a slow heart rate and pallor, not tachycardia, wheeze and angioedema.

12. [CORE] Which problem is the priority for Ms. Okonkwo?

a. Nausea and the risk of aspiration if she vomits
b. Airway compromise and shock from anaphylaxis
c. Spread of infection from the cellulitis
d. Anxiety about her sudden change in condition

Answer: b — A swelling airway, bronchospasm and hypotension can lead to respiratory and cardiac arrest within minutes, so airway and circulation come first (b) (section 6.5). Nausea (a) and anxiety (d) are real but are part of the reaction and improve when it is treated. The cellulitis (c) still needs treatment, but it is not the immediate threat.

13. [CORE] Which actions should the nurse take now? Select all that apply.

a. Stop the antibiotic infusion and disconnect the tubing
b. Call for help and activate the rapid response team
c. Give IM epinephrine into the mid-anterolateral thigh per the medical directive
d. Give an oral antihistamine and recheck her in 15 minutes
e. Help her stand at the bedside to ease her breathing
f. Flush the IV line quickly to keep it open
g. Raise the head of the bed while keeping her legs up, and give oxygen

Answer: a, b, c, g — Stopping the trigger (a), calling for help (b), giving IM epinephrine at once (c) and positioning for breathing while supporting circulation, with oxygen (g), are first actions (Table 6.4). An antihistamine (d) does not treat breathing or circulation problems and must not delay epinephrine. Standing or sitting up suddenly (e) can cause collapse. Flushing the line (f) would push the antibiotic left in the tubing into her vein; the tubing is disconnected and access kept with a new line.

14. [CORE] The nurse prepares epinephrine from a 1 mg/mL ampoule. Which order is correct for Ms. Okonkwo's first dose?

a. 0.5 mL of the 1 mg/mL solution, IV push over 1 minute
b. 5 mL of the 1 mg/mL solution, IM into the deltoid
c. 0.5 mL of the 1 mg/mL solution, injected subcutaneously into the abdomen
d. 0.5 mL of the 1 mg/mL solution, IM into the mid-anterolateral thigh

Answer: d — The standard adult dose is 0.5 mg, which is 0.5 mL of the 1 mg/mL solution, given IM into the mid-anterolateral thigh (d) (Medications box). The IM dose must never be given IV (a), because it can cause a sharp rise in blood pressure and bleeding in the brain. Option b is ten times the dose and uses a site that is not recommended. The subcutaneous route (c) is not the recommended route.

15. [CORE] At 1440 the nurse evaluates Ms. Okonkwo after two doses of epinephrine, oxygen and an IV fluid bolus. Which findings best show that treatment is effective?

a. Blood pressure 116/70 mm Hg, no wheezes, normal voice, oxygen saturation 96%
b. Heart rate 112 with palpitations, and she says she feels anxious
c. Hives fading after an antihistamine, blood pressure 88/50 mm Hg
d. Calm and drowsy, respiratory rate 10, oxygen saturation 89%

Answer: a — A restored blood pressure, cleared wheeze, normal voice and good oxygen saturation (a) show that perfusion and the airway have improved (section 6.5). A fast heart rate, palpitations and anxiety (b) are expected effects of epinephrine and do not show whether the reaction is controlled. Fading hives with persistent hypotension (c) mean the reaction is not controlled. Drowsiness with slow breathing and low saturation (d) signals deterioration and needs escalation.

16. [CORE] On the evening after a bowel resection, a patient's heart rate has risen from 82 to 114 over 4 hours. Blood pressure has changed from 128/78 to 116/94 mm Hg. The patient is restless and the skin is cool. The abdominal dressing is dry. Which interpretation is correct?

a. The findings are reassuring because the blood pressure is still above 90 mm Hg systolic
b. The patient may be bleeding and is compensating; this needs urgent escalation
c. The restlessness is most likely pain, so analgesia is the first step
d. A dry dressing shows that the drop in blood pressure has another cause

Answer: b — A rising heart rate, a pulse pressure that has narrowed from 50 to 22, cool skin and restlessness are early cues of hypovolemic shock while blood pressure is still maintained (b) (section 6.4). Hypotension is a late sign (a). Pain (c) does not explain the narrowing pulse pressure and cool skin, and assuming pain delays escalation. Bleeding can be internal, so a dry dressing (d) does not rule it out.

17. [CORE] A patient with an acute MI has blood pressure 82/54 mm Hg, cool clammy skin and confusion. A chest X-ray shows pulmonary congestion, and oxygen saturation has fallen from 95% to 89%. Which action by the nurse is most appropriate?

a. Lower the head of the bed flat and raise the legs to improve venous return
b. Start a rapid 1 L crystalloid bolus under an existing order for "fluid for hypotension"
c. Escalate urgently and report the congestion before any fluid is given
d. Encourage oral fluids to correct the low blood pressure

Answer: c — This is cardiogenic shock with congestion. Fluids are given cautiously, and a fluid challenge is tried only when there are no signs of congestion, so the nurse escalates urgently and reports the congestion before any fluid (c) (section 6.4). Lying flat with legs raised (a) adds to the load on the failing heart and worsens breathing. A rapid 1 L bolus (b) can worsen pulmonary congestion. Oral fluids (d) will not correct shock and are unsafe in a confused patient.

18. [CORE] A patient admitted after a fall has a new spinal cord injury at the level of the sixth cervical vertebra. Blood pressure is 82/48 mm Hg and heart rate 48. Which type of shock best fits these findings?

a. Neurogenic shock from loss of sympathetic tone
b. Hypovolemic shock from bleeding at the injury site
c. Cardiogenic shock from a heart attack during the fall
d. Obstructive shock from a tension pneumothorax

Answer: a — Hypotension with a slow heart rate after a cervical cord injury fits neurogenic shock, caused by loss of sympathetic output and unopposed parasympathetic activity (a) (section 6.5). Hypovolemic shock (b) usually causes a fast heart rate. Cardiogenic shock (c) and tension pneumothorax (d) typically cause tachycardia and other cues, such as congestion or sudden breathlessness, that are not described.

19. [CORE] Four hours after cardiac surgery, a patient's chest tube drainage suddenly stops. Blood pressure falls to 78/50 mm Hg, the neck veins are distended and the heart sounds are muffled. What should the nurse do first?

a. Milk and strip the chest tube to restore drainage and recheck in 30 minutes

b. Give a fluid bolus and reassess the blood pressure before calling the surgeon

c. Document the findings and continue to monitor every 15 minutes

d. Call for immediate help as policy directs and report suspected tamponade

Answer: d — Hypotension, distended neck veins and muffled heart sounds (Beck's triad) after cardiac surgery suggest cardiac tamponade, which needs immediate escalation for drainage (d) (section 6.5). Waiting 30 minutes (a) or monitoring alone (c) delays life-saving treatment, and stripping a chest tube is not a substitute for escalation. Fluids (b) should not delay drainage.

20. [CORE] Which patient meets the clinical criteria for septic shock?

a. Pneumonia, lactate 1.4 mmol/L, MAP 70 mm Hg after 2 L of crystalloid

b. Urinary infection, lactate 3.4 mmol/L, MAP 64 mm Hg after adequate fluids, norepinephrine started to reach 65 mm Hg

c. Cellulitis, lactate 2.8 mmol/L, MAP 68 mm Hg after adequate fluids, no vasopressor needed

d. Abdominal infection, lactate 2.4 mmol/L, MAP 60 mm Hg before any fluids have been given

Answer: b — Septic shock requires a vasopressor to keep the MAP at 65 mm Hg or higher and a lactate above 2 mmol/L despite adequate fluids (b) (section 6.5; Chapter 4, section 4.6). Patient a has a normal lactate and needs no vasopressor. Patient c needs no vasopressor. Patient d has not yet had fluid resuscitation.

21. [CORE] A patient in septic shock is receiving norepinephrine through a peripheral IV in the forearm. Which action by the nurse is correct?

a. Flush the norepinephrine line with saline each hour to keep it patent

b. Give an IV antibiotic through the norepinephrine line to avoid another IV start

c. Inspect the site often and stop the infusion into that site if swelling or blanching appears

d. Stop the norepinephrine at once when the MAP reaches 75 mm Hg

Answer: c — The nurse inspects a peripheral vasopressor site often and acts at once on extravasation according to policy (c) (section 6.6). Flushing the line (a) or pushing another drug through it (b) would push the vasopressor in the tubing into the patient faster than intended. A vasopressor is reduced gradually as ordered, never stopped abruptly (d).

22. [CORE] A patient in shock weighs 80 kg. Urine output was 30 mL in each of the past 2 hours. Which interpretation is correct?

a. Output is below 0.5 mL/kg/h, a sign of poor kidney perfusion that should be reported

b. Output is adequate because it is at least 30 mL in every hour

c. Output cannot be judged until a full 24-hour total is available

d. Output is low only if the patient also has a raised serum potassium

Answer: a — For an 80 kg patient, 0.5 mL/kg/h is 40 mL/h, so 30 mL/h is below it and signals underperfused kidneys (a) (section 6.6). A fixed 30 mL/h threshold (b) ignores body weight. Hourly output is the measure used in shock; waiting 24 hours (c) delays action. Low output is significant on its own (d).

23. [CORE] An 81-year-old who takes a beta-blocker and has long-standing hypertension (usual blood pressure 150/86 mm Hg) has had a GI bleed. Heart rate is 84 and blood pressure 106/64 mm Hg. She is newly confused. Which interpretation is best?

a. Her vital signs are within normal limits, so the confusion is probably delirium from an unfamiliar setting

b. A heart rate of 84 shows that she is not losing a significant amount of blood

c. Her blood pressure is well above 90 mm Hg systolic, so shock is unlikely

d. She may be in shock: the beta-blocker can blunt tachycardia, and her pressure is well below her usual

Answer: d — Beta-blockers weaken the heart rate response to blood loss, and a pressure of 106/64 mm Hg is far below her usual 150/86 mm Hg; new confusion may reflect poor brain perfusion (d) (Lifespan Considerations box). Assuming delirium (a) or relying on the heart rate (b) or a systolic cut-off of 90 mm Hg (c) could miss shock in an older adult.

24. [CORE] The nurse teaches a patient who has been prescribed an epinephrine autoinjector after anaphylaxis. Which statement shows the patient understands?

a. "If I use the autoinjector and feel better, I won't need to go to the hospital."

b. "I will use it at the first sign of a reaction, call 9-1-1, and go to the hospital even if I feel better."

c. "I will take an antihistamine first and use the autoinjector only if that doesn't work."

d. "I will keep it in the refrigerator so that it lasts longer."

Answer: b — Epinephrine is used as soon as a reaction starts, whether known or suspected, followed by a call to 9-1-1 and a hospital visit even if symptoms ease, because they can return (b) (Patient Education box). Skipping hospital care (a) misses a biphasic reaction. An antihistamine (c) must never delay epinephrine. Autoinjectors are kept at room temperature, not refrigerated (d).

25. [CORE] An RPN on a surgical unit finds that a patient's heart rate has risen from 88 to 122 since the last check, the blood pressure has fallen from 124/76 to 98/80 mm Hg, and the drain has filled with bright red blood. The RN assigned to the team is on a break. What should the RPN do?

a. Recheck the vital signs in 30 minutes, then report to the RN when the RN returns

b. Change the drain bag and record the volume, then continue the rest of the assessment

c. Call for help at once as policy directs, and inform the RN

d. Ask the patient's family to watch for any further change while the RPN finishes other care

Answer: c — Every nurse who notices deterioration acts at once and escalates; the RPN calls for help directly, through the rapid response team or the most responsible provider as policy directs, and consults the RN as the patient's needs change (c) (section 6.4; Chapter 1, section 1.3). Waiting for the RN (a), focusing on the drain (b) or delegating monitoring to the family (d) delays care for likely hemorrhagic shock.

26. [CORE] A hospital's anaphylaxis medical directive authorizes nurses who have completed its anaphylaxis education to give IM epinephrine. An RPN who has completed that education finds a patient in anaphylaxis. Which statement about the RPN's scope is correct?

a. The RPN may give the epinephrine under the directive, because the RPN has the authority, competence and context to do so

b. The RPN must wait for an RN to give the epinephrine, because only RNs can act in emergencies

c. The RPN may give the epinephrine only after a physician gives a verbal order for this patient

d. The RPN may not give the epinephrine, because the patient's condition is unstable

Answer: a — Under CNO's Scope of Practice standard, the RPN considers authority (here, the medical directive), competence (the completed education) and context; with all three in place, the RPN can act (a) (section 6.5; Chapter 1, section 1.3). Nothing limits emergency action to RNs (b). The directive provides the authority, so a separate verbal order is not required (c). Patient instability does not bar an RPN from life-saving action authorized by a directive (d); employer policy and province or territory matter.

27. [RN] Which hemodynamic pattern is typical of distributive shock?

a. Low cardiac output, high filling pressures and high SVR

b. Low cardiac output, low filling pressures and high SVR

c. Low cardiac output with high right-sided pressures

d. Low SVR with a normal or high cardiac output

Answer: d — Distributive shock is caused by loss of vascular tone, which lowers SVR; cardiac output is usually normal or high (d) (Going Deeper box). Option a describes cardiogenic shock, option b hypovolemic shock and option c obstructive shock from pulmonary embolism.

28. [RN] An ICU nurse is titrating norepinephrine to a MAP target of 65 mm Hg. The MAP is now 78 mm Hg. Which action follows safe titration principles?

a. Stop the infusion now, because the MAP is above target, and recheck it in 15 minutes

b. Reduce the rate in a small step within the ordered limits and recheck the blood pressure within minutes

c. Leave the rate unchanged until the next scheduled vital signs

d. Reduce the rate to half and recheck the MAP in 1 hour

Answer: b — Titration uses small steps within the ordered limits, with frequent rechecks (b) (Going Deeper box). Stopping abruptly (a) or making a large cut (d) can cause rebound hypotension, and waiting an hour misses the response. Leaving the rate unchanged (c) ignores the order to titrate to the target.

29. [RN] Why does a patient in hypovolemic or cardiogenic shock usually have cool, pale skin?

a. Systemic vascular resistance falls, so blood pools in the skin

b. Cardiac output rises, which moves heat away from the skin too quickly

c. Vasoconstriction raises systemic vascular resistance and diverts blood away from the skin

d. The skin receives more blood than usual, but the blood carries less oxygen

Answer: c — When cardiac output falls, the sympathetic system constricts vessels, raising SVR and moving blood away from the skin toward vital organs (c) (Going Deeper box). Falling SVR (a) is the distributive pattern. Cardiac output falls in these types of shock (b). Skin blood flow falls, not rises (d).

30. [RN] A patient's heart rate is 125 beats/min and stroke volume is 40 mL. Which statement is correct?

a. Cardiac output is 5.0 L/min; the fast heart rate is keeping cardiac output up despite a low stroke volume

b. Cardiac output is 3.1 L/min; the patient's stroke volume is normal for an adult

c. Cardiac output is 50 L/min, which is very high and suggests distributive shock

d. Cardiac output cannot be calculated without knowing the systemic vascular resistance

Answer: a — Cardiac output equals heart rate times stroke volume: 125 × 40 mL = 5,000 mL, or 5.0 L/min (a). The tachycardia is compensating for a low stroke volume (Going Deeper box). Option b uses the wrong product and calls a low stroke volume normal. Option c misplaces the decimal. SVR is not needed to calculate cardiac output (d).

II Cross-Cutting Clinical Priorities in Adult Care

UNIT CLINICAL SCOPE & INTEGRATION

Addresses five clinical domains that intersect every adult medical-surgical inpatient unit: safe perioperative and perianesthesia nursing care, age-friendly acute care for older adults (delirium, dementia, falls, and polypharmacy), medical-surgical oncology and systemic therapy safety, palliative care and Medical Assistance in Dying (MAID), and trauma-informed substance use care and harm reduction.

07 Perioperative Nursing

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Describe the phases of perioperative care, the settings in which surgery happens and the perioperative team.
2. Complete a focused preoperative assessment, including medications, frailty, obstructive sleep apnea and anesthesia risk.
3. Prepare patients for surgery, including fasting, skin preparation, teaching and the preoperative checklist.
4. Explain the nurse's role in informed consent and in the Surgical Safety Checklist.
5. Compare types of anesthesia and sedation, and recognize anesthesia emergencies.
6. Provide safe postanesthesia care, including airway, temperature, postoperative nausea and vomiting, pain and handover.
7. Prevent, recognize and escalate common postoperative complications, including venous thromboembolism, using enhanced recovery principles.
8. Distinguish RN and RPN roles in perioperative care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 5	Clinician; Scholar	Foundations of Practice
3, 6, 7	Clinician; Educator; Coordinator	Foundations of Practice; Collaborative Practice
4, 8	Advocate; Professional; Collaborator	Legal Practice; Professional Practice

Introduction

Surgery touches the lives of many adults in Canada. One person walks into a day surgery clinic for cataract removal and is home by supper. Another is admitted for a knee replacement, and a third arrives through the emergency department needing an operation that cannot wait. Whatever the procedure, the patient's safety depends on careful preparation, clear communication and close monitoring before, during and after the operation.

Perioperative nursing is the care nurses give across this whole span. Nurses work in preadmission clinics, same-day surgery units, operating rooms, postanesthesia care units, surgical inpatient units and the community. In every setting, the nurse assesses, teaches, advocates and watches for early signs that something is going wrong.

This chapter follows the patient through surgery. Section 7.1 describes the perioperative journey and the team. Section 7.2 covers preoperative assessment and preparation, and Section 7.3 covers consent, the day of surgery and the Surgical Safety Checklist. Sections 7.4 to 7.6 continue with anesthesia and sedation, postanesthesia care, postoperative complications, venous thromboembolism (VTE) prophylaxis and enhanced recovery after surgery (ERAS). Related topics live elsewhere: consent, scope and teamwork (Chapter 1), surgical site infection (Chapter 4), pain (Chapter 5), deterioration and shock (Chapter 6), delirium (Chapter 8), VTE treatment (Chapter 19), bowel surgery and ostomies (Chapter 25) and orthopedic surgery (Chapter 33).

7.1 The Perioperative Journey

Three Phases

Nurses usually describe surgery in three phases. The **preoperative** phase starts when the patient and surgeon decide to operate and ends when the patient is transferred to the operating room (OR). The **intraoperative** phase covers the time in the OR, from arrival to

transfer to the recovery area. The **postoperative** phase begins with admission to the recovery area and continues until the patient has recovered, whether in hospital, at home or both.

Most patients wake in a **postanesthesia care unit (PACU)**, a unit that gives short-term care immediately after operations and invasive procedures (British Columbia Ministry of Health, 2024). The Canadian Anesthesiologists' Society (CAS) guidelines require one in every facility that provides anesthesia (Dobson et al., 2026). PACU care is often described in phases: Phase I is close, continuous monitoring as the patient emerges from anesthesia, and Phase II is lighter monitoring for stable patients nearing discharge criteria. The phase reflects the patient's physiological recovery, not the room they are in (College of Physicians and Surgeons of British Columbia [CPSBC], 2026). Postanesthesia care is taught in section 7.5.

Ambulatory surgery (day surgery) means the patient goes home on the day of the procedure, with written instructions and a responsible adult (Dobson et al., 2026). **Inpatient surgery** means the patient stays in hospital afterwards. Many patients having major elective surgery come in under **same-day admission**: they prepare at home, arrive on the morning of the operation and are admitted afterwards. Their teaching usually happens weeks earlier, so the nurse on the day of surgery checks that the preparation actually happened.

The Perioperative Team

Surgical care is teamwork, and the general principles of collaboration and scope are covered in Chapter 1, section 1.3. The surgical team includes several roles:

- **Surgeon:** decides with the patient whether to operate, obtains informed consent and performs the procedure.
- **Anesthesiologist:** assesses the patient, plans and gives the anesthetic, and directs early recovery. The CAS guidelines also recognize family practice anesthesia physicians, family physicians who have completed an accredited postgraduate anesthesia program, as anesthesia providers (Dobson et al., 2026).
- **Anesthesia assistant:** a formally designated team member with specific training in anesthesia assistance, whose tasks are approved by the department of anesthesia and the facility (Dobson et al., 2026).
- **Perioperative nurses:** the scrub nurse works within the sterile field, handling instruments and keeping counts; the circulating nurse works outside it, coordinating the room, documenting and advocating for a patient who cannot speak under anesthesia. The Operating Room Nurses Association of Canada (ORNAC) publishes national standards for perioperative nursing (ORNAC, 2023).
- **PACU, surgical unit and community nurses:** monitor emergence from anesthesia, then continue recovery care, teaching and discharge planning.

Access and Wait Times

Timely access is part of safe surgery. The Canadian Institute for Health Information (CIHI) reports wait times for priority procedures, including median and 90th percentile waits and the percentage of patients treated within benchmarks (CIHI, n.d.). For planned hip and knee replacement, the benchmark is surgery within 26 weeks (182 days) of the date the patient was ready to be treated; for cataract surgery, it is within 16 weeks (112 days). CIHI's indicator pages give these results for each province (CIHI, 2026a, 2026b). Waiting is also a chance to prepare: prehabilitation (section 7.2) can start early.

Where a person lives also shapes access. Many people in rural, remote and northern communities, including many First Nations, Inuit and Métis people, travel long distances for surgery, away from family and support (Chapter 1, section 1.2; Chapter 2). The nurse plans for travel, escorts, follow-up close to home and the cost of repeated trips.

7.2 Preoperative Assessment and Preparation

The Preoperative Assessment

The preoperative assessment finds risks that can be reduced and gives the teams what they need to plan. It may happen in a preadmission clinic, by telephone or on the day of surgery. The CAS guidelines direct the anesthesia history to include past medical and surgical problems, medications taken now and recently, drug reactions, past problems with anesthesia, and any family history of

reactions to anesthesia (Dobson et al., 2026). Family history matters because some serious reactions, such as malignant hyperthermia (discussed later in this chapter), are inherited. The nurse asks, "Has anyone in your family had a bad reaction to an anesthetic?" and records the answer exactly.

The nurse's assessment usually covers:

- **Heart and lungs:** chest pain, shortness of breath, palpitations, recent respiratory infection, and baseline vital signs and oxygen saturation.
- **Functional capacity:** how much activity the patient manages, such as climbing a flight of stairs without stopping.
- **Smoking, vaping, alcohol and other substance use:** asked without judgment (Chapter 11).
- **Possibility of pregnancy:** with testing when indicated by policy.
- **Cognition:** baseline memory, orientation and decision-making, so that later changes can be recognized and consent supported (section 7.3).
- **Supports:** who will drive the patient home and help afterwards, and barriers such as distance or cost.

Frailty is reduced physiological reserve that leaves a person less able to recover from a stressor such as surgery. It is common in older adults but is not the same as age. The Clinical Frailty Scale, a Canadian tool, is taught in Chapter 8. Identifying frailty early helps the team plan support from the start.

Obstructive sleep apnea (OSA) is repeated collapse of the upper airway during sleep, which interrupts breathing. Much OSA is undiagnosed (Chung et al., 2016), and it matters because anesthetics, sedatives and opioids relax the airway and blunt breathing. The **STOP-Bang** questionnaire, from the University Health Network in Toronto, is a quick screening tool with eight yes-or-no items. Four are questions: loud snoring, daytime tiredness, breathing pauses or choking noticed by someone else, and high blood pressure, treated or not. Four are facts: body mass index above 35 kg/m², age over 50 years, neck circumference above 40 cm, and male sex. Each "yes" scores one point. A score of 0 to 2 suggests low risk of moderate to severe OSA, 3 or 4 an intermediate risk, and 5 to 8 a high risk; certain combinations move an intermediate score to high (Chung et al., 2016). A high score does not diagnose OSA. It flags a patient the anesthesia team needs to know about.

The anesthesiologist summarizes overall health with the **American Society of Anesthesiologists (ASA) Physical Status** classification, which the CAS guidelines direct to be recorded for every patient (Dobson et al., 2026):

- **ASA I:** a healthy person.
- **ASA II:** mild systemic disease, such as well-controlled hypertension.
- **ASA III:** severe systemic disease, such as poorly controlled diabetes or chronic obstructive pulmonary disease.
- **ASA IV:** severe systemic disease that constantly threatens life, such as sepsis.
- **ASA V:** a critically ill patient who is expected to die without the operation.
- **ASA VI:** a person declared dead by neurological criteria whose organs are being recovered for donation.

Adding "E" marks emergency surgery, where delay would significantly increase the threat to life or a body part (Canadian Anesthesiologists' Society, 2025). The class describes the patient, not the risk of the operation.

Reviewing Medications

A complete medication history includes prescription and over-the-counter drugs, natural health products, and drugs taken only occasionally or by weekly injection. The nurse confirms each product with the patient and documents what was taken and when. Some medications continue through surgery and some are paused. **The plan for each medication comes from the prescriber or the anesthesia team, not the nurse.** The nurse finds the medications that matter, makes sure the team knows, and teaches the patient the plan (Table 7.1).

Anticoagulants and antiplatelet drugs force a trade-off: continuing them raises bleeding risk, and stopping them raises the risk of clots, stroke or stent thrombosis. The team weighs these risks for each patient, sometimes drawing on clinical guidance from Thrombosis Canada (Thrombosis Canada, n.d.). Anticoagulation is taught in Chapter 19.

Diabetes medications need a plan because fasting and surgical stress change glucose control (Chapter 22). Two newer drug classes need special attention. Health Canada reviewed reports of diabetic ketoacidosis (DKA) after surgery in people taking sodium-glucose cotransporter-2 (SGLT2) inhibitors, such as empagliflozin, dapagliflozin and canagliflozin; Health Canada recommends stopping these drugs temporarily before surgery, is working with manufacturers to update the Canadian product monographs, and recommends monitoring for DKA afterwards (Health Canada, n.d.-b). Glucagon-like peptide-1 (GLP-1) receptor agonists, such as semaglutide, dulaglutide, liraglutide and tirzepatide, slow stomach emptying. Health Canada found a possible link between these drugs and pulmonary aspiration during general anesthesia or deep sedation, and the CAS has warned that some patients taking them arrive with food still in the stomach despite fasting (Canadian Anesthesiologists' Society, 2023; Health Canada, n.d.-a).

The plan for opioids and opioid agonist treatment (OAT), such as methadone or buprenorphine, is made with the prescriber and pain team (Chapter 5). Every allergy is recorded with the reaction it caused, because a rash and anaphylaxis call for very different precautions (Chapter 6).

Table 7.1 Preoperative medication review: what to ask and why (Canadian Anesthesiologists' Society, 2023; Health Canada, n.d.-a, n.d.-b; Thrombosis Canada, n.d.)

Medication group	Examples	Why it matters	Nursing action
Anticoagulants	Warfarin, apixaban, rivaroxaban, dabigatran; heparins	Continuing them raises bleeding risk; stopping them raises clot risk	Ask what was taken and when; document; confirm the team's plan; teach the patient that plan
Antiplatelet drugs	Acetylsalicylic acid, clopidogrel, ticagrelor	Bleeding risk must be balanced against the risk of stent thrombosis or stroke	Ask about recent stents or heart attacks; document; confirm the plan with the prescriber or anesthesia team
Insulin	Long-acting and rapid-acting insulins	Fasting and surgical stress change insulin needs; risk of low or high glucose	Ask about usual doses and last dose; check glucose as ordered; confirm the plan; teach signs of low glucose
SGLT2 inhibitors	Empagliflozin, dapagliflozin, canagliflozin	Linked to diabetic ketoacidosis after surgery, including in patients who stopped the drug only shortly before	Ask about last dose; report if taken against instructions; watch for DKA after surgery as ordered
GLP-1 receptor agonists	Semaglutide, dulaglutide, liraglutide, tirzepatide	Slowed stomach emptying may leave food in the stomach despite fasting, raising aspiration risk	Ask specifically, including weekly injections and weight-loss use; make sure the anesthesia team knows
Opioids and opioid agonist treatment	Methadone, buprenorphine, prescribed opioids	Interruption risks withdrawal and poorly controlled pain	Confirm current treatment and prescriber; ensure the pain team knows; see Chapter 5
Natural health products	Herbal remedies, supplements, vitamins	Patients may not mention them; some can interact with prescribed drugs	Ask directly; document; let the pharmacist and anesthesia team review
All other regular medications	Blood pressure, heart, seizure and mental health drugs	Some are taken on the morning of surgery and some are not	Confirm each against the anesthesia team's instructions; document the last dose

CLINICAL JUDGMENT

A Medication Question on the Morning of Surgery

Gloria Tremblay, 68, arrives at 0630 for a scheduled bowel resection. She has type 2 diabetes. At her preadmission visit she was told to stop her SGLT2 inhibitor before surgery, and the instructions are in her chart.

- **Recognize cues:** While reviewing her medications, the nurse asks when she last took each one. Gloria says, "I took my usual pills yesterday morning. I forgot that one was supposed to stop." She is alert and oriented, with stable vital signs. She says she has been thirsty since starting her bowel preparation.
- **Analyze cues:** The drug was taken inside the window her team set. Fasting, bowel preparation and the stress of surgery all add to the risk of ketoacidosis described for this drug class.
- **Prioritize hypotheses:** The most important concern is that she could develop diabetic ketoacidosis around surgery. Other possibilities include dehydration from the bowel preparation.

- **Generate solutions:** The decision to proceed, delay or order tests belongs to the anesthesia team and surgeon. The nurse's options are to report promptly and clearly, and to have the information ready.
- **Take action:** The nurse calls the anesthesiologist and then the surgeon using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6), giving the drug name, when it was last taken, the instructions she had received, her vital signs and her symptoms. The nurse carries out any orders, such as blood tests, and documents the conversation. The nurse reassures Gloria without blaming her.
- **Evaluate outcomes:** The nurse confirms that the plan is clear to the team and to Gloria and records it. If surgery is delayed, the nurse asks Gloria what made the instructions hard to follow, and helps the team find a clearer way to give them.

Tests Before Surgery

Preoperative tests should answer a question about the patient, not be ordered by routine. Choosing Wisely Canada's anesthesiology recommendations, developed with the CAS, advise against baseline blood work (complete blood count, coagulation tests or serum biochemistry) and against a baseline electrocardiogram (ECG) for people without symptoms having low-risk non-cardiac surgery. They also advise against a baseline chest X-ray for people without symptoms unless it is part of a surgical or cancer workup, and against resting echocardiography and cardiac stress testing for people without symptoms having non-cardiac surgery of low or intermediate risk (Choosing Wisely Canada, 2025). A careful history and physical examination usually find what routine tests would, and unneeded tests can lead to further testing that does not help. Tests are still done when the patient's conditions, medications or surgery call for them (Dobson et al., 2026).

Fasting and Carbohydrate Loading

Fasting before anesthesia lowers the chance that stomach contents will be inhaled into the lungs while protective reflexes are dulled. The current CAS guidelines set minimum fasting times before elective procedures: six hours after any meal that includes solid food, and two hours after clear fluids for adults, with separate times for infants and children. Unless there is a reason not to, the CAS encourages adults to keep drinking clear fluids, such as water, pulp-free juice, carbohydrate drinks, and black tea or coffee, until two hours before elective surgery (Dobson et al., 2026).

These are minimums, not targets. The old habit of "nothing by mouth after midnight" often leaves patients fasting far longer than needed, and the Enhanced Recovery After Surgery (ERAS) Society's colorectal guideline strongly recommends following modern fasting guidelines rather than fasting overnight (Gustafsson et al., 2019). Some patients, such as those taking GLP-1 receptor agonists, may be given different instructions. **The nurse teaches the patient to follow the anesthesia team's instructions** and, on the day of surgery, asks exactly what was eaten or drunk and when. Anything outside the instructions is reported to the anesthesia team, who decide what happens next.

In ERAS pathways, patients may be given a carbohydrate drink before surgery. The ERAS colorectal guideline strongly recommends these drinks, based on moderate evidence that they improve well-being and reduce insulin resistance and low-quality evidence that they reduce complications or speed recovery; the recommendation is weak for people with well-controlled diabetes or obesity (Gustafsson et al., 2019). The drink is given only as ordered on the pathway. ERAS is discussed later in the chapter.

Skin Preparation

The World Health Organization (WHO) regards a bath or shower with plain or antimicrobial soap before surgery as good clinical practice; the nurse teaches bathing as hospital policy directs. Hair is left in place unless it must be removed, and then only with clippers. WHO strongly discourages shaving at any time, whether before surgery or in the OR, because shaving carries a higher risk of surgical site infection than clipping or leaving hair in place (World Health Organization, 2018). Surgical site infection is taught in Chapter 4.

Prehabilitation and Teaching

Prehabilitation means improving a patient's physical and mental fitness in the weeks before surgery so they have more reserve to recover, often through exercise, nutrition and psychological support. The ERAS colorectal guideline found moderate evidence that multimodal prehabilitation improves functional capacity but low-quality evidence that it improves outcomes after surgery, so it is not yet a mandatory pathway element. Stopping smoking has stronger support: the guideline recommends stopping at least four weeks

before surgery to reduce lung and wound-healing complications (Gustafsson et al., 2019). The nurse offers cessation support at every contact.

The same guideline strongly recommends routine, dedicated preoperative counselling (Gustafsson et al., 2019). Teaching covers:

- **Deep breathing and coughing:** slow, deep breaths and effective coughs to open the small airways and clear secretions, with a pillow pressed over the incision (splinting) to reduce pain.
- **Incentive spirometer:** a hand-held device that shows the patient how deeply they are breathing in, encouraging slow, full breaths, if the hospital uses one (Figure 7.1).
- **Leg exercises:** ankle pumps and foot circles to keep blood moving in the legs while in bed.
- **Early mobilization:** sitting up, standing and walking as soon as the team allows, with help.

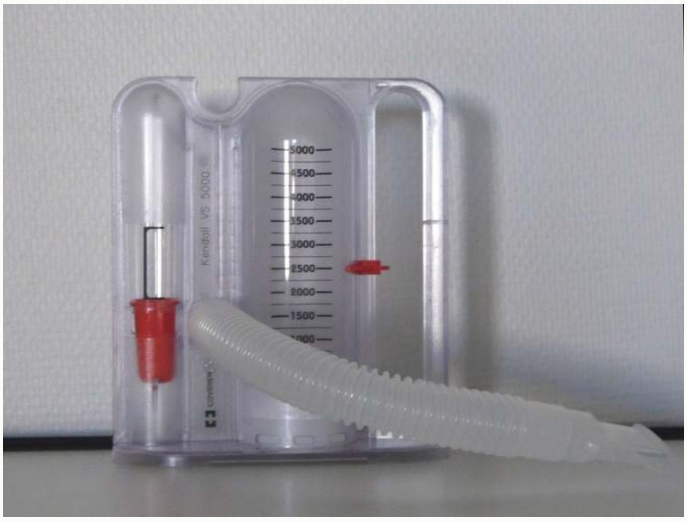

Figure 7.1 An incentive spirometer, which encourages slow, deep breaths after surgery.

- **The pain plan:** how pain will be assessed and treated, and why reporting it early helps (Chapter 5).
- **What to expect:** where the patient will wake up and what tubes or drains may be in place.

The nurse uses plain language, demonstrates, and asks the patient to explain or show the skill back (teach-back); pictures and short written steps help patients with limited literacy. For patients who prefer a language other than English, the nurse uses a qualified interpreter, not a family member (Chapter 1, section 1.7).

7.3 Consent and the Day of Surgery

The Nurse's Role in Consent

Informed consent for surgery is obtained by the surgeon, who explains the procedure, its risks and benefits, the alternatives, and what happens if the patient declines. The law on consent, capacity and substitute decision-makers in Ontario's *Health Care Consent Act, 1996*, is taught in Chapter 1, section 1.5; this section covers how that law plays out on the day of surgery.

The nurse's role is to check, not to obtain, consent. The nurse confirms that consent is documented, that the procedure and side named on the form match the booking and the patient's own words, and that the patient understands what will happen. A simple question works well: "Can you tell me in your own words what operation you are having today?" If the patient cannot describe it, has new questions about risks or alternatives, or says they feel pressured, the nurse tells the surgeon before the patient goes to the OR. The nurse does not try to explain the surgeon's part of the discussion or reassure the patient into signing.

Consent can be withdrawn at any time, including on the stretcher outside the OR. If a patient says they no longer want the operation, the nurse stops preparations and informs the surgeon and anesthesiologist at once. If the nurse doubts that a patient can make the decision, for example because of new confusion or the effects of sedating medication, the nurse reports this; the surgeon assesses capacity, and a substitute decision-maker may be needed. When the patient's preferred language is not English, a qualified interpreter takes part in the consent discussion, and this is documented. Many hospitals allow nurses to witness the patient's signature; witnessing means confirming who signed, not confirming that the patient understood the surgery.

Final Preparation

On the morning of surgery, the nurse works through the hospital's preoperative checklist. The exact items vary, but a typical checklist confirms:

- **Identity:** two patient identifiers checked against the wristband and chart, with the patient taking part (Chapter 1, section 1.6).
- **Allergies:** documented and shown on an allergy band.
- **Consent:** signed, matching the booked procedure and side, and understood.
- **Site marking:** the operative site marked as policy requires, typically by the surgeon or a member of the surgical team, with the patient awake and taking part.
- **Fasting:** the times of last food and last clear fluid, compared with the instructions.
- **Medications:** given or held as ordered; any medication taken against instructions reported.
- **Baseline vital signs, weight and glucose:** recorded, with any abnormal or changed finding reported before transfer.
- **Personal items:** jewellery, glasses, hearing aids, dentures and prostheses removed or kept according to policy, and stored safely. Hearing aids and glasses may stay until anesthesia begins so the patient can communicate.
- **Voiding:** the patient has emptied the bladder unless a catheter is planned.
- **Test results and blood products:** ordered results on the chart; blood bank sample sent if required.

Religious and cultural items, such as a medicine bundle, a religious medal, a turban or a kirpan, deserve respect. The nurse asks what the item means to the patient, follows policy and the patient's wishes about whether it can stay with them, how it can be secured, and when it will be returned, and documents the plan. Chapter 2 discusses cultural safety.

Finally, the nurse gives a structured handover to the OR team, sharing anything the checklist did not show: anxiety, a hearing impairment, a medication question, or a family member waiting for a call. Any change in the patient's condition, such as new chest pain, a fast or irregular pulse, or new confusion, is reported before transfer, not left for the OR team to find.

Figure 7.2 A surgical team at work in an operating room. Before the first incision, the team pauses for the time-out. (credit: "AfS surgical team at the operating room" by Almondbite3/Wikimedia Commons, CC BY-SA 4.0)

The Surgical Safety Checklist

The **Surgical Safety Checklist** is a structured set of checks that the whole surgical team completes together at set points during each operation. It grew out of the WHO's Safe Surgery Saves Lives program. In a study at eight hospitals in eight cities around the world, Haynes and colleagues (2009) compared 3,733 patients having non-cardiac surgery before the checklist was introduced with 3,955 patients afterwards. During the hospital stay, up to 30 days after surgery, deaths dropped from 1.5% of patients to 0.8%, and inpatient complications from 11.0% to 7.0% (Haynes et al., 2009; Figure 7.2).

In Canada, the Canadian Patient Safety Institute (CPSI, now part of Healthcare Excellence Canada) and the Royal College of Physicians and Surgeons of Canada led a Canadian adaptation with partner organizations (Alberta Health Services, 2012; Healthcare Excellence Canada, n.d.). The Canadian checklist has three phases, summarized in Table 7.2. The **briefing** happens before anesthesia begins; the **time-out**, before the skin incision; and the **debriefing**, before the patient leaves the OR (Health Standards Organization [HSO], 2024). Hospitals adapt the checklist to their own settings, so the nurse learns the version used locally.

The checklist works only if people speak. Any team member who sees a mismatch, a missing item or a safety concern is expected to say so, and the team pauses until it is resolved. Speaking up in a hierarchy is hard, and Chapter 6 discusses tools that help.

Table 7.2 The Surgical Safety Checklist's three phases (summary based on the Canadian version) (Alberta Health Services, 2012; HSO, 2024)

Phase	When	Main checks (summarized)	The nurse's part

Phase	When	Main checks (summarized)	The nurse's part
Briefing	Before anesthesia begins	Who the patient is, what operation and where, consent, allergies, fasting, airway or aspiration concerns, equipment and positioning needs	Confirms identity, consent and allergies with the patient awake; raises concerns from the preoperative assessment
Time-out	Just before the skin incision	Team members name themselves and their roles; surgeon, anesthesiologist and nurse confirm patient, procedure and site aloud; expected critical events, antibiotic and VTE prophylaxis, imaging	Takes part aloud; stops the process if anything does not match
Debriefing	At the end of the operation, before the patient leaves the OR	Name of the procedure done, counts of sponges, needles and instruments, specimen labels, equipment problems, recovery plan	Confirms counts and specimen labels; contributes to the handover plan for the PACU

CANADIAN CONTEXT

The Surgical Safety Checklist in Canada

Use of a safe surgery checklist is a Required Organizational Practice (ROP) in the HSO standards that Accreditation Canada uses to accredit health care organizations. The ROP calls for the team to agree on a three-phase checklist and use it for every surgical procedure in the OR, for compliance to be monitored, and for the results of evaluating its use to be shared with the team and used to improve (HSO, 2024).

An Ontario study looked at what happened after hospitals adopted the checklist. Urbach and colleagues (2014) compared about 109,000 procedures in the three months before each hospital adopted it with about 106,000 in the three months after, at 101 hospitals. The adjusted risk of dying within 30 days of surgery or during the hospital stay was 0.71% before and 0.65% after, and the adjusted complication rate was 3.86% before and 3.82% after; neither change was statistically significant (Urbach et al., 2014). Results like these suggest that how a team uses the checklist matters, not only whether it has been adopted; the ROP likewise asks organizations to evaluate its use and act on the results.

SCOPE IN PRACTICE

Consent, Checklists and Perioperative Roles

The College of Nurses of Ontario (CNO) Scope of Practice standard frames every perioperative role in terms of authority, competence and context (Chapter 1, section 1.3).

- **Authority:** The surgeon has the authority and duty to obtain informed consent for surgery. Neither registered nurses (RNs) nor registered practical nurses (RPNs) obtain it, but both can verify that consent is documented and understood, witness signatures where policy allows, report doubts and stop preparation if consent is withdrawn.
- **Competence:** Perioperative and PACU care require added education. Whether an RPN works in the scrub role, in a preoperative clinic or in the PACU depends on that nurse's education and competence, employer policy and the patient's needs.
- **Context:** Rules differ by setting and by province or territory. For example, accreditation standards for non-hospital surgical facilities in British Columbia require two registered nurses in the PACU whenever a patient is receiving care there (CPSBC, 2026). Assigning patients by stability is a common employer practice, not a CNO rule.

Every nurse who notices deterioration, such as a falling oxygen saturation or new confusion, acts at once and escalates. The RPN consults the RN as the patient's needs change, and every team member can call a pause during the Surgical Safety Checklist.

7.4 Anesthesia and Sedation

The anesthesiologist chooses the type of anesthesia with the patient, based on the surgery, the patient's health (section 7.2) and the patient's wishes. Many patients receive more than one type. Table 7.3 compares the main types.

General Anesthesia

General anesthesia is a drug-induced state of unconsciousness from which the patient cannot be roused, even by pain (ASA, 2024). Because the patient often cannot keep the airway open or breathe adequately, and circulation may be affected, the anesthesia team

supports both (ASA, 2024), keeping the airway open with an endotracheal tube in the trachea or a supraglottic airway that sits above the larynx. Drugs that relax or paralyze the muscles are added when the surgery needs them.

Common after-effects include drowsiness, sore throat or hoarseness, nausea and vomiting, shivering and short-lived confusion (section 7.5). Rarely, a patient remembers events during anesthesia (awareness): a United Kingdom national audit found about 1 report for every 19,000 general anesthetics, and explanation and reassurance seemed to help (Cook et al., 2014). The nurse listens without dismissing the report and informs the anesthesia team.

Neuraxial and Regional Anesthesia

Neuraxial anesthesia places local anesthetic near the spinal cord. In **spinal anesthesia**, one injection into the cerebrospinal fluid in the lower back produces rapid, dense numbness and weakness of the lower body. In **epidural anesthesia**, local anesthetic is given into the epidural space, usually through a thin catheter that can stay in place for repeat doses and pain relief after surgery (epidural analgesia; Chapter 5, section 5.4). A **peripheral nerve block** is an injection of local anesthetic near the nerves that supply one limb or area; a catheter may continue the block as an infusion.

Neuraxial blocks also affect the sympathetic nerves, so blood pressure can fall, and they affect bladder control (section 7.6). After any block, the nurse:

- checks that sensation and movement return in the expected pattern and time, and reports a block that spreads higher, weakness that returns after it had resolved, or new back pain at once (Chapter 5, section 5.4);
- checks blood pressure and has the patient sit and dangle the legs before first standing;
- monitors voiding;
- protects a numb limb, which cannot feel pressure, heat or injury, by positioning, padding and checking the skin;
- prevents falls: after a leg block the patient walks only with help;
- plans ordered analgesia before the block wears off (Chapter 5).

Local Anesthesia and Procedural Sedation

In **local infiltration**, the surgeon or another provider injects local anesthetic into the tissue at the site of a minor procedure, and the patient stays awake. The total dose of local anesthetic from all sources is recorded to reduce the risk of toxicity (Dobson et al., 2026).

Procedural sedation uses drugs to depress consciousness for a procedure such as an endoscopy or a cardioversion. The ASA (2024) describes sedation as a continuum:

- **Minimal sedation:** the patient is relaxed and answers normally when spoken to. Thinking and coordination may be slowed, but breathing and circulation are unaffected.
- **Moderate sedation:** the patient is drowsy but responds purposefully to voice or a light touch, keeps the airway open without help and breathes adequately.
- **Deep sedation:** the patient cannot be roused easily and responds purposefully only to repeated or painful stimulation. The patient may need help to keep the airway open, and breathing may become inadequate.

Because a patient can slip deeper than intended, whoever gives sedation must be able to rescue a patient from the next level (ASA, 2024).

The nurse who monitors sedation has no other task. Beforehand, the nurse records baseline vital signs, oxygen saturation (SpO2) and level of consciousness, confirms fasting (section 7.2), allergies and consent (section 7.3), and checks that oxygen, suction, airway equipment and the emergency cart are ready. During the procedure, the nurse watches:

- airway patency and the rate and depth of breathing;
- SpO2 and, where policy requires, **capnography**, the continuous measurement of exhaled carbon dioxide (end-tidal CO2), which the CAS guidelines require for moderate or deep sedation provided under them (Dobson et al., 2026);
- level of sedation, with the scale the facility uses;
- heart rate, blood pressure and the ECG, as ordered.

If the patient becomes hard to rouse, snores, stops breathing or desaturates, the nurse stimulates the patient, opens the airway as taught, tells the provider to stop and calls for help. Monitoring continues until the patient meets the facility's recovery criteria. Whether a nurse may give the sedating drugs depends on authority, competence and context, including employer policy and the province or territory (Chapter 1, section 1.3).

Anesthesia Emergencies

The nurse recognizes these rare, life-threatening emergencies early, calls for help and stays with the patient.

- **Malignant hyperthermia (MH)** is an inherited muscle reaction triggered by volatile anesthetic gases and succinylcholine (Glahn et al., 2024). Early cues include an unexplained rise in end-tidal CO2, a fast heart rate, rapid breathing, muscle stiffness, sweating and mottled skin; a rapid temperature rise often comes later (Glahn et al., 2024).
- **Local anesthetic systemic toxicity (LAST)** occurs when local anesthetic reaches a toxic level in the blood and affects the brain and heart. Early cues include a metallic taste, changes in hearing such as ringing in the ears, and agitation; seizures and heart rhythm problems may follow. LAST can begin with heart problems alone or appear 30 to 60 minutes after an injection, and infusions carry risk for days (Neal et al., 2018).
- **Laryngospasm** is a sustained closure of the vocal cords that partly or fully blocks the airway, for example as a patient wakes (Gavel & Walker, 2014; section 7.5).

The nurse calls the anesthesia or code team, stops any local anesthetic infusion, supports the airway and gives oxygen as policy directs. CAS requires an MH kit wherever triggering agents are used, and LAST cognitive aids and lipid emulsion 20% wherever nerve blocks or infusions of local anesthetic are given (Dobson et al., 2026).

Table 7.3 Types of anesthesia and sedation compared (ASA, 2024; Brouwer et al., 2021; Dobson et al., 2026; Neal et al., 2018)

Type	What it does	Examples of use	Nursing points afterward
General anesthesia	Drug-induced unconsciousness; the patient cannot be roused; the anesthesia team supports breathing and circulation	Major abdominal, chest and neurosurgical procedures	Airway, breathing and SpO2; drowsiness; nausea and vomiting; temperature; sore throat; confusion on waking
Spinal anesthesia	One injection of local anesthetic into the cerebrospinal fluid; dense numbness and weakness of the lower body	Hip and knee replacement; lower-abdominal surgery	Return of movement and sensation; low blood pressure; urinary retention; falls on first standing
Epidural anesthesia	Local anesthetic given into the epidural space, usually through a catheter that can stay in for pain relief	Major abdominal and chest surgery; continued as epidural analgesia	Level of the block; blood pressure; leg strength; catheter site; new back pain or weakness reported at once (Chapter 5)
Peripheral nerve block	Local anesthetic injected near the nerves to one limb or area; sometimes continued by infusion	Shoulder, hand, knee and foot surgery	Protect the numb limb; falls; pain plan before the block wears off; watch for LAST with infusions
Local infiltration	Local anesthetic injected into tissue at the site; the patient stays awake	Skin lesion removal; minor procedures	Bleeding at the site; total dose recorded; LAST cues if large amounts were used
Procedural sedation	Drugs depress consciousness on a continuum from minimal to deep sedation	Endoscopy; cardioversion; fracture reduction	Airway, breathing, SpO2 and capnography as policy requires; sedation level; recovery criteria; a responsible adult for the trip home

GOING DEEPER

Malignant Hyperthermia and Local Anesthetic Systemic Toxicity

Required for RN students; optional for PN students.

Malignant hyperthermia. In people with an inherited susceptibility, volatile anesthetic gases or succinylcholine cause abnormally high calcium levels inside muscle cells, so the muscles contract and burn energy uncontrollably (Malignant Hyperthermia Association of the United States [MHAUS], n.d.-b). Carbon dioxide and heat build up. Later signs include high potassium, very high creatine kinase, dark urine from myoglobin, severe dysrhythmias and clotting failure (Glahn et al., 2024). No single sign is specific, so the team looks for a pattern.

Anesthesia leads treatment as soon as MH is suspected: the team stops all triggering agents, ventilates with high-flow 100% oxygen, calls for help, gives intravenous (IV) dantrolene (marketed in Canada; Health Canada, 2026) and cools the patient. Nurses fetch the MH kit, prepare dantrolene as directed, apply cooling, draw blood and record events. Monitoring continues for at least 24 hours in a critical care or recovery unit because signs can return (Glahn et al., 2024). The MHAUS hotline (1-800-644-9737) gives health professionals 24-hour emergency advice (MHAUS, n.d.-b). Afterward, the triggers are recorded as adverse reactions, the patient is referred for testing, relatives are told and a medical alert bracelet is advised (MHAUS, n.d.-a).

Local anesthetic systemic toxicity. Local anesthetics block sodium channels in nerve and heart tissue. Risk rises with older age, low muscle mass, heart disease (especially conduction problems, ischemia and heart failure), liver disease and the site and total dose of the block (Neal et al., 2018). Airway management comes first, because low oxygen and high carbon dioxide worsen toxicity. Seizures are treated, usually with a benzodiazepine, and the physician leads early lipid emulsion 20% therapy and modified advanced life support. After LAST, monitoring continues for at least 2 hours after a brief seizure and 4 to 6 hours after cardiovascular instability (Neal et al., 2018, 2021).

7.5 Care After Anesthesia (PACU)

Patients recover from anesthesia in the PACU under close observation; every facility providing anesthesia must have one (Dobson et al., 2026).

Phases of Postanesthesia Care

As section 7.1 explains, recovery moves from **Phase I**, with continuous monitoring and close nursing care until the airway, breathing, circulation and consciousness are stable, to **Phase II**, with less frequent monitoring as a stable patient nears discharge criteria (CPSBC, 2026). Some patients may go straight to another unit that can give the right level of care, if documented (Dobson et al., 2026). Staffing follows need: British Columbia's Phase I minimum ratios, based on national perianesthesia nursing standards, range from two nurses for one critically ill or unstable patient to one nurse for two conscious, stable patients without complications (British Columbia Ministry of Health, 2024).

The anesthesiologist comes with the patient and hands over care to the PACU nurse in a structured way (Dobson et al., 2026). It covers what happened during surgery and anesthesia, relevant history such as sleep apnea, and the plan for pain and nausea. Continuous pulse oximetry is required early in recovery, capnography is required for intubated or deeply sedated patients, and alarms stay on with limits suited to the patient (Dobson et al., 2026).

Airway and Breathing

Airway obstruction is an urgent early risk: in a drowsy patient, the relaxed tongue can fall back against the throat. Cues include snoring or noisy breathing, little or no airflow and a falling SpO2. The nurse rouses the patient, uses a jaw thrust as taught, inserts an oral airway if trained and policy allows, gives oxygen as ordered and calls the anesthesia team if the obstruction does not clear at once.

Laryngospasm, a sustained closure of the vocal cords, can partly or completely block the airway as a patient emerges from anesthesia, and it can quickly cause hypoxemia and a slow heart rate (Gavel & Walker, 2014). Breathing becomes noisy, or breathing efforts move no air at all. The nurse calls the anesthesia team at once and gives oxygen as taught while help comes.

Hypoventilation, slow or shallow breathing, can follow residual anesthetic, opioids or incompletely reversed muscle relaxants; rising sedation is an early warning (Chapter 5, section 5.4). Hypoxemia, a low blood oxygen level, can also follow atelectasis, aspiration or fluid overload. Patients with obstructive sleep apnea or a high STOP-Bang score (section 7.2) are more sensitive to opioids and sedatives, so the nurse keeps them upright or side-lying when allowed, on continuous oximetry and using their own continuous positive airway pressure (CPAP) machine as ordered.

Circulation and Temperature

Low blood pressure may come from residual anesthetic, a neuraxial block, opioids or a fluid deficit, but bleeding is always considered: the nurse compares readings with baseline and checks the dressing, drains and the bed under the patient (Chapter 6, section 6.4). New dysrhythmias are reported (Chapter 16).

Inadvertent perioperative hypothermia is an unplanned core temperature below 36.0 °C around the time of surgery (National Institute for Health and Care Excellence [NICE], 2016). Anesthesia blunts temperature control. Canadian guidelines call for warming to target a core temperature of 36 °C to 37 °C, unless hypothermia is planned, and active warming equipment must be immediately available (Dobson et al., 2026). The NICE (2016) guideline advises measuring temperature on arrival in recovery and every 15 minutes, using forced-air warming when the temperature is below 36.0 °C and not transferring the patient to the ward until it is 36.0 °C or higher.

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) affects about 30% of patients having elective surgery and up to 80% of some high-risk patients (Elvir-Lazo et al., 2020). The simplified Apfel score counts four risk factors: female sex, not smoking, a history of PONV or motion sickness, and opioids after surgery. Risk rises from about 10% with no factors to about 80% with all four. Other risk factors include age under 50, volatile anesthetics, longer anesthesia and some procedures, such as laparoscopic, gallbladder and other intra-abdominal surgery (Elvir-Lazo et al., 2020).

Current guidance is to assess each patient's risk, reduce baseline risk and give patients at moderate or high risk preventive drugs that work in different ways (Elvir-Lazo et al., 2020; Gan et al., 2020). When PONV occurs within 6 hours after surgery despite preventive drugs, the rescue drug should come from a different drug class (Elvir-Lazo et al., 2020). The nurse asks about nausea rather than waiting for vomiting, gives ordered antiemetics, keeps suction at the bedside, moves the patient slowly and supports opioid-sparing pain relief (Chapter 5). A drowsy patient who vomits is turned onto the side or sat up to protect the airway. Nausea can also begin after a day-surgery patient goes home (Elvir-Lazo et al., 2020).

Pain and Emergence Delirium

Pain is assessed as soon as the patient can respond and treated as described in Chapter 5, so the patient can breathe deeply and move.

Some patients wake confused, restless or agitated; others are confused but quiet and drowsy. This **emergence delirium** begins during or soon after waking from general anesthesia. In a study of 915 adults aged 65 to 90 after major surgery, 37% had it in the PACU, most often the quiet (hypoactive) type, and it was linked to later postoperative delirium (Zhang et al., 2020). Agitation can lead to falls and pulled lines. The nurse first looks for problems that can be corrected, such as hypoxemia, pain, cold, a full bladder, low blood pressure and low blood glucose. The nurse stays with the patient, reorients calmly, protects lines and the wound, and reports to the anesthesia team. Confusion that persists or begins later is assessed as delirium (Chapter 8).

Readiness to Leave the PACU

The anesthesiologist decides when a patient leaves the PACU, though facility policy may delegate this (Dobson et al., 2026). Many units use a version of the Aldrete recovery score (Aldrete & Kroulik, 1970; Aldrete, 1995). It rates five areas from 0 to 2: how many limbs the patient can move on request, the quality of breathing, blood pressure compared with the pre-anesthesia value, level of consciousness, and oxygenation. A total of 9 or more is commonly used, along with controlled pain and nausea, a temperature of 36.0 °C or higher and, after neuraxial anesthesia, a regressing block. Before going home, day-surgery patients must meet the facility's criteria, checked with a validated tool, for example the modified Postanesthetic Discharge Scoring System (Dobson et al., 2026).

For transfer to an inpatient unit, the PACU nurse gives handover with SBAR (Chapter 6, section 6.2), including PACU events, vital-sign trends, the last analgesic and antiemetic doses, intake and output, wound and drains, and any block. The receiving nurse completes a full assessment on arrival.

7.6 Postoperative Care and Complications

On the surgical unit, the nurse supports recovery and catches the complications in Table 7.4 early.

The First Postoperative Day

On arrival from the PACU, the nurse checks the airway, breathing, circulation, level of consciousness, vital signs, SpO2, pain, nausea, dressing and drains, IV infusion, urine output and, after a block, sensation and movement. Vital signs are repeated as ordered

and as policy requires, more often in the first hours. Temperature is measured on arrival and then with routine observations (NICE, 2016). Each set of vital signs feeds the early warning score, and a rising score triggers escalation (Chapter 6, section 6.1).

The nurse tracks fluid balance: IV fluids, oral intake, urine, drains and vomiting (Chapter 3). In enhanced recovery pathways, drinking and eating start early; the ERAS colorectal guideline states that an oral diet can usually begin within 4 hours after surgery (Gustafsson et al., 2019). The patient sits up and walks early, with help.

Respiratory Complications

Atelectasis is the collapse of small air sacs (alveoli) in part of the lung. After surgery, shallow breathing from pain, opioids, anesthesia and lying still lets the lung bases collapse. Cues include reduced breath sounds at the bases, faster breathing and a falling SpO2. Postoperative pneumonia is infection of the lung tissue; fever, a productive cough, crackles, rising respiratory rate, falling SpO2 and new confusion in an older adult are cues (Chapter 13).

Prevention centres on getting the patient upright and walking. The nurse encourages deep breaths and coughs several times an hour while awake, with a pillow pressed over an abdominal or chest incision to splint it, and gives enough pain relief to make this possible. Incentive spirometers are still widely used (section 7.2), but a Cochrane review of upper abdominal surgery found low-quality evidence that they prevented lung complications no better than deep breathing, physiotherapy or no treatment (do Nascimento Junior et al., 2014). The nurse therefore treats the spirometer as one tool among several and never as a substitute for walking. A falling SpO2 with faster breathing is reported. A sudden fall with chest pain or a racing heart raises the question of pulmonary embolism.

Venous Thromboembolism

Surgery raises the risk of **venous thromboembolism (VTE)**: a deep vein thrombosis (DVT) in the leg or pelvis, or a pulmonary embolism (PE) when a clot travels to the lungs. Immobility, injury to veins and the body's clotting response to surgery all contribute; major orthopedic, abdominal and cancer surgery carry high risk. Each surgical patient's VTE and bleeding risks are assessed with a recognized tool on admission and again when the patient's condition changes (NICE, 2019). Not every surgical patient needs prophylaxis; the method depends on the patient, the surgery and the bleeding risk (Anderson et al., 2019).

Prevention has three parts:

- **Early mobilization and hydration.** Walking and leg exercises keep blood moving, and dehydration is avoided (NICE, 2019).
- **Mechanical prophylaxis. Intermittent pneumatic compression (IPC)** devices are sleeves that inflate in cycles to squeeze the legs and push blood toward the heart. They are worn for as much of the time as possible until the patient is mobile. Anti-embolism stockings must be measured and fitted, removed daily for skin checks and avoided in patients with peripheral arterial disease, nerve damage with loss of feeling, or fragile skin (NICE, 2019).
- **Anticoagulant prophylaxis.** When VTE risk outweighs bleeding risk, the prescriber orders an anticoagulant, often a low-molecular-weight heparin. Some patients continue it at home; for example, after major cancer surgery in the abdomen, prophylaxis may be extended to 28 days (Gustafsson et al., 2019; NICE, 2019). The nurse gives it on time, watches for bleeding and teaches injection technique when needed. Because heparins come from animal sources, the nurse tells the prescriber when a patient objects for religious or ethical reasons, so an alternative can be considered (NICE, 2019).

DVT may cause swelling, pain, warmth and redness of one calf or thigh. Redness is harder to see on darker skin, so the nurse compares both legs for swelling, warmth and tenderness. PE may cause sudden shortness of breath, chest pain that worsens with breathing, a fast heart rate, rapid breathing, a falling SpO2, anxiety, coughing up blood or fainting. With suspected PE, the nurse stays with the patient, raises the head of the bed, gives oxygen as ordered, calls the rapid response team or the most responsible provider and reports with SBAR (Chapter 6; Chapters 15 and 19). The leg is never massaged.

Urinary Retention

Postoperative urinary retention is the inability to empty a full bladder after surgery. In one study of 936 general surgery patients, spinal anesthesia, surgery lasting 60 minutes or more, age 60 or older, a small bladder capacity and a bladder volume of 250 mL or more on the first PACU scan predicted the need for a catheter (Brouwer et al., 2021). The ERAS colorectal guideline adds male sex, epidural analgesia and pelvic surgery (Gustafsson et al., 2019). Many patients feel no urge: 71% of those who needed a catheter in

that study did not (Brouwer et al., 2021). The nurse therefore relies on time since the last void, suprapubic fullness or discomfort, restlessness and, in older adults, new confusion, and uses a bladder scanner as policy allows. If the bladder is full and the patient cannot void, the nurse reports it and catheterizes as ordered. An overstretched bladder can be damaged, temporarily or permanently (Brouwer et al., 2021). Indwelling catheters come out early; in low-risk patients after colorectal surgery, on the first day after surgery (Gustafsson et al., 2019). Catheter-associated urinary tract infection is covered in Chapter 4 (Figure 7.3).

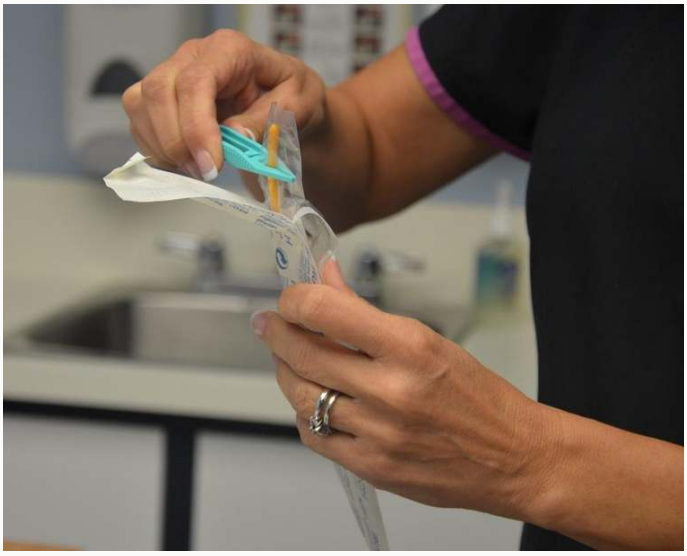

Figure 7.3 A nurse opens the package of a sterile indwelling urinary catheter. A catheter is inserted only on an order and removed as early as possible. (credit: "Choose smallest catheter size possible" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Bowel Function and Ileus

After surgery, the bowel recovers in stages; passing gas, then stool, and tolerating food show that it is working. **Postoperative ileus** is a temporary slowing of bowel movement after surgery. Cues include abdominal distension and discomfort, nausea and vomiting, no gas or stool, and poor tolerance of food. The nurse reports these cues, keeps the patient fasting if ordered, inserts or manages a nasogastric tube if ordered, and monitors fluids and electrolytes, especially potassium (Chapter 3).

ERAS measures that help prevent ileus include limiting opioids, minimally invasive surgery, avoiding routine nasogastric tubes, careful fluid therapy, early eating and walking (Gustafsson et al., 2019). Chewing gum is not recommended as a routine part of ERAS for colorectal surgery, because a large multicentre trial found no benefit (Gustafsson et al., 2019). Ostomy care is in Chapter 25.

Wound Complications

A **hematoma** is a collection of blood under the incision. Cues include swelling, bruising, tightness and increasing pain. The nurse marks and reports it; after neck surgery, such as thyroid surgery, a hematoma can obstruct the airway, so swelling there is reported at once (Iliff et al., 2022). Surgical site infection is covered in Chapter 4. The nurse looks at the incision at each assessment (Figure 7.4).

Dehiscence is the separation of the edges of a closed surgical incision, with or without exposure of the tissues, organs or implants beneath it (World Union of Wound Healing Societies [WUWHS], 2018). It usually occurs 4 to 14 days after surgery. Major risk factors include obesity, diabetes, smoking, emergency surgery, age over 65, a long operation, perioperative hypothermia and wound infection. A sudden increase in pain or in serosanguineous drainage (thin, pink fluid) from the incision may be the first warning (WUWHS, 2018). **Evisceration** is the protrusion of abdominal organs through a dehisced wound, a surgical emergency (Clinical Safety box).

Bleeding and Delirium

Bleeding after surgery may be visible, in dressings and drains, or hidden in the abdomen, chest or tissues. A rising heart rate, narrowing pulse pressure, restlessness and falling urine output can appear before blood pressure falls. The nurse escalates at once and follows the approach to hemorrhage and hypovolemic shock in Chapter 6, section 6.4.

Postoperative delirium is an acute disturbance of attention and thinking that usually begins in the first days after surgery and is common in older adults. Pain, hypoxemia, infection, urinary retention, constipation, poor sleep and some drugs can trigger it. The nurse screens for delirium, treats causes with the team and uses the prevention measures in Chapter 8.

Enhanced Recovery After Surgery

Enhanced recovery after surgery (ERAS) is a set of evidence-based practices across the whole surgical journey that reduce the stress of surgery and speed recovery. The ERAS Society publishes guidelines for many surgeries. Its colorectal guideline includes (Gustafsson et al., 2019):

- teaching and counselling before admission, and prehabilitation (exercise and nutrition before surgery), for which evidence is still developing;
- avoiding prolonged fasting, with clear fluids, including carbohydrate drinks, closer to surgery (follow the anesthesia team's instructions; section 7.2);
- preventing PONV and hypothermia;
- opioid-sparing multimodal analgesia (Chapter 5);
- avoiding routine nasogastric tubes and giving fluids carefully;
- early oral intake, early mobilization and early removal of urinary catheters;
- thromboprophylaxis; and
- auditing how well the team follows the pathway.

Nurses carry much of ERAS: they teach the patient what to expect, get the patient drinking, eating and walking, manage pain, remove catheters on schedule and record whether each element happened.

Going Home

After day surgery, the patient must meet the facility's discharge criteria and be accompanied home, or to a place such as a hotel, by a responsible adult. Patients are told not to drive or operate hazardous machinery for 24 hours, and they receive written instructions on pain and complications (Dobson et al., 2026). Inpatients go home with teaching on medications, including anticoagulant injections, wound care, activity, signs to report and whom to call (NICE, 2019), and with a follow-up appointment.

Rural, remote and northern patients may live hours from the hospital that did their surgery. The nurse plans before discharge: medications and dressing supplies the patient can get locally, home care or a community health nurse for wound care, a virtual follow-up when possible, and clear advice on where to go if problems arise. First Nations and Inuit patients who travelled from their communities for surgery may need coordination with medical travel and the community's nursing station, arranged in a culturally safe way (Chapter 2). An interpreter is used for discharge teaching when needed (Chapter 1, section 1.7).

Table 7.4 Common postoperative complications: timing, cues and first nursing actions (Brouwer et al., 2021; Gustafsson et al., 2019; NICE, 2019; WUWHS, 2018)

Complication	Typical timing	Cues	First nursing actions
Hypoxemia and atelectasis	Often in the PACU and first days	Falling SpO2; faster breathing; reduced breath sounds at the bases; drowsiness	Sit up; deep breathing and coughing; oxygen as ordered; check sedation; report a falling trend
Pneumonia	Often after the first few days	Fever; productive cough; crackles; rising respiratory rate; new confusion	Assess; report; obtain ordered tests; mobilize; oxygen as ordered (Chapter 13)
Hemorrhage	Often in the first 24 hours	Rising heart rate; narrowing pulse pressure; restlessness; soaked dressing or high drain output; falling urine output	Call for help; apply pressure to visible bleeding; lie flat; IV access; SBAR (Chapter 6)

Complication	Typical timing	Cues	First nursing actions
Urinary retention	First hours after surgery or catheter removal	No void; suprapubic fullness; restlessness; often no urge	Bladder scan as policy allows; report; catheterize as ordered
Ileus	First days	Distension; nausea and vomiting; no gas or stool	Report; fasting and nasogastric tube if ordered; fluids and electrolytes
Surgical site infection	Usually days after surgery, sometimes after discharge	Redness, warmth, swelling, pain, drainage; fever	Assess and report; swab or culture as ordered (Chapter 4)
Dehiscence or evisceration	Usually days 4 to 14	Sudden pain or pink drainage; wound edges apart; organs visible	Stay; call for help; cover with sterile saline-moistened dressing; nothing by mouth (Clinical Safety box)
Deep vein thrombosis	Any time from the first days to weeks, including after discharge	One-sided leg swelling, pain, warmth, redness	Do not massage; report; prepare for ordered tests (Chapter 19)
Pulmonary embolism	Any time from the first days to weeks, including after discharge	Sudden breathlessness; pleuritic chest pain; fast heart rate; falling SpO2; anxiety	Stay; raise head of bed; oxygen as ordered; rapid response; SBAR (Chapter 15)
Delirium	Often in the first days	Inattention; fluctuating confusion; agitation or unusual drowsiness	Look for causes (oxygen, pain, bladder, infection); keep safe; report (Chapter 8)

CLINICAL SAFETY

Wound Evisceration

Evisceration usually follows dehiscence of an abdominal incision. The patient may report that something "gave way" or feel a sudden gush of pink fluid, and loops of bowel or other tissue may be visible in the wound. It is a surgical emergency. First actions, as hospital policy directs:

- Stay with the patient and call for help; ask a colleague to notify the surgeon and, if the patient is unstable, the rapid response team.
- Cover the exposed organs with sterile dressings moistened with sterile normal saline, and keep them moist. Do not try to push the organs back.
- Position the patient to reduce tension on the abdomen, for example lying with the head of the bed slightly raised and knees bent, as policy directs.
- Keep the patient fasting (nothing by mouth) in preparation for surgery.
- Monitor vital signs, SpO2 and level of consciousness for signs of shock (Chapter 6).
- Reassure the patient, prepare for return to the operating room and document the time, findings and actions.

LIFESPAN CONSIDERATIONS

Older Adults and Surgery

Frailty, not age alone, predicts how well an older adult recovers from surgery (section 7.2).

- **Delirium prevention:** keep glasses and hearing aids in place, orient the patient often, protect sleep, get the patient up and walking early, keep the patient eating and drinking, treat pain, and avoid drugs that can trigger delirium, such as some sedatives and anticholinergics, unless the prescriber decides they are needed (Chapter 8).
- **Hidden causes of confusion:** a full bladder, low oxygen and constipation can all appear as restlessness or confusion.
- **Hypothermia:** older adults may lose heat quickly in the operating room and PACU, so the nurse measures temperature and warms actively (NICE, 2016).
- **Kidney function:** kidney reserve falls with age, which affects fluid balance and drug clearance. The nurse tracks urine output and creatinine as ordered (Chapter 3).
- **Falls:** nerve blocks, opioids, low blood pressure on standing and new surroundings all raise risk. Keep the call bell, glasses and walking aid within reach, and help with the first walks (Chapter 8).
- **Wound healing:** age over 65 is a risk factor for dehiscence (WUWHS, 2018).

PATIENT EDUCATION

Going Home After Day Surgery

- **Getting home:** A responsible adult must take you home. Follow the hospital's instructions about how long someone should stay with you.
- **For 24 hours:** Do not drive or use machinery or power tools (Dobson et al., 2026). Avoid alcohol, and do not sign legal papers or make important decisions until you are thinking clearly; your instructions will say for how long.
- **Pain:** Take your pain medicines as your written plan says. Start before a nerve block wears off if you were told to.
- **Your wound:** Keep the dressing clean and dry, and follow the instructions for showering and changing it.
- **Call your surgeon's office or the number on your instructions if you have:** a fever, increasing redness, swelling or drainage from the wound, bleeding that soaks the dressing, vomiting that will not stop, or you cannot pass urine.
- **Call 9-1-1 if you have:** sudden shortness of breath, chest pain, coughing up blood, or heavy bleeding. Pain, swelling or warmth in one calf also needs urgent attention, because it can be a sign of a blood clot.

PRACTICE STORY

"He Just Wasn't Himself"

Names and details are fictional; this is a composite story.

Nurse: Tanya Beaulieu, RPN. Years in practice: 8. Setting: orthopedic surgical unit, community hospital, Ontario.

Mr. Walter Zielinski was 84 and had his hip fracture repaired under spinal anesthesia the morning before. His daughter told us he did the crossword every morning. His catheter came out at 1000.

At 2200 I found him pulling at his blanket and trying to swing his good leg over the bed rail. He called me by his late wife's name. His vital signs were close to his baseline: heart rate 96, blood pressure 148/82 mm Hg, temperature 37.2 °C, SpO2 95% on room air. He said his hip "wasn't too bad." His intake and output record showed no void since the catheter came out.

His lower abdomen felt firm above the pubic bone. Our policy lets nurses do a bladder scan when retention is suspected, so I scanned him: about 850 mL. I lowered the bed and asked the nursing assistant to sit with him while I found Priya Nair, the RN on our team. She came to assess him with me and paged the surgical resident. We reported with SBAR, and the resident ordered an in-and-out catheterization and a delirium assessment. I inserted the catheter and drained just over 800 mL.

Within an hour he was calmer and fell asleep. In the morning he still mixed up the day, so the team kept the delirium prevention plan going: his glasses and hearing aids, his daughter's visits, getting up for breakfast and a voiding schedule with bladder scans.

I keep thinking about how easy it would have been to call it "sundowning" and ask for something to settle him. He couldn't tell us his bladder was full. His behaviour was the only way he could tell us something was wrong.

Reflect: What cues suggested that Mr. Zielinski's confusion had a treatable cause? Which parts of this situation did the RPN manage within her own authority and competence, and why did she consult the RN as his needs changed?

Chapter 7 Summary

Introduction

- Perioperative nurses work in preadmission clinics, same-day surgery, the OR, the PACU, surgical units and the community.
- This chapter follows the patient from the decision to operate through recovery; related topics are taught in Chapters 1, 4, 5, 6, 8, 19, 25 and 33.

7.1 The Perioperative Journey

- Surgery has preoperative, intraoperative and postoperative phases; PACU care moves from Phase I (close monitoring) to Phase II (approaching discharge) according to physiological recovery.
- Ambulatory surgery patients go home the same day with written instructions and a responsible adult; many inpatients come in under same-day admission.
- The team includes surgeons, anesthesiologists (and family practice anesthesia physicians), anesthesia assistants, scrub and circulating nurses, PACU nurses and surgical unit nurses.

- CIHI reports wait times against benchmarks, such as 26 weeks for hip and knee replacement and 16 weeks for cataract surgery; rural, remote and northern patients often travel for surgery.

7.2 Preoperative Assessment and Preparation

- The assessment covers past anesthesia problems and family history, heart and lungs, functional capacity, substance use, pregnancy possibility, cognition, frailty and supports.
- STOP-Bang screens for obstructive sleep apnea; the ASA Physical Status classification describes overall health.
- The prescriber or anesthesia team sets the plan for anticoagulants, antiplatelets, insulin, SGLT2 inhibitors, GLP-1 receptor agonists and opioid agonist treatment; the nurse asks, documents, confirms and teaches.
- Routine tests are not recommended for people without symptoms having low-risk surgery.
- The CAS minimum fasting times for adults are six hours after a meal containing solids and two hours after clear fluids; patients follow the anesthesia team's instructions.
- Hair is removed only if needed, with clippers; teaching covers breathing, coughing and splinting, leg exercises, early mobilization, pain and what to expect.

7.3 Consent and the Day of Surgery

- The surgeon obtains consent; the nurse checks it is documented and understood and reports doubts or a withdrawal at once.
- The preoperative checklist confirms identity, allergies, consent, site marking, fasting, medications, baseline findings and personal items; changes in condition are reported before transfer.
- The Surgical Safety Checklist has three phases: briefing before anesthesia, time-out before incision and debriefing before the patient leaves the OR.
- A large international study linked the checklist to fewer deaths and complications; an Ontario study after adoption found no significant change, so how teams use it matters.

7.4 Anesthesia and Sedation

- General anesthesia causes a loss of consciousness from which the patient cannot be roused; the anesthesia team supports the airway, breathing and circulation.
- Spinal and epidural anesthesia and nerve blocks numb part of the body; afterward the nurse checks movement, sensation, blood pressure and voiding, protects numb limbs and prevents falls.
- Procedural sedation lies on a continuum; the monitoring nurse watches the airway, breathing, SpO2, capnography where required and level of sedation, and acts at once if sedation becomes too deep.
- Whether a nurse may give sedation depends on authority, competence and context, including employer policy and province or territory.
- Malignant hyperthermia, local anesthetic systemic toxicity and laryngospasm are rare emergencies; the nurse recognizes early cues and calls for help.

7.5 Care After Anesthesia (PACU)

- Phase I care supports recovery of the airway, breathing, circulation and consciousness; Phase II prepares day-surgery patients to go home.
- A structured handover from the anesthesiologist, continuous oximetry and capnography for intubated or deeply sedated patients are Canadian requirements.
- Airway obstruction, laryngospasm and hypoventilation are urgent early risks; patients with sleep apnea need extra vigilance.
- Hypothermia is a core temperature below 36.0 °C; the nurse warms actively and measures temperature often.
- PONV risk rises with female sex, not smoking, a history of PONV or motion sickness and postoperative opioids.
- PACU discharge uses written criteria such as an Aldrete-type score, followed by an SBAR handover.

7.6 Postoperative Care and Complications

- The first postoperative day focuses on regular assessment, early warning scores, fluid balance, pain control, early eating and early walking.
- Walking, deep breathing and coughing prevent atelectasis; evidence that incentive spirometry alone prevents lung complications is weak.
- VTE prevention combines risk assessment, early mobilization, mechanical devices and ordered anticoagulants; suspected PE is escalated at once.
- Urinary retention is often silent; bladder scanning as policy allows and early catheter removal are key.
- Ileus, dehiscence and evisceration need prompt recognition; evisceration is a surgical emergency.
- ERAS pathways depend on nurses for teaching, nutrition, mobilization and catheter removal; discharge planning includes a responsible adult after day surgery and tailored plans for rural and northern patients.

Key Terms (44)

ambulatory surgery: Surgery after which the patient goes home on the same day; also called day surgery or same-day surgery.

anesthesia assistant: A formally designated team member with specific training in anesthesia assistance who carries out tasks approved by the department of anesthesia and the facility.

ASA Physical Status classification: A six-class system used by anesthesiologists to describe a patient's overall health before anesthesia, with "E" added for emergency surgery.

atelectasis: collapse of the small air sacs (alveoli) in part of the lung, common after surgery when breathing is shallow.

briefing: The checklist phase completed before anesthesia begins.

capnography: continuous measurement of the carbon dioxide in exhaled breath (end-tidal CO2), used to monitor breathing.

debriefing: The checklist phase completed at the end of an operation, before the patient is moved out of the operating room, covering counts, specimens, equipment problems and the recovery plan.

dehiscence: separation of the edges of a closed surgical incision, with or without exposure of the tissues or organs beneath.

emergence delirium: confusion, restlessness, agitation or unusual quietness and drowsiness that begins during or soon after waking from general anesthesia.

enhanced recovery after surgery (ERAS): a set of evidence-based practices across the surgical journey that reduce the stress of surgery and speed recovery.

epidural anesthesia: local anesthetic given into the epidural space, usually through a catheter that can stay in place for pain relief after surgery.

evisceration: protrusion of abdominal organs through a dehisced surgical wound; a surgical emergency.

frailty: Reduced physiological reserve that leaves a person less able to recover from a stressor such as surgery.

general anesthesia: a drug-induced state of unconsciousness from which the patient cannot be roused, even by pain.

hematoma: a collection of blood in the tissues, such as under a surgical incision.

inadvertent perioperative hypothermia: an unplanned core body temperature below 36.0 °C around the time of surgery.

incentive spirometer: A hand-held device that shows how deeply a patient breathes in, encouraging slow, full breaths.

informed consent: Agreement to treatment given by a capable person after receiving the information a reasonable person would need, free of pressure; for surgery, obtained by the surgeon.

inpatient surgery: Surgery after which the patient is admitted to hospital.

intermittent pneumatic compression (IPC): leg sleeves that inflate in cycles to squeeze the legs and move blood toward the heart, used to prevent venous thromboembolism.

intraoperative: The phase from arrival in the operating room until transfer to the recovery area.

local anesthetic systemic toxicity (LAST): a toxic reaction of the brain and heart when local anesthetic reaches a high level in the blood.

local infiltration: injection of local anesthetic into the tissue at the site of a minor procedure.

malignant hyperthermia (MH): an inherited, life-threatening hypermetabolic reaction of skeletal muscle triggered by volatile anesthetic gases and succinylcholine.

neuraxial anesthesia: anesthesia produced by placing local anesthetic near the spinal cord, as in spinal and epidural anesthesia.

obstructive sleep apnea (OSA): Repeated collapse of the upper airway during sleep that interrupts breathing.

perioperative nursing: Nursing care given across the whole surgical experience, from the decision to operate through recovery.

peripheral nerve block: injection of local anesthetic near a nerve or group of nerves that supply one limb or area.

postanesthesia care unit (PACU): A unit that gives short-term, closely monitored care immediately after operations and invasive procedures.

postoperative: The phase from admission to the recovery area until the patient has recovered.

postoperative ileus: a temporary slowing of bowel movement after surgery.

postoperative nausea and vomiting (PONV): nausea, retching or vomiting after anesthesia and surgery.

postoperative urinary retention: inability to empty a full bladder after surgery.

prehabilitation: Improving physical and mental fitness in the weeks before surgery to build reserve for recovery.

preoperative: The phase from the decision to operate until transfer to the operating room.

procedural sedation: the use of drugs to depress consciousness so a patient can tolerate a procedure, on a continuum from minimal to deep sedation.

same-day admission: Arrival from home on the morning of surgery, with admission to a surgical unit afterwards.

site marking: Marking the operative site on the patient's skin before surgery, as policy requires, to prevent wrong-site surgery.

spinal anesthesia: a single injection of local anesthetic into the cerebrospinal fluid that numbs and weakens the lower body.

splinting: Pressing a pillow or hands over an incision to reduce pain during coughing or movement.

STOP-Bang: An eight-item yes-or-no screening questionnaire for obstructive sleep apnea.

Surgical Safety Checklist: A structured set of checks completed aloud by the whole surgical team at three set points during each operation.

time-out: The checklist phase completed just before the skin incision, in which the team confirms patient, procedure and site aloud.

venous thromboembolism (VTE): a blood clot in a vein, including deep vein thrombosis and pulmonary embolism.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Mei-Ling Chen (Questions 1–4): Mei-Ling Chen, 58, arrives at the same-day surgery unit at 0700 for a laparoscopic cholecystectomy scheduled for 1000. She has type 2 diabetes, takes metformin and a weekly semaglutide injection, and speaks fluent English. The nurse is completing her preoperative preparation.

1. [CORE] While the nurse reviews the consent form, Ms. Chen says, "The surgeon was in a hurry. I'm not really sure what they are taking out or why." What is the nurse's best action?

a. Explain the risks and benefits of cholecystectomy using the hospital's teaching sheet.

b. Remind Ms. Chen that she has already signed and that the form is legally valid.

c. Inform the surgeon before transfer that Ms. Chen does not understand the procedure.

d. Ask Ms. Chen's spouse to explain the operation to her while she waits.

Answer: c — The surgeon obtains informed consent, and a patient who cannot describe the operation may not have given informed consent, so the nurse reports this to the surgeon before the patient goes to the OR (c). Explaining risks and benefits is the surgeon's role in the consent discussion; the nurse's teaching sheet cannot replace it (a). A signature alone does not prove understanding, and pressing the patient ignores her concern (b). A family member cannot carry out the surgeon's duty to inform (d). See section 7.3.

2. [CORE] Ms. Chen tells the nurse, "I had a slice of toast with peanut butter at 0600, and a glass of water at 0630." Her fasting instructions followed the anesthesia team's usual guidance. What should the nurse do?

a. Report the times and what she ate to the anesthesia team before she goes to the OR.

b. Document the intake and continue preparation, because surgery is still three hours away.

c. Tell Ms. Chen that her surgery is cancelled and arrange for her to go home.

d. Remove the water from the record, because clear fluids do not count toward fasting.

Answer: a — The CAS guidelines set a minimum of six hours after a meal containing solids; toast at 0600 falls inside that window for a 1000 surgery, so the nurse reports exactly what was eaten and when to the anesthesia team, who decide what happens next (a). Continuing without reporting ignores a breach of the fasting minimum (b). The nurse does not cancel surgery; the anesthesia team and surgeon decide (c). Clear fluids are allowed until two hours before, but they are still recorded accurately, not removed from the record (d). See section 7.2.

3. [CORE] Ms. Chen mentions that she took her weekly semaglutide injection two days ago. Why is it important that the anesthesia team knows this?

a. Semaglutide strongly increases the risk of bleeding during laparoscopic surgery.

b. Semaglutide is linked to diabetic ketoacidosis when surgery is done under fasting.

c. Semaglutide must be given again in the PACU to prevent high blood glucose.

d. Semaglutide slows stomach emptying, so food may remain despite usual fasting.

Answer: d — GLP-1 receptor agonists such as semaglutide slow gastric emptying; Health Canada found a possible link with pulmonary aspiration during general anesthesia or deep sedation, so the anesthesia team needs to know (d). Bleeding risk is the concern with anticoagulants and antiplatelets, not GLP-1 receptor agonists (a). The perioperative ketoacidosis warning applies to SGLT2 inhibitors (b). The nurse does not plan postoperative doses; any plan comes from the prescriber (c). See section 7.2 and Table 7.1.

4. [CORE] The nurse completes the preoperative checklist for Ms. Chen. Which finding must the nurse report to the anesthesia team and surgeon before transfer to the OR?

a. She emptied her bladder at 0915 and declined a urinary catheter.

b. Her pulse is 122 beats per minute and irregular; at 0700 it was 76 and regular.

c. Her wedding ring is taped in place according to hospital policy.

d. Her capillary glucose is 6.8 mmol/L, similar to her usual readings.

Answer: b — A new fast, irregular pulse is a change in condition that must be reported before transfer, not left for the OR team to find (b). Voiding before surgery is expected, and a catheter was not planned (a). Securing a ring according to policy is acceptable (c). A glucose value similar to her usual readings is not a change that needs urgent reporting (d). See section 7.3.

5. [CORE] A nurse is teaching a patient in a preadmission clinic who is scheduled for abdominal surgery. Which points belong in the teaching? Select all that apply.

a. Hold a pillow firmly over the incision when coughing.

b. Pump the ankles and circle the feet regularly while in bed.

c. Avoid coughing for the first two days to protect the incision.

d. Take slow, deep breaths, using an incentive spirometer if one is provided.

e. Stay in bed until the day after surgery to let the incision rest.

f. Tell the nurse early when pain makes it hard to breathe deeply or walk.

Answer: a, b, d, f — Splinting with a pillow reduces pain during coughing (a); ankle pumps and foot circles keep blood moving in the legs (b); slow, deep breaths, with an incentive spirometer where used, open the small airways (d); and reporting pain early lets the team treat it so the patient can breathe deeply and move (f). Avoiding coughing allows secretions to build up (c). Staying in bed delays the early mobilization that teaching should encourage (e). See section 7.2.

6. [CORE] The surgical team asks the nurse to prepare a patient's abdomen, which has heavy hair growth, before surgery. Which action follows current guidance?

a. Shave the area with a new disposable razor just before the patient goes to the OR.

b. Remove hair with clippers, only if the surgical team says removal is necessary.

c. Shave the area the evening before so any small cuts have time to heal.

d. Apply a depilatory cream to the whole abdomen as a routine step.

Answer: b — The WHO recommends leaving hair in place or, if removal is truly necessary, using clippers (b). Shaving causes small skin breaks and is strongly discouraged at any time, whether just before surgery or the night before (a, c). Routine hair removal of any kind, including depilatory cream, is not recommended when removal is not needed (d). See section 7.2.

7. [CORE] A nurse is screening patients for obstructive sleep apnea with the STOP-Bang questionnaire. Which patient has the highest STOP-Bang score?

a. A 45-year-old woman who snores loudly and feels tired during the day.

b. A 38-year-old man with a body mass index of 37 kg/m² and no other findings.

c. A 70-year-old woman with treated hypertension and a neck circumference of 36 cm.

d. A 62-year-old man who snores loudly and has a neck circumference of 43 cm.

Answer: d — The 62-year-old man scores four points: loud snoring, age over 50, neck circumference over 40 cm and male sex (d). The 45-year-old woman scores two, for snoring and tiredness (a). The 38-year-old man scores two, for body mass index above 35 kg/m² and male sex (b). The 70-year-old woman scores two, for hypertension and age over 50; her neck circumference is under 40 cm (c). See section 7.2.

8. [CORE] A student nurse asks when the time-out phase of the Surgical Safety Checklist takes place. Which response is accurate?

a. "It takes place in the preoperative unit, when the nurse completes the hospital checklist."

b. "It takes place in the operating room before anesthesia is started."

c. "It takes place just before the skin incision, with the team confirming aloud."

d. "It takes place before the patient leaves the OR, when counts are confirmed."

Answer: c — The time-out happens just before the skin incision; team members introduce themselves and the surgeon, anesthesiologist and nurse confirm the patient, procedure and site aloud (c). The preoperative unit checklist is a separate hospital process (a). The briefing takes place before anesthesia begins (b). The debriefing, including counts, takes place before the patient leaves the OR (d). See section 7.3 and Table 7.2.

9. [CORE] A registered practical nurse (RPN) in an Ontario hospital asks whether she can work in the postanesthesia care unit. Which response best reflects the CNO's approach to scope?

a. "It depends on your education and competence, employer policy and the patients' needs."

b. "CNO rules allow RPNs to care only for stable patients, so PACU work is not permitted."

c. "RPNs may work there only if they obtain the surgical consent for each of their patients."

d. "Any nurse can work in the PACU, because perioperative care needs no added education."

Answer: a — CNO frames scope in terms of authority, competence and context, so the RPN's role in the PACU depends on her education and competence, employer policy and patient needs (a). Assigning by stability is a common employer practice, not a CNO rule (b). The surgeon obtains surgical consent; no nurse does (c). PACU care requires added education and competence (d). See section 7.3, Scope in Practice box.

Case: Mrs. Lucille Arsenault (Questions 10–15): Mrs. Lucille Arsenault, 71, had a right total knee arthroplasty under spinal anesthesia yesterday morning. She has hypertension and a body mass index of 34 kg/m². She is receiving ordered anticoagulant prophylaxis, IPC sleeves and oral analgesics, including an opioid. At 0800 today her vital signs were temperature 37.4 °C, heart rate 84, respiratory rate 18, blood pressure 138/76 mm Hg and SpO2 95% on room air. She has spent most of the day in bed, saying she is "too sore and too sleepy" to use her incentive spirometer, and her IPC sleeves were removed for physiotherapy at 1100 and not put back on. At 1530 she calls the nurse and says, "All of a sudden I can't get my breath, and it hurts on the right side of my chest when I breathe in." Assessment: heart rate 118, respiratory rate 28, blood pressure 112/70 mm Hg, temperature 37.6 °C, SpO2 89% on room air. She is anxious and restless. Breath sounds are reduced at both bases. Her right knee dressing is dry, and the right leg is swollen as expected after surgery. Her left calf is tender and slightly larger than it was this morning.

10. [CORE] Which findings at 1530 require immediate follow-up? Select all that apply.

a. SpO2 89% on room air

b. Swelling of the right leg below the dressing

c. Heart rate 118 with a respiratory rate of 28

d. Sudden chest pain that worsens on breathing in

e. Temperature 37.6 °C

f. New tenderness and enlargement of the left calf

g. Body mass index of 34 kg/m²

Answer: a, c, d, f — A fall in SpO2 to 89% (a), a sharp rise in heart rate and breathing rate (c), sudden pleuritic chest pain (d) and new tenderness and swelling of the opposite calf (f) are new changes that need action now (section 7.6). Swelling of the operated leg (b) is expected after knee arthroplasty and is unchanged. A temperature of 37.6 °C (e) is a slight rise that is common after surgery and is not the most urgent finding. Her body mass index (g) is a risk factor, not a new finding that needs follow-up.

11. [CORE] The nurse analyzes the cues. Which finding most strongly favours pulmonary embolism over atelectasis as the cause of Mrs. Arsenault's low SpO2?

a. Reduced breath sounds at both lung bases

b. Sudden breathlessness with pleuritic pain and a newly tender left calf

c. Reluctance to use the incentive spirometer

d. Sleepiness after taking an opioid analgesic

Answer: b — Sudden breathlessness with pleuritic chest pain, together with signs of a possible DVT in the other leg (b), points to PE (section 7.6). Reduced breath sounds at the bases (a) and poor use of the incentive spirometer (c) fit atelectasis, which usually develops more gradually. Opioid sleepiness (d) can cause hypoventilation but does not explain sudden pleuritic pain, tachycardia and a tender calf.

12. [CORE] Which hypothesis is the priority?

a. Opioid-related sedation causing shallow breathing

b. Atelectasis from staying in bed

c. Anxiety about her slow recovery

d. Pulmonary embolism causing impaired gas exchange

Answer: d — Pulmonary embolism (d) can cause rapid deterioration and death, and her cues fit it best, so it is the priority hypothesis even before tests confirm it (section 7.6). Opioid sedation (a) and atelectasis (b) may contribute but do not explain the sudden pleuritic pain and calf findings, and acting on them first could delay treatment. Anxiety (c) is a response to her symptoms, not the cause of hypoxemia.

13. [CORE] Which actions should the nurse include in the plan of care now? Select all that apply.

a. Stay with Mrs. Arsenault and call for help through the rapid response team or the most responsible provider

b. Massage the left calf to relieve the tenderness

c. Raise the head of the bed and give oxygen as ordered or as the medical directive allows

d. Encourage her to walk in the hallway to open her lungs

e. Report using SBAR, including her SpO2 trend and the left calf findings

f. Prepare her for ordered diagnostic tests, such as imaging of the chest and legs

g. Give the next scheduled opioid dose early to relieve the chest pain

Answer: a, c, e, f — The nurse stays and escalates (a), supports oxygenation (c), gives a clear SBAR report that includes the key cues (e) and prepares for ordered tests (f) (section 7.6; Chapter 6). Massaging the calf (b) could dislodge a clot. Walking (d) helps prevent atelectasis but is unsafe with suspected PE and hypoxemia. An early opioid dose (g) could depress breathing and mask her symptoms; pain relief is given as ordered after the team assesses her.

14. [CORE] The nurse has called the rapid response team. While waiting, which action should the nurse take first?

a. Apply oxygen as the directive allows and recheck SpO2

b. Reapply the IPC sleeves to both legs to prevent another clot

c. Coach her to use the incentive spirometer 10 times

d. Document the 1530 assessment in the electronic record

Answer: a — Oxygenation is the immediate threat, so applying oxygen as authorized and rechecking SpO2 (a) comes first (section 7.6). Reapplying IPC sleeves (b) is not appropriate on a leg with a suspected clot until the team decides. Incentive spirometry (c) does not treat PE. Documentation (d) is completed once the patient is safe.

15. [CORE] Mrs. Arsenault is started on treatment for a confirmed pulmonary embolism. Which finding 2 hours later shows that her condition is improving?

a. SpO2 92% on room air with a heart rate of 120

b. Respiratory rate 30 and she says she feels "a bit calmer"

c. SpO2 95% on ordered oxygen, heart rate 96, respiratory rate 20 and less chest pain

d. Blood pressure 100/62 mm Hg and she is now drowsy

Answer: c — Better SpO2, slower heart and breathing rates and less pain (c) show improving gas exchange and circulation (section 7.6). An SpO2 of 92% with a persistent heart rate of 120 (a) and a respiratory rate of 30 (b) show that she is still in distress, whatever she reports. Falling blood pressure with new drowsiness (d) suggests deterioration and needs urgent escalation.

16. [CORE] A patient had a knee arthroscopy under spinal anesthesia 2 hours ago and is now on the surgical day-care unit. He wants to get up to use the washroom. What should the nurse do first?

a. Help him walk to the washroom, because walking soon after surgery helps prevent complications such as blood clots

b. Offer a urinal and tell him he must stay in bed until tomorrow morning

c. Check the return of movement and sensation in his legs and his blood pressure before helping him sit up

d. Give an ordered opioid, because standing will increase his knee pain

Answer: c — After spinal anesthesia, the nurse confirms that movement and sensation have returned and checks blood pressure, because weakness and hypotension can cause a fall (c) (section 7.4). Walking before checking (a) risks a fall. Bed rest until tomorrow (b) is unnecessary and delays recovery. An opioid before standing (d) adds sedation and hypotension and does not address the main safety risk.

17. [CORE] During a colonoscopy under moderate sedation, the monitoring nurse finds that the patient responds only when the nurse rubs his sternum, his SpO2 has fallen from 96% to 89%, and the capnography waveform has flattened. What should the nurse do first?

a. Stimulate the patient, open the airway as taught and tell the physician to stop the procedure while calling for help

b. Record the change and reassess the patient's sedation level and SpO2 in 5 minutes

c. Ask the physician to give another dose of sedative because the patient is about to move and the procedure is nearly done

d. Turn off the capnography alarm because the patient is still breathing

Answer: a — The patient has slipped into deep sedation with poor ventilation, so the nurse acts on the airway and breathing at once, has the procedure stopped and calls for help (a) (section 7.4). Waiting 5 minutes (b) allows hypoxemia to worsen. More sedative (c) would deepen sedation further. A flattened waveform shows inadequate breathing, and alarms must stay on (d).

18. [CORE] Which patient has the highest risk of postoperative nausea and vomiting?

a. A 68-year-old man who smokes, having a hernia repair under local anesthesia

b. A 55-year-old man who does not smoke, having a hip replacement under spinal anesthesia with a nerve block

c. A 45-year-old woman who smokes, having a hand procedure under a nerve block with no opioids planned

d. A 34-year-old woman who does not smoke, has motion sickness and will receive opioids after laparoscopic surgery

Answer: d — She has all four simplified Apfel risk factors (female sex, not smoking, motion sickness, postoperative opioids), plus age under 50 and laparoscopic surgery (d) (section 7.5). The patient in (a) has no Apfel factors other than possible opioids and is having local anesthesia. The patient in (b) has one or two factors. The patient in (c) is female but smokes and will not receive opioids.

19. [CORE] A patient arrives in the PACU after a 3-hour bowel resection. His temperature is 35.6 °C and he is shivering. Which action is most appropriate?

a. Give him one extra cotton blanket and recheck his temperature in 4 hours, once he is more awake

b. Start forced-air warming as ordered or as policy directs, and recheck his temperature every 15 minutes

c. Transfer him to the surgical unit, where he can warm up in a quiet room

d. Hold all warming until the surgeon has seen him and confirmed that warming is safe

Answer: b — A core temperature below 36.0 °C is inadvertent perioperative hypothermia; active warming and frequent temperature checks are needed (b) (section 7.5). A single blanket with a recheck in 4 hours (a) is too little, too late. The patient should not leave the PACU until his temperature is at least 36.0 °C (c). Warming does not need to wait for the surgeon (d).

20. [CORE] The PACU nurse is preparing to transfer a patient to the surgical unit after abdominal surgery under general anesthesia. Which finding means the patient is not yet ready to leave?

a. He opens his eyes when spoken to and answers questions

b. His blood pressure is within 10 mm Hg of his preoperative value

c. His SpO2 drops to 88% on room air whenever he dozes off

d. He moves all four limbs on request

Answer: c — Desaturation when he dozes (c) shows that his breathing is not yet adequate without support; he needs further assessment and the anesthesia team should be told (section 7.5). Responding to voice (a), stable blood pressure close to baseline (b) and moving all four limbs (d) are findings that support readiness for discharge from the PACU.

21. [CORE] Six hours after hip surgery under spinal anesthesia, a 78-year-old man has not voided since his catheter was removed in the PACU. He is restless and keeps trying to get out of bed, but denies needing to urinate. His vital signs are stable. What should the nurse do next?

a. Scan his bladder as policy allows and report the result and his restlessness to the most responsible provider or RN as appropriate

b. Ask the prescriber for a sedative, because he denies needing to void and his restlessness puts him at risk of falling

c. Encourage him to drink 1 L of water to stimulate voiding

d. Reassess him at the end of the shift, because many patients take several more hours to void after spinal anesthesia

Answer: a — Spinal anesthesia and age raise the risk of retention, and many patients with a full bladder feel no urge, so the nurse checks the bladder and reports the findings (a) (section 7.6). A sedative (b) treats the behaviour instead of the cause, and a full bladder can itself cause restlessness. Extra fluid (c) would overfill a bladder that cannot empty. Waiting until the end of the shift (d) risks bladder damage and worsening confusion.

22. [CORE] On day 3 after a bowel resection, a patient has a distended abdomen, has vomited twice and has not passed gas. Which action should the nurse take?

a. Encourage her to chew gum, because chewing gum is a routine part of ERAS for restarting the bowel after surgery

b. Encourage her to eat a full meal to stimulate the bowel

c. Give the ordered opioid more often, because her abdominal discomfort is keeping her from walking

d. Report the findings and keep her fasting as ordered while monitoring fluids and electrolytes

Answer: d — These cues suggest postoperative ileus. The nurse reports them, follows orders for fasting and possibly a nasogastric tube, and monitors fluids and electrolytes (d) (section 7.6). The ERAS colorectal guideline does not recommend chewing gum as a routine measure (a). A full meal (b) would increase vomiting. More frequent opioids (c) slow the bowel further.

23. [CORE] A patient is going home on anticoagulant injections after major abdominal cancer surgery. Which statement shows that the teaching has been effective?

a. "If my calf swells, I'll rub it gently until it goes down."

b. "I'll keep giving the injections for as long as my surgeon prescribed them, even when I feel well."

c. "I can stop the injections once I'm walking around the house, because walking keeps my blood moving."

d. "If I suddenly get short of breath, I'll rest and call the surgeon's office in the morning."

Answer: b — Prophylaxis after major abdominal cancer surgery may continue for weeks, and the patient must finish the prescribed course (b) (section 7.6). A swollen calf should never be rubbed (a); it needs urgent assessment. Walking does not replace a prescribed anticoagulant course (c). Sudden shortness of breath may be a pulmonary embolism and needs 9-1-1, not rest and a call in the morning (d).

24. [CORE] A patient on day 6 after a laparotomy coughs and says, "Something just gave way." The nurse sees loops of bowel in the open incision. What should the nurse do first?

a. Stay with the patient, call for help, and cover the bowel with sterile dressings moistened with sterile normal saline

b. Gently push the bowel back into the abdomen with a sterile gloved hand, then apply a dry dressing

c. Leave the room to page the surgeon, then return to take vital signs and check the wound

d. Give the patient a drink of water to ease the cough

Answer: a — Evisceration is a surgical emergency: the nurse stays, calls for help and protects the organs with a sterile saline-moistened dressing (a) (section 7.6, Clinical Safety box). Pushing the bowel back (b) can injure it and introduce infection. Leaving the patient (c) is unsafe; a colleague pages the surgeon. The patient must have nothing by mouth (d) in preparation for surgery.

25. [CORE] The nurse is reviewing discharge teaching with a patient after cataract surgery under procedural sedation. Which statement needs further teaching?

a. "My son is driving me home and will stay with me tonight."
b. "I'll call the number on my instructions if my pain gets worse instead of better."
c. "I'll drive myself to the pharmacy this evening to pick up my eye drops."
d. "I won't sign any legal papers until tomorrow."

Answer: c — Patients are told not to drive for 24 hours after anesthesia or sedation (c) (section 7.6). Having a responsible adult take her home and stay (a), calling about worsening pain (b) and putting off important decisions (d) are correct.

26. [CORE] An RPN on a surgical unit is caring for a patient on day 1 after bowel surgery. At 1000, the patient's SpO2 is 90% on room air (95% at 0600), respiratory rate 24, and the patient says breathing "feels harder." The RN on the team is in another patient's room. What is the RPN's most appropriate action?

a. Encourage incentive spirometry and recheck the SpO2 at the next scheduled set of vital signs this afternoon
b. Document the findings and mention them to the RN at noon, once the RN has finished with the other patient
c. Wait until the patient's early warning score reaches the rapid response threshold
d. Sit the patient up, apply oxygen if a medical directive allows, and consult the RN now, escalating directly if the patient worsens

Answer: d — Every nurse who notices deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change, and calls for help directly if the patient worsens (d) (section 7.6; Chapter 1, section 1.3). Waiting for the next scheduled check (a) or until noon (b) delays care. The nurse escalates on clinical concern and need not wait for the score to reach a threshold (c) (Chapter 6).

27. [RN] During a laparoscopic cholecystectomy under general anesthesia with a volatile agent, which findings are early cues of malignant hyperthermia? Select all that apply.

a. An unexplained rise in end-tidal CO2
b. Heart rate rising without another explanation
c. Rigidity of the jaw muscles after succinylcholine
d. Bradycardia
e. Falling end-tidal CO2
f. Profuse sweating and mottled skin

Answer: a, b, c, f — An unexplained rise in end-tidal CO2 (a), inappropriate tachycardia (b), masseter rigidity after succinylcholine (c) and sweating with mottled skin (f) are early cues (section 7.4, Going Deeper). MH causes tachycardia, not bradycardia (d). Hypermetabolism raises CO2 production, so end-tidal CO2 rises, not falls (e). A high temperature is often a later sign.

28. [RN] The anesthesiologist suspects malignant hyperthermia in a patient in the operating room. Which action by the team comes first?

a. Apply cooling blankets and wait to see whether the temperature falls
b. Stop the volatile anesthetic and succinylcholine, and ventilate with high-flow 100% oxygen
c. Send blood for genetic testing for MH susceptibility
d. Finish the surgery quickly before treating the patient

Answer: b — Treatment begins with removing the triggers and hyperventilating with 100% oxygen while dantrolene is prepared (b) (section 7.4, Going Deeper). Cooling (a) is part of treatment but does not stop the reaction, and waiting delays it. Genetic testing (c) comes after recovery. The surgeon is told so surgery can be stopped or postponed; finishing first (d) delays treatment.

29. [RN] Fifteen minutes after an ultrasound-guided nerve block for shoulder surgery, a patient in the block area says, "I have a metal taste in my mouth and my ears are ringing." He is restless. What do these cues suggest?

a. Early local anesthetic systemic toxicity
b. A vasovagal reaction to the needle
c. Expected effects of a successful nerve block
d. Malignant hyperthermia

Answer: a — A metallic taste, ringing in the ears and agitation are early central nervous system cues of LAST; seizures and heart rhythm problems can follow (a) (section 7.4). A vasovagal reaction (b) causes pallor, slow heart rate and fainting, not altered taste or hearing. A successful block (c) causes numbness of the limb, not these symptoms. MH (d) is triggered by volatile anesthetics and succinylcholine, not local anesthetics.

30. [RN] A patient receiving a continuous femoral nerve block infusion on day 2 after knee replacement becomes confused, then has a seizure. Which action should the nurse take first?

a. Give lipid emulsion from the LAST kit without waiting for the physician
b. Increase the nerve block infusion rate to treat the patient's pain
c. Stop the local anesthetic infusion, call for help, and protect and support the airway
d. Leave the patient to find the LAST checklist

Answer: c — The nurse stops the source of local anesthetic, calls for help and makes airway management the first priority, because low oxygen and high carbon dioxide worsen toxicity (c) (section 7.4, Going Deeper). Lipid emulsion (a) is given early, but it is ordered and led by the physician. Increasing the infusion (b) would worsen toxicity. The nurse stays with the patient and sends someone else for the checklist and kit (d).

08 Older Adults in Acute Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Distinguish normal aging from disease, and explain how frailty shapes the risks of acute care.
2. Recognize, prevent and manage delirium, and distinguish it from dementia and depression.
3. Provide person-centred care for people living with dementia, including responding to responsive behaviours and partnering with caregivers.
4. Screen for depression in older adults and respond to signs of risk.
5. Prevent falls and functional decline in hospital, and respond safely after a fall.
6. Identify potentially inappropriate medications for older adults and explain the nurse's role in deprescribing.
7. Apply least-restraint principles, Ontario restraint law, and capacity and consent principles in caring for older adults.
8. Plan safe transitions from hospital, including support for caregivers.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4, 6	Clinician; Scholar	Foundations of Practice
3, 5, 8	Clinician; Advocate; Coordinator	Foundations of Practice; Collaborative Practice
7	Advocate; Professional	Legal Practice; Ethical Practice

Introduction

On any medical or surgical unit in Canada, many of the patients in the beds are older adults. Almost one in five people in Canada was 65 or older on July 1, 2025 (Statistics Canada, 2025), and people in later life are often the ones admitted with pneumonia, heart failure, a fractured hip or a planned joint replacement. Hospital care can cure the illness that brought an older person in and still leave them worse off. Delirium, falls, loss of strength and loss of independence can all start during a stay that was meant to help.

This chapter prepares the nurse to protect older adults from those harms. Section 8.1 describes aging, frailty and the hazards of the hospital stay. Section 8.2 covers delirium in full, and section 8.3 covers dementia and depression in hospital. Sections 8.4 to 8.6 continue with falls and functional decline, safer use of medications, restraint minimization, elder abuse and transitions out of hospital. Related topics live elsewhere: consent, capacity and substitute decision-makers (Chapter 1), infection in older adults (Chapter 4), pain assessment in people living with dementia (Chapter 5), postoperative delirium (Chapter 7), palliative care (Chapter 10), alcohol withdrawal (Chapter 11) and pressure injuries (Chapter 35).

8.1 Aging, Frailty and Acute Care

An Aging Canada

Canada's population is getting older. On July 1, 2025, 8,108,467 people in Canada were aged 65 or older, which was 19.5% of the population; the share ranged from 5.2% in Nunavut to 25.2% in Newfoundland and Labrador (Statistics Canada, 2025). The oldest group is growing quickly. The 2021 Census counted more than 861,000 people aged 85 or older, 12% more than in 2016, and Statistics Canada (2022) projects that this group could roughly triple, to nearly 2.5 million people, by 2046.

Normal Aging and Disease

The most important age-related change for acute care is a loss of **physiological reserve**, the spare capacity that organs draw on under stress. An older person may manage well day to day yet have little margin when illness, surgery or a new drug adds strain.

Several age-related changes affect hospital care:

- **Kidneys:** the number of working nephrons falls with age. In carefully screened healthy kidney donors, glomerular filtration rate (GFR) fell by about 6.3 mL/min/1.73 m² per decade (Denic et al., 2016). Because older adults usually have less muscle, a serum creatinine in the reference range can hide reduced kidney function, which matters for drug dosing and for the risk of acute kidney injury (Denic et al., 2016).
- **Thirst and fluids:** older adults usually drink enough in daily life, but when they are short of fluid or heat-stressed they feel less thirsty and drink less, so fluid balance recovers more slowly (Kenney & Chiu, 2001). An older patient who is ill, confused or unable to reach a cup can become dehydrated quickly (see Chapter 3).
- **Temperature:** fever may be lower or absent in an older adult with a serious infection; atypical presentation of infection is taught in Chapter 4.
- **Skin, senses and sleep:** thinner skin breaks down more easily (Chapter 35); vision and hearing loss make a strange ward harder to understand; sleep becomes lighter, and hospital noise disturbs it further.

None of these changes is a disease. New confusion, incontinence, falls or a sudden inability to walk are not "just old age"; they signal that something is wrong. Assuming otherwise is a form of **ageism**: stereotyping, prejudice or discrimination against people because of their age. In care, ageism looks like talking to the daughter instead of the patient or offering less treatment without asking what the person wants.

Frailty

Frailty is a state in which a lifetime of small declines across many body systems has used up the body's reserves, so that a minor stressor, such as a urinary tract infection or a new drug, causes a large and sometimes lasting change in health (Clegg et al., 2013). Frailty is linked to falls, disability, hospital admission and death, and recognizing it helps the team match treatment to the person and plan goal-directed care (Clegg et al., 2013). Frailty is related to age but is not the same thing; many very old people are not frail.

The **Clinical Frailty Scale (CFS)** is a Canadian tool that summarizes an older adult's overall fitness or frailty after a clinical encounter. It came out of the Canadian Study of Health and Aging (Rockwood et al., 2005). It is not a questionnaire. The clinician uses judgment to place the person on a nine-level scale, from very fit to terminally ill, according to how they manage mobility, daily activities and their illnesses (Geriatric Medicine Research, Dalhousie University, n.d.). Version 2.0, released in 2020, made small changes to the level names and descriptions (Rockwood & Theou, 2020).

The CFS rates the person's usual state before the current illness, so the nurse asks family how the person was managing before they became sick. It has not been widely validated in younger people or in people with a stable disability affecting one body system, and it requires clinical judgment (Rockwood & Theou, 2020). Teams use the score to anticipate risk and guide conversations about goals of care, never by itself as a reason to withhold treatment.

Hospital-Associated Disability

Hospital-associated disability is a new loss of the ability to carry out a basic activity of daily living, such as bathing, dressing or walking across a room, that appears during a hospital stay and is not caused directly by the illness itself. Covinsky et al. (2011) describe it as common in hospitalized older adults, and it can develop even when the illness that brought the person in is treated successfully.

Much of this disability comes from the hospital routine. Bed rest causes rapid muscle loss, intravenous poles and urinary catheters discourage walking, and patients are often helped with tasks they could do themselves (Covinsky et al., 2011). The nurse counters these harms by recording how the person managed before admission, getting them up and walking early and often, encouraging them to wash and dress themselves, removing tethering devices as soon as possible, and starting discharge planning on admission. Falls and mobility are taught in section 8.4.

Alternate Level of Care

Alternate level of care (ALC) describes a patient who no longer needs the intensity of hospital care but stays in a hospital bed until a more suitable setting is available, such as rehabilitation, complex continuing care, home care or long-term care (Canadian Institute for Health Information [CIHI], 2026a; Canada's Drug Agency, 2025). In 2024–2025, 6.1% of acute inpatient hospital stays in Canada included ALC days (CIHI, 2026a). Because ALC patients stay longer, their share of hospital days is larger: in 2022–2023, patients designated ALC accounted for an estimated 17.0% of hospital days, ranging from 6.8% to 26.1% across provinces and territories (Canada's Drug Agency, 2025).

Older adults are the most common group of ALC patients (Canada's Drug Agency, 2025), and a long wait in an acute care bed is not harmless. ALC patients are at risk of hospital-acquired infection and of deconditioning and loss of function, and people living with frailty or dementia face added risks of falls and delirium (Canada's Drug Agency, 2025). ALC status is a reason to keep the person moving, engaged and eating, and to keep the care plan active rather than custodial.

Diverse Older Adults

Life experience shapes how older adults meet the health system. Indigenous older adults may carry the effects of residential schools and racism in health care, along with strengths of family, community, language and culture. In many First Nations, Inuit and Métis communities, Elder is a role the community gives for knowledge and wisdom, not a word for any older person; the nurse asks how the patient wishes to be addressed and whether they want family, an Elder or an Indigenous patient navigator involved (see Chapter 2).

Many older 2SLGBTQI+ adults grew up when their identities were criminalized or treated as illness, and some hide who they are from care providers; the nurse asks inclusively about family and supports, which may include a partner or chosen family. Older newcomers may speak little English or French, and professional interpreters, not relatives, are used for clinical conversations (see Chapter 1, section 1.7). For older adults from rural, remote and northern communities, discharge planning must account for distance, travel and local services.

CANADIAN CONTEXT

An Aging Population and Hospital Care

Canada's oldest age group is growing quickly. Statistics Canada (2022) projects that the number of people aged 85 or older could roughly triple between 2021 and 2046, to nearly 2.5 million. This is the age group most likely to live with frailty, dementia and several chronic conditions at once.

Hospitals already feel the pressure. In 2022–2023, patients designated ALC used an estimated 17.0% of hospital days in Canada; older adults are the most common group of ALC patients, many of them waiting for rehabilitation, home care or long-term care (Canada's Drug Agency, 2025). When acute beds are full, emergency departments back up and surgeries are delayed.

Nurses can help in practical ways:

- Ask about the patient's usual function and home supports on admission, and record them.
- Get older patients out of bed and walking early, unless there is a clear reason not to.
- Start discharge planning on day one, with the patient, family and team.
- Keep ALC patients active and engaged so they do not lose the abilities they will need in the next setting.

8.2 Delirium

What Delirium Is

Delirium is a sudden disturbance of attention and awareness, with changes in thinking, memory, perception or language, that develops over hours to days, tends to come and go during the day, and is caused by a medical condition, a drug or several factors together (Wilson et al., 2020). The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), is the most widely used reference standard for diagnosis (Wilson et al., 2020). The core problem is inattention: the person cannot focus, follow a conversation or keep track of a question.

Delirium is common in hospital and often missed. The Registered Nurses' Association of Ontario (RNAO, 2016) reports that it affects up to half of hospitalized older adults, with higher rates in intensive care, after hip fracture and after surgery such as cardiac surgery. Across 17 studies of the 4AT in older adults in acute medicine, surgery, a care home and emergency departments, delirium was present in 24.2% of assessments overall (Tieges et al., 2021).

Delirium is dangerous. In a meta-analysis of older patients followed after discharge, delirium was linked with a higher risk of death (adjusted hazard ratio 1.95), admission to a care institution (odds ratio 2.41) and, in two studies followed for about four years, a much higher risk of dementia (Witlox et al., 2010). Delirium also increases the risk of falls and loss of function. Because it signals that the brain is failing under stress from an underlying illness, new delirium is treated as an urgent change in condition that the nurse reports at once.

Three Subtypes

Delirium is described by how the person behaves:

- **Hyperactive delirium:** the person is restless, agitated or fearful, may pull at lines and tubes, try to climb out of bed, or see and hear things that are not there. It is noticed quickly because it disrupts care.
- **Hypoactive delirium:** the person is quiet, drowsy, slow to respond and withdrawn, moves little and eats little. It is often missed because the person seems calm or tired (National Institute for Health and Care Excellence [NICE], 2023), and it can be mistaken for depression (RNAO, 2016).
- **Mixed delirium:** the person moves between the two patterns, sometimes within the same shift.

The hypoactive form is the one the nurse must look for deliberately. A patient who "slept all day", stopped eating or "isn't herself" needs an assessment for delirium, not a quiet room.

Risk Factors and Precipitants

Delirium usually results from the meeting of a vulnerable brain and one or more triggers (Wilson et al., 2020). The more vulnerable the person, the smaller the trigger needed to tip them into delirium.

Predisposing factors are present before admission. NICE (2023) identifies people as at risk if they are 65 or older, have past or present cognitive impairment or dementia, have a current hip fracture, or are severely ill. Frailty, vision or hearing impairment and a previous episode of delirium add to the risk.

Precipitating factors are new insults during the illness or stay:

- infection, hypoxia, dehydration and electrolyte changes such as hyponatremia (Chapters 3 and 4);
- pain that is not recognized or treated (Chapter 5);
- surgery and anesthesia (Chapter 7);
- urinary retention and constipation;
- sleep loss, immobility, and urinary catheters or other tethering devices;
- drugs, especially those with anticholinergic effects, benzodiazepines and other sedatives, and opioids (section 8.5);
- withdrawal from alcohol or sedatives (Chapter 11).

Often several causes act together, so finding one does not end the search.

Screening

Delirium is easier to recognize when the nurse knows the person's usual self. On admission, the nurse asks family or caregivers how the person normally thinks, talks and manages, then uses a validated tool to screen people at risk. NICE (2023) advises checking for risk factors when people first present to hospital and observing all patients at least daily for recent changes, and RNAO (2016) recommends assessment at least daily and whenever a change is noticed. Many hospitals screen each shift; the nurse follows employer policy.

The **Confusion Assessment Method (CAM)** is the main screening tool used in this book (Inouye et al., 1990). It asks the assessor to judge four features after a brief interaction and cognitive test:

- an acute change from the person's baseline, or a course that fluctuates during the day;
- inattention;
- disorganized thinking;
- an altered level of consciousness, either reduced (drowsy, hard to rouse) or heightened (hyperalert).

The first two features form the core. A screen is positive when both core features are present together with at least one of the other two (Inouye et al., 1990). In its original study, the CAM took less than five minutes. Assessors are trained to use the tool as its developers intend.

The **4AT** is a brief alternative that usually takes less than two minutes and is designed for routine use in everyday clinical practice (Bellelli et al., 2014; Tieges et al., 2021). It looks at the person's alertness, a short orientation test, a simple attention task and whether there has been an acute change or fluctuation, and a higher score suggests possible delirium. A review of 17 studies found that it detects delirium accurately in older adults across several settings (Tieges et al., 2021).

A positive screen is not a diagnosis. It is a finding that the nurse reports promptly so the prescriber can assess the patient and search for the cause.

Table 8.1 Delirium, dementia and depression compared (RNAO, 2016; NICE, 2023; Wilson et al., 2020)

Feature	Delirium	Dementia	Depression
Onset	Sudden, over hours to days	Slow, over months to years	Over weeks to months, often after loss or illness
Course	Comes and goes during the day; often worse at night	Gradual, steady decline	Persistent low mood most of the day
Attention	Poor; cannot focus or follow a conversation	Usually intact until later stages	May be reduced; effort is poor
Consciousness	Altered; drowsy or hyperalert	Clear until late stages	Clear
Thinking	Disorganized, rambling or illogical	Memory loss and trouble with reasoning and language	Slowed; negative and hopeless thoughts
Mood	Fearful, irritable, flat or changeable	Varies; may be anxious or apathetic	Sad, empty or irritable; loss of interest and pleasure
Reversibility	Often reversible when the cause is treated; recovery may be slow or incomplete	Progressive; not reversible	Treatable; usually improves with care
What the nurse does first	Reports at once and looks for causes	Learns the person's history, routines and needs	Asks about thoughts of suicide and reports

The three conditions can occur together. Delirium often develops in a person already living with dementia, and hypoactive delirium can look like depression (RNAO, 2016) (Table 8.1).

Preventing Delirium

Much delirium in hospital can be prevented with simple, consistent care. The Hospital Elder Life Program (HELP) tested a **multicomponent prevention** approach in 852 patients aged 70 or older admitted to hospital. The intervention targeted six risk factors: cognitive impairment, sleep loss, immobility, vision impairment, hearing impairment and dehydration. Delirium developed in 9.9% of patients on the intervention unit and 15.0% of those receiving usual care (matched odds ratio 0.60), and intervention patients had fewer days and episodes of delirium (Inouye et al., 1999). A later meta-analysis of 14 studies found that multicomponent programs lowered the odds of delirium (odds ratio 0.47) and of falls (odds ratio 0.38) (Hshieh et al., 2015). RNAO (2016) recommends a tailored, non-drug, multicomponent prevention plan for every person at risk.

Prevention depends on the whole team doing the basics every day, on every shift (Table 8.2). Avoiding unnecessary moves between rooms and units also helps the person stay oriented (NICE, 2023).

Table 8.2 Multicomponent delirium prevention: what the nurse does (Inouye et al., 1999; NICE, 2023; RNAO, 2016)

Area	Nursing actions	Why
Orientation and engagement	Introduce yourself and your role; keep a clock and calendar in view; talk about the day; encourage visits and familiar activities	Helps the person make sense of a strange place
Vision and hearing	Make sure glasses, hearing aids and dentures are in use, clean and working; check for ear wax; face the person and speak clearly	The brain misreads what it cannot see or hear
Sleep	Group night-time care; dim lights and reduce noise; offer a warm drink, toileting and comfort instead of a sleeping pill	Sleep loss worsens attention and mood
Hydration and nutrition	Keep drinks within reach and offer them often; help with meal set-up and feeding; check dentures; track intake	Dehydration and poor intake are common triggers
Bowel and bladder	Avoid or remove urinary catheters early; check for retention and constipation; offer regular toileting	Retention, constipation and catheters can provoke delirium
Mobility	Get the person up and walking early and often; do range-of-motion exercises for those who cannot walk	Immobility weakens body and mind
Pain	Assess pain regularly, including non-verbal signs in people who cannot report it (Chapter 5)	Untreated pain is a trigger
Medications and oxygen	Ask for a medication review; question new sedatives and drugs with anticholinergic effects; check oxygen saturation	Drugs and hypoxia are frequent causes

Caring for a Patient With Delirium

Care has five parts. First, the nurse reports the change promptly and clearly, using SBAR (see Chapter 6), and in Ontario an RPN consults the RN as the patient's needs change. Second, the team looks for and treats the causes (NICE, 2023). The nurse supports this by checking vital signs, oxygen saturation and blood glucose, looking for signs of infection, checking for urinary retention and constipation, assessing pain, reviewing recent medications with the pharmacist and prescriber, and asking about alcohol use.

Third, the nurse keeps the person safe while respecting their dignity. Calm, short explanations, reorientation, a quiet well-lit room, a familiar staff member and a family member at the bedside often do more than any drug. Physical and chemical restraints increase harm and are used only as a last resort (section 8.6). Fourth, the nurse continues all the prevention measures in Table 8.2, because they also help the person recover.

Fifth, medications are used carefully. Antipsychotics do not treat delirium itself (Wilson et al., 2020) and are not given routinely. Guidelines reserve them for short-term use when a person is severely distressed or is a danger to themselves or others and calming approaches have not worked (Gage & Hogan, 2014; NICE, 2023). Antipsychotics carry added risk in people with Parkinson disease or dementia with Lewy bodies (Gage & Hogan, 2014; NICE, 2023). Benzodiazepines and other sedative-hypnotics are not a first choice for delirium or agitation in older adults; benzodiazepines are reserved for situations such as alcohol withdrawal, which is taught in Chapter 11 (Canadian Geriatrics Society, 2025).

Delirium is usually temporary (NICE, 2023), but symptoms can persist, and some people do not return to their earlier level of function (Gage & Hogan, 2014; Witlox et al., 2010). The nurse explains this to the patient and family, records the episode in the discharge summary, and makes sure the diagnosis reaches the person's primary care record (NICE, 2023).

CLINICAL JUDGMENT

A Quiet Change After Surgery

Names and details are fictional; this is a composite story.

Rosa Ferreira, 82, is on day 2 after surgical repair of a hip fracture. On admission she was chatty, lived alone and used a cane. Today the night nurse reports that she was "tired" and "slept well". At 1000 she is curled in bed with her breakfast untouched.

Recognize cues: Mrs. Ferreira opens her eyes to her name but drifts off mid-sentence. She cannot say the days of the week backwards. Her lower abdomen is full, and she has passed little urine since her catheter was removed yesterday. Her temperature is 37.4 °C. The medication record shows a sleep aid with strong anticholinergic effects given at 2300.

Analyze cues: The change is new, she cannot hold attention, and she is drowsier than normal.

Prioritize hypotheses: Hypoactive delirium is the leading concern. Possible causes include urinary retention, the sleep aid, pain, infection and dehydration.

Generate solutions: Complete the CAM, do a bladder scan, assess pain, check oxygen saturation and recent intake, and call her son about her usual self.

Take action: The CAM is positive. The bladder scan shows a large volume. The nurse reports to the surgical resident using SBAR and receives an order for catheterization and a review of her sleep medication. The nurse asks her son to visit with her glasses and hearing aid.

Evaluate outcomes: The nurse repeats the CAM each shift. Over the next two days, Mrs. Ferreira becomes more alert, walks to the bathroom with help and eats half her meals. The team continues prevention measures, tells her son that recovery may take a few weeks, and documents the episode for her discharge plan.

PATIENT EDUCATION

Families as Partners in Preventing Delirium

Families know the person best and are often the first to notice that something is wrong. The nurse invites them to help:

- Bring in glasses, hearing aids, dentures and walking aids, and make sure they are used (Figure 8.1).
- Bring a few familiar things from home, such as photos or a favourite blanket.
- Tell staff about the person's usual self: how they think and talk, their routines, what calms them and what upsets them.
- Talk about the day, the date and family news, and help the person stay in touch with home.
- Help with meals and drinks, and with walking when staff say it is safe.
- Tell the nurse at once about any sudden change, such as new confusion, unusual sleepiness, or the person "not being themselves".

Delirium is common and usually improves, but it can be frightening for the person and the family. The nurse explains what it is, that the person is not "going crazy", and that recovery may be slower than the illness that caused it.

Figure 8.1 Placing a hearing aid. Glasses and hearing aids that are in use, clean and working help prevent delirium and falls, and help the person take part in care.

8.3 Dementia and Depression in Hospital

Dementia

Dementia is an umbrella term for conditions in which memory and other thinking abilities decline gradually and steadily, enough to interfere with daily life (RNAO, 2016). Types include Alzheimer disease, vascular dementia, Lewy body dementia and frontotemporal dementia, and some people have mixed dementia, a combination of more than one type (Public Health Agency of Canada [PHAC], 2026). Symptoms differ from one person to the next.

Dementia is common in older patients. Canadian surveillance data from 2013–2014 (excluding Saskatchewan) found that 7.1% of people aged 65 and older were living with diagnosed dementia, rising to 24.6% of those aged 85 and older, and that about two-thirds of seniors with dementia were women (PHAC, 2017). The age-standardized rate of new diagnoses among people aged 65 and older fell from 1,507 to 1,411 per 100,000 between 2012–2013 and 2022–2023 (PHAC, 2026), but the number of people affected keeps growing as the population ages.

Hospital is a hard place for a person living with dementia. New noise, faces and routines, combined with acute illness, put them at high risk of delirium; when delirium develops on top of dementia, the change can be mistaken for "the dementia getting worse" (RNAO, 2016). Pain is often under-recognized because the person may not be able to describe it, and is assessed with tools such as the Pain Assessment in Advanced Dementia (PAINAD) scale (see Chapter 5, section 5.2). Decisions about treatment involve the person as far as they are able, along with their substitute decision-maker (see Chapter 1, section 1.5).

Person-Centred Care

Person-centred care means knowing the patient as a whole person, honouring their choices and sharing decisions with them and those close to them (RNAO, 2016). For a person living with dementia, it begins with learning who they are: their life history and work, the name they like to be called, their routines for waking, eating, bathing and sleeping, what comforts them, and what has upset them before. Many hospitals use a short "about me" form that family completes and that stays at the bedside.

Family and other care partners are part of the care team. They can explain what the person's words and actions mean, help at mealtimes and calm the person through frightening moments. Consistent staff, a predictable routine and plain communication help too. The nurse approaches from the front, introduces themselves each time, speaks in short sentences, gives one step at a time, allows time to answer and pays attention to tone and body language.

Responsive Behaviours

Responsive behaviours are the actions, words and gestures through which a person living with dementia, a mental health or substance use condition, or another neurological condition reacts to something that matters to them in their surroundings, whether personal, social or physical (Behavioural Supports Ontario [BSO], n.d.). Examples include calling out, pacing, repeating the same question, resisting care, grabbing, hitting and sexually expressive actions. The term is preferred by people living with these conditions because it puts the focus on what can be changed (BSO, n.d.). The behaviour is often a way of communicating an unmet need (BSO, n.d.), such as pain, fear, hunger, thirst, a full bladder, boredom, cold, a noisy room or an unfamiliar person doing intimate care.

The nurse treats a responsive behaviour as a clue. The first step is to look for a trigger: when did it start, what was happening, and is the person ill, in pain or developing delirium? Non-drug approaches come first (RNAO, 2016): meet the need, change the approach or the environment, try again later, involve someone familiar, and offer meaningful activity. Behavioural Supports Ontario teams and geriatric mental health services can advise on complex situations.

Antipsychotics have a small role and real risks. In 2005, Health Canada warned that older adults with dementia treated with atypical antipsychotics for behavioural symptoms had a higher risk of death than those given placebo (about 1.6 times higher), mostly from heart-related events and infections such as pneumonia (Health Canada, 2005). Antipsychotics also carry particular risks for people living with Lewy body dementia or Parkinson disease (Gage & Hogan, 2014; NICE, 2023). A 2025 Canadian guideline on behavioural and psychological symptoms of dementia includes recommendations on deprescribing (reducing or stopping) antipsychotics and other psychotropic drugs (Hatch et al., 2025). The nurse reports a new or worsening behaviour, documents what was tried, and asks for regular review of any antipsychotic.

Depression

Depression is a sustained disturbance of mood, often with loss of interest or pleasure, that changes how a person thinks, feels and functions (RNAO, 2016). It is not a normal part of aging. RNAO (2016) estimates that it affects about 15% of older adults living in the community and about 35% of those in long-term care facilities.

In older adults, depression does not always look like sadness. Signs that should prompt screening include many physical complaints, new anxiety, ongoing trouble sleeping, refusing to eat or neglecting personal care, and complaints about memory (Canadian Coalition for Seniors' Mental Health [CCSMH], 2021). Hypoactive delirium and early dementia can look similar, so the nurse checks for delirium first (Table 8.1). When depression is suspected, a validated screening tool is used, such as the Geriatric Depression Scale (GDS) or the Patient Health Questionnaire-9 (PHQ-9) (CCSMH, 2021; RNAO, 2016).

Depression in later life carries a risk of suicide. RNAO (2016) notes that depression can lead to death by suicide, particularly among men older than 85. When depression is suspected or present, the nurse asks directly and calmly about thoughts of self-harm or suicide (CCSMH, 2021); research has not found that asking about suicide increases suicidal thoughts (Dazzi et al., 2014). A patient who has thoughts of suicide needs immediate safety measures and urgent assessment (RNAO, 2016): the nurse stays with the person or arranges close observation, removes items that could cause harm, and reports at once to the RN, prescriber or mental health team according to policy. The 9-8-8: Suicide Crisis Helpline, launched across Canada on November 30, 2023, offers support by phone call or text 24 hours a day in English and French (PHAC, 2023). When there is an immediate risk to safety, the nurse calls 9-1-1 or the hospital's emergency team.

8.4 Falls and Functional Decline

Falls and loss of function are common, often preventable harms of a hospital stay for older adults.

Falls in Older Adults

The RNAO defines a **fall** as an unintentional event that ends with a person resting on the ground, the floor or another lower level, whether or not an injury occurs (RNAO, 2017). Several risk factors usually act together.

Canadian surveillance data show the size of the problem (PHAC, 2024):

- In 2017–2018, 5.8% of adults aged 65 and older living in households reported a serious injury from a fall in the previous 12 months.
- Outside Quebec, yearly fall-related hospitalizations of adults aged 65 and older rose 47% between 2008/2009 and 2019/2020, to 72,392. The rate stayed near 15 per 1,000, so the rise reflects a larger older population.
- Throughout this period, about 87% of injury-related hospitalizations in this age group were due to falls.
- In 2019, 5,581 Canadians aged 65 and older died from a fall.

A hip fracture was involved in 34% of fall-related hospitalizations of older adults in 2019/2020 (PHAC, 2024; Chapter 33). Older adults hospitalized after a fall stayed, on average, about 5 days longer in acute care and about 4 days longer as ALC patients than those hospitalized for any cause (PHAC, 2024; see section 8.1). A fall can also leave a lasting **concern about falling**, the term the World Falls Guidelines prefer to "fear of falling"; the person may then avoid activity, which weakens muscles and balance further (Montero-Odasso et al., 2022).

A fall in hospital may be the first sign of a new illness, such as pneumonia or a heart attack without chest pain (Montero-Odasso et al., 2022; Chapter 4), so the nurse treats it as a possible cue of deterioration.

Risk Factors

Risk factors are **intrinsic** (within the person) or **extrinsic** (in the environment, equipment or care). The main ones are linked to nursing actions in the table that follows (Table 8.3).

- **Intrinsic:** a previous fall; gait, balance and strength problems; delirium, dementia and depression; orthostatic hypotension and dizziness; impaired vision or hearing; urgency, incontinence and nocturia; foot problems and pain; neurological conditions such as Parkinson's disease; and medications, especially drugs that act on the brain or lower blood pressure (Montero-Odasso et al., 2022).
- **Extrinsic:** clutter, poor lighting and wet floors; unsafe footwear; intravenous (IV) lines, drains, catheters and oxygen tubing; a bed left high or unlocked; and a call bell or walking aid out of reach (RNAO, 2017).

The nurse screens every adult for fall risk at admission and after any significant change in health, using fall history, observed gait and mobility, and clinical judgment (RNAO, 2017). Neither RNAO (2017) nor the World Falls Guidelines support a risk score alone in hospitals; the latter recommend a multifactorial assessment of each hospitalized adult over 65 (Montero-Odasso et al., 2022). Where policy requires a tool, the nurse completes it and then acts on the person's specific risks.

Table 8.3 Fall risk factors and nursing actions (Montero-Odasso et al., 2022; RNAO, 2012, 2017)

Risk factor	Why it raises risk	Nursing actions
Previous fall	Signals risk factors that are still present; two or more falls in a year marks high risk	Ask about falls at admission; flag the risk in handover; request a multifactorial assessment
Gait, balance and strength problems	Among the most consistent predictors of future falls; bed rest weakens muscles quickly	Walk with the patient; keep the walking aid within reach; refer to physiotherapy
Delirium, dementia and depression	Impair attention, judgment and memory of safety teaching	Screen for delirium (section 8.2); orient; involve family; round often; avoid restraints

Risk factor	Why it raises risk	Nursing actions
Orthostatic hypotension	Blood pressure falls on standing, causing dizziness or fainting	Measure lying and standing blood pressure; teach slow position changes; report results
Impaired vision or hearing	Hazards and instructions are missed, especially at night	Keep glasses and hearing aids on and clean; use a night light; speak face to face
Urgency, incontinence and nocturia	Hurried, unsupervised trips to the bathroom, often in the dark	Offer scheduled toileting, including before sleep; keep the path clear; answer call bells quickly
Medications that act on the brain or lower blood pressure	Cause drowsiness, poor balance or a drop in blood pressure	Review the medication list with the prescriber and pharmacist; watch closely after new doses (section 8.5)
Unsafe footwear and environment	Slippery socks, clutter, wet floors and poor lighting cause trips and slips	Provide non-slip footwear; clear clutter; dry spills; light the room
Lines, tubes and bed set-up	Tubing tethers or trips the person; a high or unlocked bed increases the drop	Keep the bed low and locked; secure tubing; ask daily whether each line is still needed

Preventing Falls

Universal fall precautions are basic safety measures used for every patient, whatever the risk (RNAO, 2017). Examples include keeping the call bell, glasses, hearing aids, walking aid and drinks within reach; a low bed with the brakes locked; good lighting, including a night light; clear paths to the bathroom; non-slip footwear; and regular rounding to anticipate toileting, pain and repositioning needs (RNAO, 2012, 2017).

For patients at higher risk, the team adds **targeted interventions** matched to the person's risk factors (Montero-Odasso et al., 2022; RNAO, 2017):

- **Supervised, progressive mobility,** with referral to physiotherapy for strength and balance (Figure 8.2).
- **Scheduled toileting,** including before sleep.
- **Orthostatic vital signs: orthostatic hypotension** is a sustained fall in systolic blood pressure of at least 20 mm Hg, or in diastolic blood pressure of at least 10 mm Hg, within 3 minutes of standing (Fedorowski et al., 2017). Blood pressure is measured after at least 5 minutes lying down, then on standing as soon as possible and each minute up to 3 minutes, while asking about dizziness (Montero-Odasso et al., 2022). The nurse reports a positive result and teaches the patient to sit before standing.

Figure 8.2 A two-wheeled folding walker used to support balance and safe mobilization in hospital and at home. (credit: “Walker. frame” by High Plains Drifter/Wikimedia Commons, Public domain)

- **Medication review** with the prescriber to reduce or stop drugs linked to falls (RNAO, 2017; section 8.5).
- **Hip protectors,** which can be considered for people at risk of hip fracture after discussing benefits and drawbacks with them (RNAO, 2017) (Figure 8.3).
- **Low beds and alarms:** a low bed reduces injury if the person rolls out, and an alarm can alert staff when a person at risk gets up (RNAO, 2012), but only if someone responds quickly.
- **Delirium prevention** (section 8.2), which may also reduce falls (Montero-Odasso et al., 2022).

Figure 8.3 A hip protector: fitted underwear with a pad over the outer hip to cushion a fall. Hip protectors can be considered for people at risk of hip fracture after a discussion of benefits and drawbacks. (credit: "AHIP Protector" by Lkshlzr/Wikimedia Commons, CC BY-SA 3.0)

Restraints and sedating drugs are not fall prevention: RNAO (2017) cautions that they can cause harm, and the World Falls Guidelines recommend against physical restraints to prevent falls in care homes (Montero-Odasso et al., 2022). The nurse teaches the patient and family in their preferred language (RNAO, 2017).

After a Fall

The nurse stays, calls for help and assesses before anyone moves the patient (see the Clinical Safety box). RNAO (2017) recommends examining for injury, treating, monitoring for injuries that appear later, and completing a **post-fall assessment** with the team. Dizziness, palpitations or a brief loss of consciousness before the fall suggest a cause such as syncope that needs medical evaluation. An injury needing treatment, being unable to get up alone for an hour or more, or two or more falls in the past year marks high risk and calls for a multifactorial assessment (Montero-Odasso et al., 2022).

A patient taking an anticoagulant such as apixaban or warfarin (Chapter 19) who strikes the head can bleed inside the skull with few signs at first. In the United Kingdom, NICE head injury guideline advises considering a computed tomography (CT) scan of the head within 8 hours of the injury for such patients, even without other signs (NICE, 2023, as cited in Royal College of Emergency Medicine et al., 2023). Canadian hospitals set their own protocols, and imaging is ordered by the prescriber, so the nurse reports the fall and the anticoagulant to the prescriber at once, starts neurological observations as policy directs (Chapter 30), watches for headache, vomiting, drowsiness, confusion or weakness (Chapter 32), and escalates any decline (Chapter 6).

A **post-fall huddle** is a short team meeting soon after a fall to work out why it happened and change the plan; RNAO (2017) includes one in an example post-fall review. The nurse documents the facts objectively, completes an incident report and informs the family or substitute decision-maker (SDM). Reporting supports learning, not blame (Chapter 1, section 1.6).

CLINICAL SAFETY

After a Fall

- **Stay and call for help.** Do not lift the patient yet.
- **Assess airway, breathing, circulation and responsiveness.** If the patient is unresponsive or not breathing normally, call the emergency team.
- **Check for injury before moving.** Look for a head strike, bleeding, pain, deformity, or a shortened or outward-turned leg. Keep the patient still if a spinal injury is possible.
- **Assess neurological status.** Check level of consciousness, orientation, pupils and limb movement, and compare with baseline.
- **Ask about anticoagulants.** Check the medication record. An anticoagulated patient with a possible head strike needs urgent notification of the prescriber.
- **Notify.** Report to the RN or charge nurse and the prescriber using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6).
- **Lift safely.** Use a mechanical lift or enough trained staff, as policy directs.
- **Monitor.** Take vital signs and neurological observations as ordered or as policy directs, and watch for delayed signs.
- **Huddle.** Review what happened with the team and update the plan.
- **Document and report.** Record facts objectively and complete an incident report.

- **Inform the family or SDM.**

Preventing Functional Decline

Functional decline is a loss of the ability to carry out daily activities such as walking, bathing, dressing and toileting (hospital-associated disability is explained in section 8.1). Bed rest contributes to delirium, pressure injuries, pneumonia and muscle loss; estimates suggest an older person can lose 1% to 5% of muscle strength for each day without moving, yet older patients on medical units have been observed out of bed for a median of only about 4% of the day (Liu et al., 2018).

MOVE ON (Mobilization of Vulnerable Elders in Ontario) was a staff-focused program on general medical units in 14 Ontario academic hospitals. Teams assessed each older patient's mobility within 24 hours of admission, got patients moving at least three times daily, and progressed activity to match each person's ability. Afterward, more patients were out of bed each day and median length of stay was shorter (Liu et al., 2018).

The nurse also helps the patient sit in a chair for meals and walk to the bathroom; screens food and fluid intake and helps with eating; asks that a urinary catheter be removed once it is no longer needed (Chapter 7); groups night-time care to protect sleep (section 8.2); and relieves pressure on the skin (Chapter 35).

8.5 Medications in Older Adults

Why Older Adults Are More Sensitive

Older adults are at greater risk of adverse drug reactions, partly because they take more drugs and live with more chronic conditions, and partly because aging changes how the body handles drugs (CIHI, 2026b). On average, kidney filtration declines with age, so drugs cleared by the kidneys can build up; body fat rises while total body water falls, which changes how drugs spread through the body; and liver mass decreases (Hurria & Lichtman, 2008). Older adults also seem to be at higher risk of harm from sedative drugs (Pottie et al., 2018), and an adverse effect can look different in them: low blood glucose may show as dizziness, weakness or confusion rather than sweating and tremor (Farrell et al., 2017). The Going Deeper box explains these changes.

Polypharmacy

Polypharmacy is the use of many medications at the same time. A systematic review found that the most common definition was five or more medications daily, but most definitions were simple counts, and the authors called for a shift toward the idea of "appropriate polypharmacy" (Masnoon et al., 2017). The count is a prompt for review, not a verdict: a person with several chronic conditions may need many drugs, while a person taking two may be taking one that harms them.

In Canada, 1 in 4 seniors (people aged 65 and older) had prescriptions from 10 or more unique drug classes during 2021, based on public drug program claims (CIHI, 2022). The share rose with age, from 18.2% of seniors aged 65 to 74 to 36.4% of those aged 85 and older (CIHI, 2022; these figures exclude Quebec). In 2021, 42.5% of long-term care residents in the provinces reporting data were prescribed an antipsychotic (CIHI, 2022).

Each added drug raises the chance of side effects and interactions. A **prescribing cascade** starts when an adverse drug effect is mistaken for a new condition and treated with another drug, which can cause further effects (Rochon & Gurwitz, 1997). For example, a drug that causes ankle swelling may lead to a diuretic, and the diuretic may then cause urgency and a rushed trip to the bathroom at night. The nurse helps break cascades by asking, whenever a new symptom appears, whether a medication could be the cause, and by noting when the symptom began in relation to medication changes.

Potentially Inappropriate Medications

A **potentially inappropriate medication (PIM)** is a drug that, for most older adults, is ineffective, carries an unnecessarily high risk, or has a safer alternative (CIHI, 2026b). Two explicit tools help prescribers, pharmacists and nurses find PIMs during a medication review:

- The **American Geriatrics Society (AGS) Beers Criteria**, last updated in 2023, list medications to avoid or use with caution in adults aged 65 and older in most settings of care other than hospice and end-of-life care (American Geriatrics Society Beers

Criteria Update Expert Panel, 2023). The criteria fall into five groups: medications generally best avoided; medications to avoid with certain conditions; medications to use with caution; harmful drug combinations; and medications to avoid or adjust when kidney function is reduced (Health in Aging Foundation, 2023). CIHI uses the Beers list to track PIM prescribing to Canadian seniors (CIHI, 2026b).

- **STOPP/START** version 3, a European consensus, contains 133 STOPP criteria (Screening Tool of Older Persons' Prescriptions), which flag drugs that may be causing harm, and 57 START criteria (Screening Tool to Alert to Right Treatment), which flag helpful drugs that may have been missed (O'Mahony et al., 2023). The criteria are organized by body system, with added sections on fall risk, opioids and drugs with anticholinergic effects.

Both tools support clinical judgment rather than replace it (Health in Aging Foundation, 2023; O'Mahony et al., 2023). A listed drug may still be the right choice for a particular person, and patients should talk with their prescriber before stopping any medication. Drug groups that often need review are summarized below (Table 8.4). The nurse does not stop a drug independently; the nurse notices, reports, teaches and advocates.

Table 8.4 Medication groups that often need review in older adults (sources as cited in each row)

Medication group	Examples marketed in Canada	Main concern	Nursing actions
Benzodiazepine receptor agonists (benzodiazepines and Z-drugs)	zopiclone; benzodiazepines	Drowsiness, poor balance, falls, fractures, memory problems and motor vehicle crashes (Pottie et al., 2018)	Ask about sleep aids; offer non-drug sleep measures; report daytime drowsiness or falls; support a prescriber-led taper
First-generation antihistamines	diphenhydramine	Anticholinergic effects: confusion, constipation, urinary retention and falls (Braithwaite et al., 2023)	Ask about over-the-counter sleep and nausea products; question as-needed orders for sleep; watch for confusion and retention
Other drugs with strong anticholinergic effects	oxybutynin	Effects add up across drugs; linked with delirium, falls and cognitive decline (Braithwaite et al., 2023)	Count all anticholinergic drugs; assess bowels, bladder and cognition; report new confusion
Antipsychotics in people living with dementia	quetiapine	Limited benefit for responsive behaviours; higher risk of stroke and death (Bjerre et al., 2018; Canadian Geriatrics Society, 2025)	Look for causes of behaviour first (section 8.3); use non-drug approaches; monitor during a prescriber-led taper
Sulfonylureas and insulin	insulin; sulfonylureas, especially long-acting ones	Hypoglycemia, which may present as confusion, weakness or dizziness and can lead to falls (Farrell et al., 2017)	Check blood glucose as ordered; recognize atypical signs; report low values and poor intake (Chapter 22)
Nonsteroidal anti-inflammatory drugs (NSAIDs)	prescription and over-the-counter NSAIDs, including cyclooxygenase-2 (COX-2) inhibitors	Raised blood pressure, fluid retention and worsening kidney function in people with hypertension, heart failure or chronic kidney disease (Canadian Society of Nephrology, 2025)	Ask about over-the-counter use; monitor blood pressure, weight and kidney function; report swelling or reduced urine output
Opioids combined with other drugs that act on the brain	any opioid taken with a benzodiazepine receptor agonist or a gabapentinoid (a drug used for nerve pain)	Added sedation, impaired balance and falls (Montero-Odasso et al., 2022; Chapter 5)	Assess sedation and breathing; time mobility safely; report excessive drowsiness at once

MEDICATIONS

Deprescribing a Sleeping Pill

Benzodiazepine receptor agonists (BZRAs) include benzodiazepines and the "Z-drugs" such as zopiclone. In older adults, they are linked with drowsiness, poor balance, falls, fractures, memory and thinking problems, and motor vehicle crashes, and their benefit

for sleep may fade within about 4 weeks (Pottie et al., 2018). A Canadian guideline recommends offering a slow taper to adults aged 65 and older who take a BZRA for insomnia, however long they have used it (Pottie et al., 2018).

- **Tapering is planned by the prescriber** with the patient; sudden stopping is avoided. No schedule is given here.
- **Withdrawal effects** such as anxiety, irritability, sweating and poor sleep are usually mild and short-lived (Pottie et al., 2018).
- **Non-drug help:** good sleep habits during the taper, and cognitive behavioural therapy for insomnia (CBT-I) if insomnia persists (Pottie et al., 2018).
- **The nurse** asks about all sleep aids, including over-the-counter products; reduces noise, light and night-time interruptions; teaches; and monitors and reports withdrawal effects.

Deprescribing

Deprescribing is the planned and supervised process of lowering the dose of, or stopping, a drug that may be doing harm or is no longer helping (Pottie et al., 2018). It is part of good prescribing, not a withdrawal of care. Deprescribing.org, a Canadian initiative whose partners include the Bruyère Research Institute and the University of Toronto, publishes evidence-based guidelines and algorithms for several drug classes, including benzodiazepine receptor agonists, proton pump inhibitors, antipsychotics and antihyperglycemics (deprescribing.org, n.d.).

The process usually involves reviewing why each drug was started, weighing its current benefits and harms against the person's goals, agreeing on a plan with the patient and family, tapering slowly when needed, and monitoring for a return of symptoms or for withdrawal effects (Bjerre et al., 2018; Pottie et al., 2018). The prescriber leads any change. Decisions are shared, and people who understand the reason and know what to expect are more willing to take part (Pottie et al., 2018).

The nurse's role includes:

- taking an accurate medication history, including over-the-counter drugs, sleep aids and natural health products;
- noticing possible adverse effects, such as new confusion, drowsiness, dizziness, falls, constipation, urinary retention or low blood glucose, and reporting them;
- advocating for a medication review after a fall or an episode of delirium (RNAO, 2017);
- teaching the patient and family why a change is proposed and what to watch for;
- monitoring during a taper, for example for anxiety and poor sleep after a sedative is reduced, or for returning distress after an antipsychotic is reduced (Bjerre et al., 2018; Pottie et al., 2018). Nurses are among the professionals who can do this follow-up (Pottie et al., 2018).

Transitions and Medication Reconciliation

Moves between settings are high-risk times for medication errors. Medication reconciliation and the best possible medication history are explained in Chapter 1, section 1.6. For older adults, the Canadian Geriatrics Society (2025) advises against prescribing any medication without a medication reconciliation review. At discharge, the nurse teaches from the reconciled list, explains which drugs were started, changed or stopped and why, and checks understanding with teach-back. A pill organizer or a pharmacy blister pack can help a person who takes many drugs or has memory problems, and the community pharmacist can continue the review and support a taper. The nurse makes sure the updated list reaches the next care provider and the family.

GOING DEEPER

Pharmacokinetics in Older Adults and Anticholinergic Burden

Required for RN students; optional for PN students.

Kidney function. GFR falls on average with age, although not in everyone. Serum creatinine comes from muscle, so an older adult with low muscle mass produces less of it, and a creatinine within the reference range can hide reduced kidney function (Hurria & Lichtman, 2008). Prescribers use the estimated GFR (eGFR) and the person's clinical picture when choosing and adjusting drugs cleared by the kidneys (Chapter 27).

Body composition. With age, the proportion of body fat rises and total body water falls. Fat-soluble drugs therefore spread through a larger volume, while water-soluble drugs spread through a smaller one (Hurria & Lichtman, 2008). A larger volume of distribution lengthens a drug's half-life, so a fat-soluble sedative can keep acting long after the dose. Water-soluble drugs can reach higher blood levels from the same dose.

Albumin. Many drugs travel in the blood bound to albumin, and only the unbound drug acts. Low albumin, common in acute illness and poor nutrition, changes how albumin-bound drugs are distributed (Hurria & Lichtman, 2008); more drug may be left unbound, so effects may be stronger than expected.

Liver. Liver mass decreases with age, although how much this slows drug metabolism is debated (Hurria & Lichtman, 2008).

Anticholinergic burden is the cumulative effect of all the drugs a person takes that have anticholinergic properties (Braithwaite et al., 2023). Effects include dry mouth, blurred vision, constipation and urinary retention, and a higher burden is linked with delirium, falls and cognitive and physical decline. Several scales score the burden, such as the Anticholinergic Cognitive Burden scale (Boustani et al., 2008) and the Drug Burden Index, with no clear guidance about which one to choose (Braithwaite et al., 2023). Drugs with mild effects can add up, so the nurse looks at the whole list.

8.6 Restraints, Capacity and Transitions

Least Restraint

A **restraint** is anything that restricts a person's movement or behaviour in a way the person cannot easily undo (RNAO, 2012). Restraints take three forms:

- **Physical restraint:** an object placed on or close to the body that limits movement and that the person cannot easily remove, such as mitts, wrist ties, or a lap or seat belt (RNAO, 2012).
- **Environmental restraint:** keeping a person in a limited area, such as a locked room or unit (RNAO, 2012).
- **Chemical restraint:** a medication given to control behaviour (RNAO, 2012), rather than to treat a diagnosed condition.

By this definition, raised bed rails that stop a person from getting out of bed when they wish to are a restraint.

Restraints can increase agitation, raise the risk of falls and injury, cause skin breakdown and, in some cases, death (RNAO, 2012); they are also linked with aspiration pneumonia and can keep a person from food and fluids (Canadian Geriatrics Society, 2025). An Ontario coroner's committee reviewed the death of an older man with cognitive impairment who slid down a reclining chair and was asphyxiated by its thigh belt; there was no recorded order or reassessment (College of Physicians and Surgeons of Ontario [CPSO], 2023). The Canadian Geriatrics Society (2025) advises against using physical restraints for the behavioural symptoms of delirium and dementia.

Least restraint means trying alternatives first and, if a restraint cannot be avoided, using the least restrictive form for the shortest possible time (RNAO, 2012). In Ontario hospitals, restraint use is governed by the *Patient Restraints Minimization Act, 2001*. Each hospital must have restraint policies that encourage alternatives; restrained patients must be monitored and reassessed; staff must be trained; and records must be kept (CPSO, 2023). Only a physician or a person specified by regulation may write an order to restrain (*Patient Restraints Minimization Act, 2001*). A hospital may restrain a patient when needed to prevent serious bodily harm to the patient or others, or under a plan of treatment the patient or SDM has consented to (CPSO, 2023; *Patient Restraints Minimization Act, 2001*). The Act keeps a caregiver's common law duty to restrain when immediate action is needed to prevent serious bodily harm (*Patient Restraints Minimization Act, 2001*). Outside such an emergency, if the patient cannot consent, the SDM decides (RNAO, 2012).

Alternatives start with finding the reason for the behaviour: pain (assessed with the PAINAD scale where needed; Chapter 5, section 5.2), a full bladder, constipation, hunger, fear or delirium (sections 8.2 and 8.3). The nurse then tries walking with the person, regular toileting, music or other enjoyable activities, a low bed, an alarm, and a family member, volunteer or sitter at the bedside (Canadian Geriatrics Society, 2025; RNAO, 2012).

If a restraint is used, it follows the order and policy: the team monitors closely, offers food, fluids and toileting often, reassesses regularly, removes the restraint at the earliest safe time and documents each step (CPSO, 2023; RNAO, 2012).

SCOPE IN PRACTICE

Restraints and Least-Restraint Care

Authority, competence and context guide every nurse's role in restraint decisions (Chapter 1, section 1.3).

- **Authority:** In Ontario hospitals, the *Patient Restraints Minimization Act, 2001* and the hospital's policy set when a restraint may be used. Only a physician or a person specified by regulation may write the order. In an emergency, when immediate action is needed to prevent serious bodily harm, the Act preserves the caregiver's common law duty to act (*Patient Restraints Minimization Act, 2001*); the nurse then follows hospital policy for notification, orders and documentation.
- **Competence:** Both RNs and registered practical nurses (RPNs) apply least-restraint principles: they assess causes of behaviour, try alternatives, apply only devices they have been trained to use, monitor the person and document. Each nurse uses only the skills they have.
- **Context:** As a patient's needs change, for example new agitation, delirium or a fall, the RPN consults the RN, and every nurse who notices deterioration acts at once and escalates (Chapter 6). Assigning patients by stability is a common employer practice, not a College of Nurses of Ontario (CNO) rule.
- Employer policy and the province or territory matter. Outside Ontario, other laws and policies apply.

Capacity and Substitute Decision-Makers

Consent, capacity and SDMs under Ontario's *Health Care Consent Act, 1996* are explained in Chapter 1, section 1.5. Two points matter most for older adults. First, capacity concerns a specific decision at a specific time, so a diagnosis of dementia does not by itself mean a person cannot decide. Second, delirium can make capacity come and go: a person who could not decide yesterday may be capable today, so the team reassesses before each new decision. The nurse reports changes in cognition, helps the person take part as fully as possible (choosing their most alert time of day; using glasses, hearing aids and an interpreter), and involves the SDM when the person is incapable for a decision.

Elder Abuse

Elder abuse is any act, single or repeated, or failure to act appropriately that harms or distresses an older person within a relationship in which trust is expected (World Health Organization [WHO], 2024). It may be physical, sexual, psychological or emotional, or financial, or take the form of neglect or abandonment (WHO, 2024). Possible cues include injuries that do not fit the explanation given, fear or withdrawal around a particular person, poor hygiene or weight loss, missed medications, and sudden changes in finances.

When abuse is suspected, the nurse:

- makes sure the person is safe, calling 9-1-1 for immediate danger (Elder Abuse Prevention Ontario [EAPO], n.d.);
- speaks with the person privately, with a professional interpreter if needed (Chapter 1, section 1.7);
- documents objectively, in the person's own words (Chapter 1, section 1.5);
- follows hospital policy, which usually involves a social worker;
- respects a capable person's choices about next steps while offering information and support.

Ontario's reporting duties depend on where the person lives. Anyone, including regulated health professionals, who knows or suspects that a resident of a long-term care home or a retirement home has been or may be harmed by abuse, neglect, improper care or financial misuse must report it, even if the information would otherwise be confidential (Community Legal Education Ontario [CLEO], 2025). Reports about long-term care homes go to the Director at the ministry, under the *Fixing Long-Term Care Act, 2021*, and reports about retirement homes go to the Registrar of the Retirement Homes Regulatory Authority, under section 75 of the *Retirement Homes Act, 2010* (CLEO, 2025). Ontario law sets no reporting duty when the older adult lives elsewhere, such as in their own home, although job duties or a professional code may create one (CLEO, 2025). The Seniors Safety Line (1-866-299-1011) offers confidential support 24 hours a day, with interpreters in more than 200 languages (EAPO, n.d.).

Planning Safe Transitions

Discharge planning begins at admission. The nurse learns about the person's home, function before the illness, supports and goals, and shares the fall risk and plan with the next provider at each transition (RNAO, 2017). In Ontario, Ontario Health atHome, formed on June 28, 2024, from the 14 former Home and Community Care Support Services organizations, provides home and community care, care coordination, information and referrals, and placement services for long-term care homes (Government of Ontario, n.d.). A person who no longer needs acute care but cannot yet safely leave may be designated ALC (section 8.1).

Family and friends often carry much of the care, and caring can take a physical, emotional and financial toll, often called **caregiver strain**. The nurse asks caregivers how they are coping, includes them in teaching, and connects them with care coordinators and community supports. Before discharge, the nurse confirms follow-up appointments, the reconciled medication list (section 8.5), fall prevention at home, and the warning signs that should prompt a call to the primary care provider or 9-1-1.

PRACTICE STORY

"She Wanted to Go Home"

Names and details are fictional; this is a composite story.

Nurse: Joanne Mercier, RN. Years in practice: 9. Setting: medical unit, community hospital, Ontario.

At 0200, Mrs. Rosa Esposito, 87, was at the nursing station in her gown, clutching her purse. "I have to go home. My husband is waiting." Mrs. Esposito is a person living with dementia who was admitted two days earlier with pneumonia, and since yesterday she had new delirium. A colleague said, "Let's get an order for a belt before she falls."

I knew a restraint would not answer the question of why she was up. I walked with her down the hall, and she settled a little. When I offered the bathroom, she could not void, and she grimaced and held her lower abdomen. Her PAINAD score showed pain. A bladder scan, done under our policy, showed a large volume of urine. On her medication record I saw she had been given diphenhydramine at 2200 for sleep.

I called the physician on call using SBAR. She ordered an in-and-out catheter and discontinued the diphenhydramine. Then I phoned her daughter, who is her SDM. She told me her father died years ago, and that when her mother is anxious she talks about going home to him. She suggested Italian music and talking about her garden. Our policy allowed a sitter for the rest of the night. After the catheter, with music playing and the sitter beside her, Mrs. Esposito slept by 0400. In the morning, her daughter brought photos from home, and the team reviewed all her medications.

Looking back, her responsive behaviour was telling us something. Restraining her would have hidden urinary retention and pain caused partly by a drug we gave her, and it could have made her delirium worse.

Reflect: What cues pointed to a physical cause for Mrs. Esposito's behaviour? If an RPN had been caring for her, when should the RPN have consulted the RN, and who could order a restraint under the Act and hospital policy?

Chapter 8 Summary

Introduction

- Older adults make up a large share of medical-surgical patients, and almost one in five people in Canada is 65 or older.
- A hospital stay can bring delirium, falls and loss of function, even when the illness is treated successfully.

8.1 Aging, Frailty and Acute Care

- Aging reduces physiological reserve; changes in kidney function, thirst, temperature response, skin, senses and sleep affect acute care, but new confusion or loss of function is never "just old age".
- Frailty is reduced reserve and increased vulnerability to stressors; the Clinical Frailty Scale rates the person's usual state and requires clinical judgment.
- Hospital-associated disability is common in older patients; early, frequent mobility and self-care, fewer tethering devices and early discharge planning help prevent it.
- Patients designated alternate level of care, among whom older adults are the most common group, face deconditioning, infection, falls and delirium while they wait.
- Care is shaped by each person's history and identity, including Indigenous, 2SLGBTQI+, newcomer and rural or northern older adults.

8.2 Delirium

- Delirium is an acute, fluctuating disturbance of attention and awareness with an underlying cause; it is common, often missed and linked to death, institutional care and dementia.
- Hypoactive delirium is quiet and easily mistaken for tiredness or depression.

- Delirium arises when triggers such as infection, drugs, retention, constipation, pain, surgery or sleep loss act on a vulnerable person.
- The CAM and the 4AT are brief screens; a positive screen is reported promptly so the cause can be found.
- Multicomponent, non-drug prevention reduces delirium and falls.
- Care means finding and treating causes, keeping the person safe without restraints where possible, involving family, and avoiding routine antipsychotics and not using benzodiazepines as a first choice.

8.3 Dementia and Depression in Hospital

- Dementia is common in older patients and greatly raises the risk of delirium; pain is often under-recognized.
- Person-centred care starts with knowing the person and working with family as partners.
- Responsive behaviours often communicate unmet needs; non-drug approaches come first, and antipsychotics carry serious risks in dementia.
- Depression in older adults may appear as withdrawal, poor intake or physical complaints; the nurse asks directly about suicide, keeps the person safe and reports at once.

8.4 Falls and Functional Decline

- Falls cause about 87% of injury-related hospitalizations of Canadians aged 65 and older (outside Quebec), and about a third of fall-related hospitalizations involve a hip fracture.
- Falls usually result from several intrinsic and extrinsic risk factors; a risk score alone does not replace assessing the person's own risks.
- Universal fall precautions apply to every patient; targeted interventions such as scheduled toileting, orthostatic vital signs and medication review are added for those at higher risk. Restraints are not fall prevention.
- After a fall, the nurse assesses before moving the patient and escalates urgently when a patient taking an anticoagulant may have struck the head.
- Early, frequent mobility, as in MOVE ON, together with help to eat, drink, toilet and sleep, helps prevent functional decline.

8.5 Medications in Older Adults

- Changes in kidney function, body composition, the liver and the brain make older adults more sensitive to drugs and their adverse effects.
- One in four Canadian seniors was prescribed 10 or more drug classes in 2021; a new symptom may be a drug effect that starts a prescribing cascade.
- The Beers Criteria and STOPP/START help identify potentially inappropriate medications but support, rather than replace, clinical judgment.
- Deprescribing is planned with the patient and led by the prescriber; the nurse finds adverse effects, teaches, advocates for review and monitors during tapering.
- Safe transitions depend on medication reconciliation, teach-back and sharing the updated list with the community pharmacist and next providers.

8.6 Restraints, Capacity and Transitions

- Restraints may be physical, environmental or chemical; they cause harm, and least-restraint care tries alternatives first.
- In Ontario hospitals, the Patient Restraints Minimization Act, 2001 and hospital policy govern restraint use, orders, monitoring and documentation.
- Capacity is decision-specific and may fluctuate with delirium, so it is reassessed for each decision, and the SDM is involved when the person is incapable.
- Reporting suspected harm to residents of long-term care and retirement homes is mandatory in Ontario; for older adults in the community, the nurse ensures safety, documents and supports a capable person's choices.

- Discharge planning starts at admission and includes caregivers, Ontario Health atHome and clear teaching.

Key Terms (37)

4AT: a brief delirium screening test, usually taking less than two minutes, that looks at alertness, orientation, attention and acute change.

ageism: stereotyping, prejudice or discrimination against people because of their age.

alternate level of care (ALC): the designation for a patient who no longer needs hospital-level care but stays in hospital until a better-suited place, such as home care or long-term care, is available.

anticholinergic burden: The cumulative effect of all the drugs a person takes that have anticholinergic properties.

Beers Criteria: The American Geriatrics Society's list of medications to avoid or use with caution in adults aged 65 and older, last updated in 2023.

caregiver strain: The physical, emotional and financial toll that caring for a family member or friend can take on the caregiver.

chemical restraint: A medication given to control behaviour rather than to treat a diagnosed condition.

Clinical Frailty Scale (CFS): a Canadian, judgment-based nine-level scale that summarizes an older adult's usual fitness or frailty after a clinical encounter.

concern about falling: Worry about falling, the term the World Falls Guidelines prefer to "fear of falling"; it can lead a person to avoid activity and lose strength and balance.

Confusion Assessment Method (CAM): a widely used delirium screening approach that judges acute change or fluctuation, inattention, disorganized thinking and level of consciousness.

delirium: a sudden, fluctuating disturbance of attention and awareness, with changes in thinking or perception, caused by a medical condition, a drug or several factors together.

dementia: a group of conditions in which memory and other thinking abilities decline gradually and steadily enough to interfere with daily life.

deprescribing: The planned and supervised process of lowering the dose of, or stopping, a drug that may be doing harm or is no longer helping.

depression: a sustained disturbance of mood, often with loss of interest or pleasure, that changes how a person thinks, feels and functions.

elder abuse: Any act, single or repeated, or failure to act appropriately that harms or distresses an older person within a relationship in which trust is expected; it may be physical, sexual, psychological or emotional, or financial, or take the form of neglect or abandonment.

fall: An unintentional event that ends with a person resting on the ground, the floor or another lower level, whether or not an injury occurs.

frailty: a state in which accumulated decline across many body systems has used up physiological reserve, so that a minor stressor can cause a large, sometimes lasting change in health.

functional decline: Loss of the ability to carry out daily activities such as walking, bathing, dressing and toileting.

hospital-associated disability: a new loss of ability to perform a basic activity of daily living that develops during a hospital stay and is not caused directly by the illness itself.

hyperactive delirium: delirium in which the person is restless, agitated or fearful and may have hallucinations.

hypoactive delirium: delirium in which the person is quiet, drowsy, slow and withdrawn; it is often missed.

least restraint: Trying alternatives first and, if a restraint cannot be avoided, using the least restrictive form for the shortest possible time.

mixed delirium: delirium in which the person moves between hyperactive and hypoactive patterns.

multicomponent prevention: a bundle of non-drug measures, such as orientation, sensory aids, sleep, hydration, nutrition and mobility, used together to prevent delirium.

orthostatic hypotension: A sustained fall in systolic blood pressure of at least 20 mm Hg, or in diastolic blood pressure of at least 10 mm Hg, within 3 minutes of standing.

person-centred care: care built on knowing the patient as a whole person, honouring their choices and sharing decisions with them and those close to them.

physiological reserve: the spare capacity that body systems draw on when illness, surgery or other stress adds strain.

polypharmacy: The use of many medications at the same time, most often defined as five or more medications daily.

post-fall assessment: A structured assessment after a fall to find injuries, including delayed ones, and the causes of the fall.

post-fall huddle: A short team meeting held soon after a fall to work out why it happened and change the plan to prevent another.

potentially inappropriate medication (PIM): A drug that, for most older adults, is ineffective, carries an unnecessarily high risk or has a safer alternative.

prescribing cascade: A sequence in which an adverse drug effect is mistaken for a new condition and treated with another drug.

responsive behaviours: actions, words and gestures through which a person living with dementia or another neurological, mental health or substance use condition reacts to something that matters to them in their surroundings, often communicating an unmet need.

restraint: Anything that restricts a person's movement or behaviour in a way the person cannot easily undo, whether physical, environmental or chemical.

STOPP/START: European criteria that flag drugs that may harm older adults (STOPP) and helpful drugs that may have been missed (START); version 3 was published in 2023.

targeted interventions: Fall prevention measures matched to a person's own risk factors, such as scheduled toileting, supervised mobility or medication review.

universal fall precautions: Basic safety measures used for every patient regardless of fall risk, such as a low, locked bed, a call bell within reach, good lighting and non-slip footwear.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Joseph Tremblay (Questions 1–4): Joseph Tremblay, 79, was admitted 3 days ago with community-acquired pneumonia. His daughter says he lives with his wife, manages his own medications and does the crossword daily. This morning he is lying still with his eyes closed, has eaten nothing since yesterday and answers questions slowly. The night nurse charted "slept well, settled." The RPN caring for him is assessing him at 0900.

1. [CORE] Which finding most strongly suggests that Mr. Tremblay may have hypoactive delirium rather than ordinary tiredness?

a. He is lying still with his eyes closed at 0900.

b. He drifts off mid-answer and cannot keep track of the question.

c. He is 79 years old and was admitted with community-acquired pneumonia.

d. His daughter says he does the crossword every day.

Answer: b — Inattention, losing track partway through a question, is the core feature of delirium and separates it from tiredness (section 8.2). Lying still with eyes closed (a) can occur with ordinary fatigue and is not specific. Age and pneumonia (c) are risk factors, not signs that delirium is present. The crossword history (d) describes his baseline; it helps judge change but is not itself a sign of delirium.

2. [CORE] The RPN completes the Confusion Assessment Method (CAM). Which combination of findings would make the screen positive?

a. Disorganized thinking and an altered level of consciousness, with no change from baseline

b. Inattention and disorganized thinking, with steady behaviour all week

c. An acute change from baseline and an altered level of consciousness, with good attention

d. An acute change from baseline, inattention and drowsiness

Answer: d — A positive CAM requires both core features, an acute change or fluctuating course and inattention, plus either disorganized thinking or an altered level of consciousness; drowsiness is an altered level of consciousness (section 8.2). Option a lacks both core features. Option b lacks acute change or fluctuation. Option c lacks inattention, which is required.

3. [CORE] The CAM is positive. Which action should the RPN take first?

a. Report the change to the RN and prescriber promptly using SBAR, including vital signs and oxygen saturation.

b. Let Mr. Tremblay sleep until lunch and reassess him then.

c. Ask the prescriber for a sedative so he rests better tonight.

d. Apply bed rails on both sides so he cannot get up alone.

Answer: a — New delirium is an urgent change in condition; the nurse reports it at once with the data the team needs to search for causes such as hypoxia or worsening infection, and in Ontario the RPN consults the RN as the patient's needs change (section 8.2). Letting him sleep (b) delays finding a treatable cause. Sedatives (c) are not a first choice for delirium in older adults and do not address the cause. Full bed rails (d) are a form of restraint that increases harm and do not address the cause (sections 8.2 and 8.6).

4. [CORE] Mr. Tremblay's wife asks how she can help. Which response by the RPN is best?

a. "It would be best for the family to stay away until he is less confused, so that he can rest quietly without visitors."

b. "Please correct him firmly every time he says something that is not true, so that he learns where he is."

c. "Bring his glasses and hearing aid, sit and talk with him about home, and tell us if he seems different."

d. "His confusion is part of getting older, so there is not much that family members can do to help him."

Answer: c — Families help prevent and ease delirium by supporting vision and hearing, orientation and familiar company, and by reporting changes because they know the person's usual self (section 8.2). Keeping family away (a) removes a calming, orienting presence. Arguing or correcting firmly (b) increases distress; gentle reorientation works better. Delirium is not a normal part of aging (d) and often improves when its causes are treated.

5. [CORE] A nurse is planning care to prevent delirium for an 84-year-old patient admitted with a urinary tract infection. Which actions belong in a multicomponent prevention plan? Select all that apply.

a. Make sure the patient's glasses and hearing aids are in use.

b. Keep the patient on bed rest until the infection has cleared.

c. Offer fluids often and keep a drink within reach.

d. Group overnight care to protect sleep.

e. Request a sleeping pill at bedtime as a routine.

f. Walk the patient to the bathroom several times a day.

Answer: a, c, d, f — Multicomponent prevention supports vision and hearing (a), hydration (c), sleep (d) and mobility (f), as shown in Table 8.2 (section 8.2). Bed rest (b) causes deconditioning and raises delirium risk. Routine sleeping pills (e) are not recommended; sedative-hypnotics are not a first choice for older adults, and non-drug sleep measures are used instead.

6. [CORE] The nurse reads that a patient has a Clinical Frailty Scale (CFS) score in the frail range. How should the nurse interpret this?

a. The patient should not receive active treatment for the current illness.

b. The score describes how unwell the patient is today because of the acute illness.

c. The patient has less reserve, so a minor stressor may cause a large change in health.

d. The score is a measure of the patient's age and will rise each year.

Answer: c — Frailty means reduced physiological reserve and greater vulnerability to stressors, which helps the team anticipate risk and plan goal-directed care (section 8.1). The CFS is never by itself a reason to withhold treatment (a). It rates the person's usual state before the current illness, not today's acute status (b). Frailty is related to age but is not the same as age (d).

7. [CORE] A patient living with dementia starts calling out and pulling at her gown each afternoon. What should the nurse do first?

a. Look for an unmet need, such as pain, a full bladder, hunger or a noisy room.

b. Ask the prescriber for an antipsychotic to use when she calls out.

c. Move her to a room at the far end of the hall where she disturbs fewer people.

d. Document that she has problem behaviours in the afternoon.

Answer: a — Responsive behaviours are often a way of communicating an unmet need, so the first step is to look for a trigger and meet the need with non-drug approaches (section 8.3). Antipsychotics (b) carry serious risks in older adults with dementia and are not first-line. Isolating her (c) does not address the cause and may increase distress. "Problem behaviours" (d) is stigmatizing language; the nurse describes the behaviour and its context.

8. [CORE] A 76-year-old man recovering from a heart attack has been withdrawn and eating little. He tells the nurse, "My family would be better off without me." What is the nurse's best response?

a. "You have a lot to live for. Let's think about your grandchildren."

b. "Many people feel low after a heart attack; it will pass when you go home."

c. "I will mention this to your doctor at the next rounds."

d. "Are you having thoughts of ending your life?"

Answer: d — When depression or suicide risk is suspected, the nurse asks directly and calmly about suicidal thoughts, then ensures safety and reports at once (section 8.3). Reassurance (a) dismisses his feelings and does not assess risk. Telling him it will pass (b) minimizes a possible risk; depression in later life carries a risk of suicide, especially among older men. Waiting for rounds (c) delays urgent assessment and safety measures.

9. [CORE] In an Ontario hospital, an RPN is caring for a patient whose 4AT screen this afternoon suggests possible delirium. The patient was alert and oriented this morning. Which action reflects safe practice?

a. Continue the current care plan and recheck at the end of the shift.

b. Report promptly to the RN and prescriber and consult the RN about the patient's changing needs.

c. Wait for the patient's family to visit and confirm whether the confusion is new before reporting it.

d. Give the as-needed sedative that is already ordered, then document the patient's response in the chart.

Answer: b — Every nurse who notices a change acts at once and escalates; under CNO's Scope of Practice standard the RPN considers authority, competence and context, and consults the RN as the patient's needs change (Chapter 1, section 1.3; section 8.2). Waiting until the end of the shift (a) or for family (c) delays finding a treatable cause. A sedative (d) is not a first choice for delirium in older adults and does not address the cause; employer policy and province or territory also shape the RPN's role.

Case: Mr. Walter Bergeron (Questions 10–15): Mr. Walter Bergeron, 84, was admitted to a medical unit 3 days ago with pneumonia. He has atrial fibrillation treated with apixaban, hypertension, benign prostatic hyperplasia with nocturia, and mild cognitive impairment, and he walks with a walker. At 2200 he was alert and oriented to person, place and time; his blood pressure lying down was 132/76 mm Hg. At 0315 the nurse finds him sitting on the floor halfway between his bed and the bathroom, without his walker. He is wearing hospital socks, there is urine on the floor, the bed is in the high position, and the call bell is clipped to the far side of the bed. He says, "I had to go, and I hit my head on the table." There is a 3 cm red, swollen area on his right forehead. He knows where he is but not the day or time. Heart rate 96 and irregular (unchanged from his baseline), blood pressure 118/70 mm Hg, respiratory rate 20, SpO2 93% on 2 L/min oxygen by nasal prongs (unchanged since the evening), temperature 37.6 °C, capillary blood glucose 6.8 mmol/L. His pupils are equal and react to light, and he moves all four limbs. His left wrist is swollen and painful.

10. [CORE] Which findings require immediate follow-up? Select all that apply.

a. The swollen area on his forehead after striking his head

b. Taking apixaban

c. Irregular heart rate of 96

d. Disorientation to day and time

e. The swollen, painful left wrist

f. Capillary blood glucose of 6.8 mmol/L

g. SpO2 93% on 2 L/min oxygen

Answer: a, b, d, e — A head strike with visible swelling (a) in a patient taking an anticoagulant (b) raises concern for bleeding inside the skull, and disorientation that was not present at 2200 (d) is a new change in mental status (section 8.4). A swollen, painful wrist (e) may be a fracture. The irregular heart rate (c) is unchanged from his baseline atrial fibrillation. A glucose of 6.8 mmol/L (f) does not explain the fall or the confusion. His SpO2 (g) is unchanged since the evening on the same oxygen, so it is not the most urgent finding, although the nurse keeps monitoring it.

11. [CORE] The nurse analyzes the cues. Why does Mr. Bergeron's apixaban increase the nurse's concern?

a. It explains why he needed to get up to the bathroom at night.

b. It raises the risk of bleeding inside the skull, which may show few early signs.

c. It makes his new disorientation an expected effect of the drug, so no further neurological assessment is needed.

d. It means his wrist must be splinted before any other assessment.

Answer: b — An anticoagulant increases the risk of bleeding inside the skull after a head strike, and the person may look well at first (section 8.4). His need to get up at night (a) comes from nocturia related to his prostate, not from the anticoagulant. New disorientation after a head strike (c) must be treated as a possible head injury, not dismissed as a drug effect. The wrist needs care (d), but the anticoagulant matters mainly because of bleeding risk, and splinting does not come before assessing for a head injury.

12. [CORE] Which hypothesis should the nurse treat as the priority?

a. A fracture of the left wrist

b. Urinary urgency from benign prostatic hyperplasia

c. Worsening delirium caused by his pneumonia

d. Bleeding inside the skull after the head strike

Answer: d — A possible intracranial bleed (d) is life-threatening, and his cues (head strike, anticoagulant, new disorientation) fit it, so it is the priority even before imaging (section 8.4). A wrist fracture (a) needs care but is not life-threatening. Urgency (b) explains why he got up but is not the most dangerous problem. Delirium from pneumonia (c) is possible, but assuming it could delay recognizing a bleed.

13. [CORE] Which action should the nurse take first?

a. Help him back to bed with another staff member so that he is warm, comfortable and safe.

b. Give his ordered as-needed analgesic for the wrist pain.

c. Stay with him, call for help, and assess him for injuries before he is moved.

d. Complete the incident report now, while the details of the fall are still fresh.

Answer: c — The nurse stays, calls for help and assesses before anyone moves the patient, so that injuries such as a fracture or spinal injury are not made worse (section 8.4, Clinical Safety box). Lifting him at once (a) could worsen an unrecognized injury. Pain relief (b) is appropriate later but does not come before assessment. The incident report (d) is completed after the patient is safe and assessed.

14. [CORE] After the initial assessment, which actions are appropriate? Select all that apply.

a. Notify the prescriber at once using SBAR, reporting the head strike, the apixaban and his new disorientation.

b. Start neurological observations as ordered or as policy directs.

c. Decide independently to skip his next apixaban dose.

d. Move him back to bed with a mechanical lift or enough trained staff.

e. Prepare him for a CT scan of the head if it is ordered.

f. Apply wrist restraints so he cannot get up again tonight.

g. Inform his substitute decision-maker of the fall as policy directs.

Answer: a, b, d, e, g — Urgent notification (a), neurological observations (b), a safe lift (d), preparation for ordered imaging (e) and informing the SDM (g) are all part of post-fall care for an anticoagulated patient with a head strike (section 8.4). Changing anticoagulant therapy (c) is a prescriber decision; the nurse reports and follows orders. Restraints (f) increase agitation and injury and are not fall prevention (sections 8.4 and 8.6).

15. [CORE] Mr. Bergeron's CT scan shows no bleeding, and a toileting schedule, a low bed and non-slip footwear are added to his plan. At 0600, which finding shows that his condition requires immediate escalation?

a. He has vomited twice and is harder to rouse than at 0400.

b. His splinted wrist pain is 3 out of 10.

c. He asks when breakfast will arrive.

d. He knows where he is but not the time, as at 0315.

Answer: a — New vomiting and a falling level of consciousness (a) are signs of a serious change, such as bleeding inside the skull, and the nurse escalates at once even though the earlier scan was normal (section 8.4; Chapter 6). Mild, controlled wrist pain (b) and asking for breakfast (c) are reassuring. Disorientation that is unchanged from 0315 (d) still needs monitoring, but it is not a new decline.

16. [CORE] An 80-year-old patient admitted with heart failure walks independently and has no history of falls. Which action is a universal fall precaution for this patient?

a. Placing a bed alarm before the patient goes to sleep

b. Requesting a physiotherapy assessment of the patient's gait and balance

c. Keeping the bed low and locked with the call bell within reach

d. Fitting the patient with hip protectors

Answer: c — Universal fall precautions, such as a low, locked bed and a call bell within reach, apply to every patient whatever the risk level (section 8.4). A bed alarm (a), a physiotherapy gait assessment (b) and hip protectors (d) are targeted interventions for people with identified risk factors.

17. [CORE] A 77-year-old reports dizziness when getting up. After lying down for 5 minutes, the patient's blood pressure is 138/80 mm Hg. Which standing reading meets the definition of orthostatic hypotension?

a. 116/76 mm Hg at 1 minute

b. 130/74 mm Hg at 1 minute

c. 128/78 mm Hg at 3 minutes

d. 134/72 mm Hg at 3 minutes

Answer: a — Orthostatic hypotension is a sustained fall of at least 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes of standing (section 8.4). A reading of 116/76 mm Hg (a) is a 22 mm Hg systolic fall. Option b is a fall of 8/6 mm Hg, option c a fall of 10/2 mm Hg, and option d a fall of 4/8 mm Hg; none meets the threshold.

18. [CORE] An 88-year-old woman admitted with cellulitis walked with a cane at home. On day 2 she says she would rather rest in bed until she feels better. Which plan best prevents functional decline?

a. Bed rest until the antibiotic course is finished, with a bedpan at night so that she can save her energy

b. A urinary catheter so that she does not need to get up at night

c. Keeping her in bed until a physiotherapist has assessed her and cleared her for any activity out of bed

d. Assessing her mobility today, then helping her walk at least three times a day and sit up for meals

Answer: d — Early mobility assessment, walking at least three times a day and sitting up for meals reflect the MOVE ON approach and help prevent hospital-associated decline (section 8.4). Bed rest and a bedpan (a) speed loss of strength. A catheter (b) adds infection risk and further limits movement. Waiting for physiotherapy before any activity (c) delays mobility that nurses can safely support.

19. [CORE] A nursing student asks about the AGS Beers Criteria and the STOPP/START criteria. Which response is accurate?

a. "They list drugs that are banned for anyone over 65."

b. "They help identify medications that may cause harm, but a listed drug may still be right for a particular person."

c. "They are meant mainly for people receiving hospice and end-of-life care."

d. "The nurse should hold any medication on the list until the prescriber has reviewed it and written a new order."

Answer: b — Both tools support clinical judgment during medication review, and a listed drug may still be appropriate for an individual (section 8.5). They do not ban drugs (a). The Beers Criteria exclude hospice and end-of-life care (c). The nurse does not hold medications independently because they appear on a list (d); the nurse reports concerns and advocates for review.

20. [CORE] An 82-year-old who has taken zopiclone every night for years says, "I've heard these pills cause falls. Should I just stop them tonight?" Which response by the nurse is best?

a. "Let's talk with your prescriber about a plan to reduce it slowly, because stopping suddenly can cause withdrawal effects."

b. "Yes, stopping tonight is safest because you are in hospital."

c. "Because you have taken it for so many years, your body has adjusted, and the fall risk no longer applies to you."

d. "You could switch to an over-the-counter sleep aid instead."

Answer: a — Deprescribing a BZRA is a slow, prescriber-led taper planned with the patient, and the nurse supports the patient in raising it (section 8.5). Stopping abruptly (b) can cause withdrawal effects. Long-term use does not remove the risk (c). Many over-the-counter sleep aids contain first-generation antihistamines with anticholinergic effects (d).

21. [CORE] A 79-year-old man received diphenhydramine at 2200 for sleep. At 0200 he is newly confused and restless, has not voided since 1800, and his lower abdomen is distended. Which action is most appropriate?

a. Give a second dose of diphenhydramine to help him settle.

b. Apply mitts so that he does not pull at his gown or his intravenous line.

c. Assess his bladder as policy directs and report the findings and the possible drug effect to the prescriber.

d. Document the behaviour, reorient him, and reassess him with the team at morning rounds.

Answer: c — New confusion with urinary retention after a first-generation antihistamine suggests anticholinergic effects; the nurse assesses the bladder and escalates (section 8.5). A second dose (a) would worsen the problem. Mitts (b) are a restraint and do not address the cause. Waiting until morning (d) delays treatment of retention and delirium.

22. [CORE] An 86-year-old woman is going home after a fall. In hospital, her zopiclone was stopped, her diuretic was changed, and a new medication was started. Which nursing action best supports safe medication use at home?

a. Giving her the hospital medication administration record to keep

b. Telling her to resume all the medications she took before admission

c. Asking her daughter to sort the pills into an organizer once they are home

d. Reviewing the reconciled list with her using teach-back and sharing it with her pharmacist

Answer: d — Teaching from the reconciled list, checking understanding with teach-back and sharing the list with the community pharmacist support a safe transition (section 8.5; Chapter 1, section 1.6). A hospital administration record (a) is not a discharge medication list. Resuming all pre-admission drugs (b) would restart the stopped zopiclone and the old diuretic. Leaving sorting to the daughter (c) without teaching invites errors.

23. [CORE] An RPN is caring for an 84-year-old woman living with dementia whose condition had been stable. Tonight she is newly restless and trying to climb out of bed. A colleague suggests wrist restraints "to keep her safe." What should the RPN do?

a. Apply wrist restraints as suggested and tell the RN about them at the end of the shift.

b. Look for causes such as pain or a full bladder, try alternatives, and consult the RN about her change in condition.

c. Ask the pharmacy to send a sedative to settle her.

d. Raise all four bed rails so that she cannot climb out of bed and fall during the night.

Answer: b — A change in condition calls for assessment of causes, least-restraint alternatives and consultation with the RN (section 8.6, Scope in Practice box). A restraint needs an order from an authorized practitioner under the Act and policy, and waiting until the end of the shift (a) delays consultation. A sedative used to control behaviour (c) is a chemical restraint and needs a prescriber's assessment. Raised bed rails that keep her in bed (d) act as a restraint and do not address the cause of her restlessness.

24. [CORE] An 81-year-old man with delirium from pneumonia was found incapable of a treatment decision 2 days ago, and his daughter, his SDM, gave consent. Today he is alert and oriented, and a new treatment is proposed. Which statement is correct?

a. His daughter must make all his treatment decisions until discharge, because she has already consented once.

b. Once a person is found incapable, that finding lasts for the whole admission.

c. His capacity should be reassessed for the new decision, because capacity can return as delirium clears.

d. Capacity needs to be assessed only for decisions about surgery.

Answer: c — Capacity is decision-specific and can change as delirium clears, so it is reassessed for each new decision (section 8.6; Chapter 1, section 1.5). The SDM decides only when the person is incapable for that decision (a). Incapacity is not fixed for a whole admission (b). Capacity applies to every treatment decision, not only surgery (d).

25. [CORE] A capable 78-year-old woman who lives in her own home with her son tells the nurse that he has been taking money from her bank account and that she is afraid to go home. Which action is most appropriate?

a. Make sure she is safe, document her words objectively, follow hospital policy, and offer information such as the Seniors Safety Line.

b. Report her son to the police right away without discussing it with her, because Ontario law requires all suspected abuse of older adults to be reported.

c. Tell her son what she said so that the family can resolve it together.

d. Reassure her that money matters are a private family issue.

Answer: a — The nurse ensures safety, documents objectively, follows policy (often involving social work) and supports a capable person's choices with information and resources (section 8.6). Ontario law sets no reporting duty for abuse of an older adult living in the community (b); mandatory reporting applies to residents of long-term care and retirement homes, and a person in immediate danger needs 9-1-1. Telling the son (c) could put her at greater risk and breach her privacy. Dismissing financial abuse (d) leaves her unprotected.

26. [CORE] Which action best begins safe discharge planning for an older adult admitted after a fall at home?

a. Contacting Ontario Health atHome the day before discharge, once the date is confirmed

b. Asking only the patient about supports at home, to protect privacy

c. Recommending long-term care placement for every older adult admitted after a fall at home

d. Learning at admission about the person's home, function and caregivers, and sharing the fall risk and plan

Answer: d — Discharge planning starts at admission and includes the person's function, home and caregivers, with fall risk and the plan shared at each transition (section 8.6). Waiting until the day before discharge (a) leaves too little time to arrange services. With the patient's consent, caregivers are usually part of planning (b). Long-term care (c) is not the default after a fall; most people can return home with the right supports.

27. [RN] An 89-year-old woman who weighs 45 kg and has low muscle mass has a serum creatinine within the laboratory's reference range. Which interpretation is most accurate?

a. Her kidney function is normal, so drugs cleared by the kidneys need no review.

b. Low muscle mass can keep creatinine low, so her kidney function may be worse than it appears.

c. Creatinine rises with age, so her normal result means her kidneys are working better than expected.

d. In older adults, creatinine mainly reflects liver function rather than kidney function.

Answer: b — Creatinine comes from muscle, so low muscle mass can keep it within the reference range even when filtration is reduced; prescribers use the eGFR and the clinical picture (section 8.5, Going Deeper box). A normal creatinine does not rule out reduced function (a). Creatinine production falls, not rises, with lower muscle mass (c). Creatinine is a marker of kidney, not liver, function (d).

28. [RN] An 83-year-old receives a highly fat-soluble sedative. Compared with a younger adult, which change is most likely?

a. A smaller volume of distribution and a shorter effect

b. Faster clearance because liver mass increases with age

c. Dilution of the drug in a higher proportion of body water

d. A larger volume of distribution, so sedation may last longer

Answer: d — Body fat increases with age, so fat-soluble drugs spread through a larger volume, which lengthens the half-life and prolongs effects such as sedation (section 8.5, Going Deeper box). The volume of distribution of a fat-soluble drug increases rather than decreases (a). Liver mass decreases, not increases, with age (b). Total body water falls with age (c).

29. [RN] A 76-year-old takes oxybutynin daily and was given diphenhydramine for sleep. Which statement about anticholinergic burden is accurate?

a. The anticholinergic effects of the drugs add up, raising the risk of confusion, retention and falls.

b. Only drugs with strong anticholinergic effects count; drugs with mild effects can be ignored.

c. In older adults, anticholinergic effects are limited to dry mouth.

d. A score on an anticholinergic burden scale can replace a clinical assessment of the patient.

Answer: a — Anticholinergic burden is the cumulative effect of all drugs with anticholinergic properties, and a higher burden is linked with delirium, falls and decline (section 8.5, Going Deeper box). Drugs with mild effects add to the total (b). Effects go well beyond dry mouth (c). Scales support but do not replace assessment, and there is no clear guidance on which scale to use (d).

30. [RN] An 85-year-old with a serum albumin of 25 g/L after weeks of poor intake starts a drug that is highly bound to albumin. Which understanding should guide the nurse's monitoring?

a. Low albumin binds more of the drug, so its effect will be weaker and shorter.

b. Albumin levels do not affect how drugs act.

c. More of the drug may be unbound and active, so effects may be stronger than expected.

d. The kidneys will clear the drug faster, so its effect will be shorter.

Answer: c — Only unbound drug is active, and low albumin can leave more of a highly bound drug unbound, so the nurse watches for stronger effects and reports them (section 8.5, Going Deeper box). Less albumin means less binding, not more (a). Albumin does affect the distribution of bound drugs (b). Low albumin does not speed kidney clearance (d).

09 Cancer Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how cancer develops and spreads, and the language of staging and grading.
2. Describe the burden of cancer in Canada and its risk factors, including inequities in access to care.
3. Explain Canadian screening programs and the nurse's role in prevention and early detection.
4. Describe surgery, radiation and systemic therapies, their common adverse effects and nursing care.
5. Recognize and escalate oncologic emergencies, including febrile neutropenia, tumour lysis syndrome, hypercalcemia, spinal cord compression, superior vena cava syndrome and extravasation.
6. Handle hazardous drugs and body fluids safely.
7. Support patients and families through diagnosis, treatment and survivorship using person-centred, culturally safe care.
8. Distinguish RN and RPN roles in cancer care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4	Clinician; Scholar	Foundations of Practice
3, 7	Educator; Advocate	Foundations of Practice; Ethical Practice
5, 6, 8	Clinician; Leader; Professional	Foundations of Practice; Professional Practice

Introduction

Cancer touches almost every family in Canada. *Canadian Cancer Statistics 2025* estimates that about 2 in 5 people in Canada will develop cancer during their lifetime, and cancer is still the country's leading cause of death (Canadian Cancer Statistics Advisory Committee, 2025). Because cancer and its treatments can affect any body system, nurses meet people with cancer on every unit: a surgical patient recovering from a bowel resection, a medical patient admitted with pneumonia partway through chemotherapy, an older adult whose fall reveals a bone metastasis, or a person in the emergency department with a fever a week after treatment.

This chapter gives the nurse a foundation for that care. Section 9.1 explains how cancer develops, spreads and is diagnosed. Section 9.2 describes the burden of cancer in Canada, prevention, screening and inequities in care. Section 9.3 introduces the main treatments and their adverse effects. Sections 9.4 to 9.6 cover oncologic emergencies, the safe handling of hazardous drugs, and living with and beyond cancer. Related topics live elsewhere: hypercalcemia, electrolytes and vascular access devices (Chapter 3), infection prevention and sepsis (Chapter 4), pain (Chapter 5), palliative care (Chapter 10), and cancers of the lung (Chapter 13), blood (Chapter 20), colon and rectum (Chapter 25), and breast and reproductive organs (Chapter 29).

9.1 Cancer Biology

From Normal Cells to Cancer

Healthy tissues renew themselves under tight control. A cell divides only when it receives signals to do so, and it passes checkpoints in the cell cycle where damaged deoxyribonucleic acid (DNA) is detected and repaired. When the damage is too great to fix, the cell dies by **apoptosis**, an orderly, programmed cell death. Cancer arises when changes build up in the genes that govern these steps (National Cancer Institute [NCI], 2024).

Carcinogenesis is the multistep process by which a normal cell becomes a cancer cell. Two families of genes matter most. A **proto-oncogene** is a normal gene that promotes cell growth and division; when it is mutated or overactive it becomes an oncogene, which pushes the cell to divide without the usual signals. A **tumour suppressor gene** normally slows division, repairs DNA or triggers apoptosis; when both copies are lost or disabled, the cell loses its brakes. A single change is rarely enough; several usually accumulate over years (NCI, 2024), which helps explain why about 9 in 10 cancers in Canada are diagnosed in people over 50 (Canadian Cancer Society, 2025a).

Most of these changes are acquired during life, from random copying errors or from **carcinogens**, agents that damage DNA. Examples include chemicals in tobacco smoke, ultraviolet (UV) radiation from the sun and viruses such as human papillomavirus (HPV) (NCI, 2024).

A smaller share of cancers, up to about 10%, are linked to inherited genetic variants present in every cell from birth (NCI, 2024). The *BRCA1* and *BRCA2* genes, for example, make proteins that repair damaged DNA. A person who inherits a harmful variant in one copy still has a working second copy, but if that copy is lost in a breast or ovarian cell, the cell can no longer repair its DNA well, and cancer becomes far more likely (NCI, n.d.-a). **Lynch syndrome** is an inherited condition caused by a harmful variant in one of the DNA mismatch repair genes (or a deletion in the nearby *EPCAM* gene). It is passed on in an autosomal dominant pattern and raises the risk of colorectal, endometrial and several other cancers, although not everyone with a variant develops cancer (Idos & Valle, 2021). A family history of several relatives with related cancers, or cancer at a young age, is shared with the team so that genetic counselling can be considered.

Hallmarks of Cancer

Cancers differ by tissue and by person, yet they share a common set of acquired capabilities. Hanahan and Weinberg (2011) organized these into the "hallmarks of cancer" framework. In plain terms, cancer cells keep themselves growing without outside permission, ignore signals that would normally stop them, avoid self-destruction, keep dividing indefinitely, recruit a blood supply, and invade and spread. Genetic instability and chronic inflammation help cells gain these traits, and cancer cells also change how they use energy and learn to hide from the immune system (Hanahan & Weinberg, 2011). Hanahan (2022) proposed further dimensions, such as the ability of cancer cells to change identity and the role of microbes and aging cells around the tumour. The framework matters at the bedside because many newer treatments aim at one hallmark; immune checkpoint inhibitors, for example, undo the cancer's escape from the immune system (section 9.3).

Benign and Malignant Tumours; Metastasis

A **neoplasm**, or tumour, is an abnormal mass of tissue that grows beyond normal control. A **benign** tumour usually grows slowly, resembles its tissue of origin and stays where it started, often within a capsule, though it can still harm by pressing on nearby structures, as inside the skull. A **malignant** tumour (cancer) is made of cells that look and behave less like normal tissue, invade surrounding structures and can spread. Cancers are often named by the tissue they arise in: carcinomas from epithelial cells, sarcomas from connective tissue, and leukemias and lymphomas from blood-forming and lymphatic cells.

Metastasis is the spread of cancer from its primary site to a distant site, where it forms a new tumour. To metastasize, cells must break away, invade nearby tissue, enter lymph or blood vessels, survive in the circulation and then settle and grow in a new tissue (Hanahan & Weinberg, 2011). Cancer spreads by three main routes:

- **Lymphatic spread:** cells travel to regional lymph nodes first, such as the axillary nodes in breast cancer.
- **Blood-borne spread:** cells reach distant organs; the bones, liver, lungs and brain are common sites.
- **Seeding:** cells shed across a body cavity, such as the peritoneal cavity in ovarian cancer.

A metastatic tumour keeps the identity of the primary cancer. Breast cancer that has spread to bone is still breast cancer, and it is treated as breast cancer.

Grading, Staging and Diagnosis

Two terms describe a cancer for treatment planning. The **grade** describes how abnormal the cancer cells look under a microscope compared with normal cells, which reflects how well differentiated they are (Figure 9.1). Low-grade cancers look more like normal tissue and tend to grow slowly; high-grade cancers tend to grow faster. The **stage** describes how far the cancer extends in the body.

Most solid tumours are staged with the **TNM (tumour, node, metastasis)** system of the Union for International Cancer Control (UICC), now in its ninth edition (2025), and the matching system of the American Joint Committee on Cancer: T describes the size and local extent of the primary tumour, N whether regional lymph nodes are involved, and M whether there is distant metastasis (UICC, n.d.). The TNM findings are combined into stage groups, usually from 0 to IV. Stage strongly predicts outcome. Among people in Canada (outside Quebec) diagnosed from 2010 to 2017, five-year net survival for female breast cancer was 100% at stage I and 23% at stage IV (Statistics Canada, 2023).

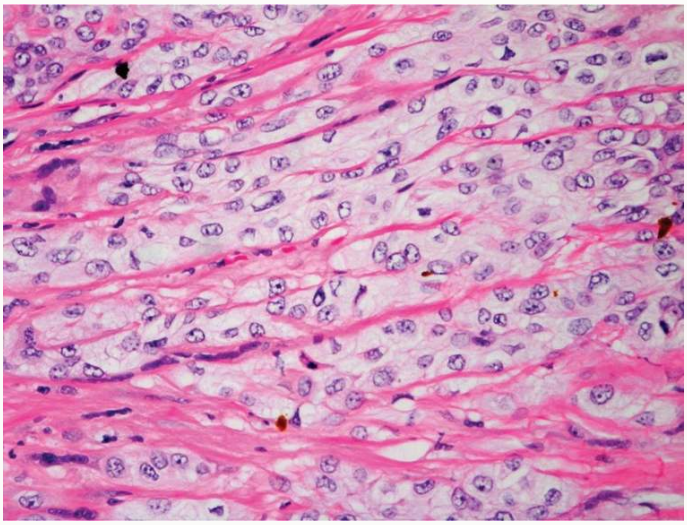

Figure 9.1 Cancer cells under the microscope (squamous cell carcinoma of the skin). In this poorly differentiated, high-grade example, the cells look very different from normal skin cells and grow into the surrounding tissue. (credit: "Micrograph of clear-cell squamous-cell carcinoma" by Valerie R. Yanofsky, Stephen E. Mercer and Robert G. Phelps/Wikimedia Commons, CC BY 4.0)

A **biopsy**, the removal of tissue for examination by a pathologist, confirms the diagnosis and gives the cancer type, grade and often biomarkers that guide treatment (NCI, n.d.-h). Imaging, such as computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET), shows the extent of disease. A **tumour marker** is a substance made by cancer cells, or by the body in response to cancer, that can be measured in blood, urine or tissue. Examples are prostate-specific antigen (PSA), carcinoembryonic antigen (CEA) in colorectal cancer and cancer antigen 125 (CA-125) in ovarian cancer. Tumour markers are most useful for following response to treatment and watching for recurrence. They have clear limits: benign conditions can raise them, not everyone with a cancer has a raised level, and most blood markers perform poorly for screening (NCI, n.d.-h).

Waiting for a confirmed diagnosis is often the hardest time for patients and families. The nurse explains what each test is for and when results are expected, names a contact person, asks how the person is coping and reports distress to the team.

9.2 Cancer in Canada: Risk, Prevention and Screening

The Burden of Cancer

Canadian Cancer Statistics 2025 estimates that 254,800 people in Canada would be diagnosed with cancer in 2025 and that 87,400 would die from it (Canadian Cancer Statistics Advisory Committee, 2025). Over a lifetime, about 2 in 5 people in Canada are expected to be diagnosed with cancer and about 1 in 4 to die of it, and males and females have an equal chance of a diagnosis. Cancer is still Canada's leading cause of death, and it is far ahead of any other cause of premature death. Lung, breast, prostate and colorectal cancers together were expected to make up almost half of the cancers diagnosed in 2025 (Canadian Cancer Statistics Advisory Committee, 2025). There is good news too. Five-year net survival, with all cancers combined, has risen from 55% in the early 1990s to an estimated 64%, and death rates have fallen for most cancer types (Canadian Cancer Society, 2025a; Canadian Cancer Statistics Advisory Committee, 2025).

CANADIAN CONTEXT

Cancer Statistics and Inequities

Canadian Cancer Statistics is produced by the Canadian Cancer Statistics Advisory Committee in partnership with the Public Health Agency of Canada, Statistics Canada and the Canadian Cancer Society. The data come from provincial and territorial cancer registries, which feed the Canadian Cancer Registry. A full report appears every second year; in between, a special report and projections for the current year are released. The 2026 projections were published as a peer-reviewed article in the *CMAJ* (Brenner et al., 2026).

National averages can hide large gaps. In a study of Registered First Nations people in Ontario from 1991 to 2010, all-cancer death rates were higher than among other people in Ontario (rate ratio 1.08 for males and 1.23 for females), and cervical cancer

> death rates among First Nations women aged 30 and older were nearly three times higher (Jamal et al., 2021). The study was carried out in close collaboration with the Chiefs of Ontario under the First Nations principles of OCAP® (Jamal et al., 2021). These gaps reflect colonial policies, distance from services and unequal access to screening and care, not biology. Progress is also uneven: after a long decline from 1984 to 2005, cervical cancer incidence has stopped falling, even as Canada works toward eliminating cervical cancer by 2040 (Canadian Cancer Society, 2025a).

Risk Factors and Prevention

Age is the strongest risk factor that cannot be changed, followed by inherited variants (section 9.1). Many other risk factors can be changed. The Canadian Population Attributable Risk of Cancer (ComPARe) study estimated that between 33% and 37% of cancers diagnosed in 2015 among adults aged 30 and older, up to about 70,000 cases, were attributable to modifiable risk factors (Poirier et al., 2019). The Canadian Cancer Society (n.d.) summarizes this as about 4 in 10 cancer cases that could be prevented through healthy living and protective policies.

- **Tobacco:** the leading preventable cause; tobacco is responsible for about 18% of the cancers diagnosed in Canada (Canadian Cancer Society, n.d.).
- **Physical inactivity and excess body weight:** next in line after tobacco among the factors ComPARe studied (Canadian Cancer Society, n.d.).
- **Alcohol:** a cause of at least seven kinds of cancer, including breast and colorectal cancer, and of nearly 7,000 cancer deaths in Canada each year; the 2023 *Canada's Guidance on Alcohol and Health* advises not drinking alcohol to reduce cancer risk and, for people who choose to drink, keeping to a low weekly limit (Canadian Partnership Against Cancer [CPAC], 2023).
- **UV radiation:** sun exposure is among the leading preventable causes (Canadian Cancer Society, n.d.), and melanoma incidence in females has risen about 2.1% a year since 1994 (Canadian Cancer Society, 2025a).
- **Radon:** a natural radioactive gas that can collect in homes. Health Canada (2026) calls radon the leading cause of lung cancer in people who do not smoke and estimates that it causes about 16% of lung cancers and more than 3,000 deaths from lung cancer in Canada every year. The Canadian guideline for indoor radon is 200 becquerels per cubic metre (Bq/m^3), and Health Canada recommends a long-term test of 3 months, ideally in fall or winter. Smoking adds to the danger: the lung cancer risk from radon is even higher in people who smoke.
- **Infections:** seven infections caused about 3.7% of cancers diagnosed among adults in Canada in 2015; HPV and *Helicobacter pylori* accounted for the most cases, followed by Epstein-Barr virus and hepatitis B and C (Volesky et al., 2019).

Many infection-related cancers can be prevented. Vaccination prevents HPV and hepatitis B infection, *H. pylori* can be treated with antibiotics, and hepatitis C can be treated (Volesky et al., 2019). High-risk HPV types that persist in the body can lead to cancers of the cervix, oropharynx, anus, penis, vagina and vulva. The National Advisory Committee on Immunization (NACI) strongly recommends HPV vaccination for everyone aged 9 to 26 and states that people aged 27 and older may be vaccinated after shared decision-making; the schedule depends on age and immune status (Public Health Agency of Canada [PHAC], 2024).

Every nursing contact is a chance for prevention. The nurse asks about tobacco use and offers cessation support, checks immunization status, and gives brief, non-judgmental information about alcohol, activity, sun protection and radon testing.

Screening

Screening means testing people who have no symptoms in order to find cancer, or changes that may become cancer, at an earlier and more treatable stage. Screening also has harms: false-positive results, anxiety, further tests and procedures, and **overdiagnosis**, the detection of cancers that would never have caused symptoms or death. Overdiagnosis leads to treatment that cannot help the person. For this reason, recommendations weigh benefits against harms, and many call for shared decision-making. Screening is for people without symptoms. A person with a breast lump, rectal bleeding or a persistent cough needs prompt diagnostic testing, not a screening test.

Two kinds of guidance apply in Canada. The Canadian Task Force on Preventive Health Care published national recommendations for primary care until it ended its mandate on March 31, 2026 (Canadian Task Force on Preventive Health Care, 2026). On June 10, 2026, the Public Health Agency of Canada announced a new National Advisory Committee on Preventive Health Services, which replaces the Task Force and will lead work on new preventive health guidelines, including for cancer screening (PHAC, 2026). The

Task Force's final guidelines remain its most recent published recommendations. For breast screening, that is the 2018 guideline (Klarenbach et al., 2018); the 2024 draft update was never finalized and has been archived (Canadian Task Force on Preventive Health Care, 2024). Provinces and territories run their own organized screening programs, and their rules often differ from the Task Force's. Ontario's programs serve as the worked example (Table 9.1).

In Ontario, several program changes are recent. Since October 8, 2024, people aged 40 to 49 can refer themselves to the Ontario Breast Screening Program, which offers publicly funded screening to people aged 40 to 74 who are women, Two-Spirit, trans or nonbinary (Ontario Health, 2024). On March 3, 2025, the Ontario Cervical Screening Program began using HPV testing in place of the Pap test, which allows most people to be screened every 5 years (Ontario Health, 2025; Ontario Ministry of Health, 2025). The Ontario Lung Screening Program uses low-dose CT for people with a long smoking history; five sites were added in March 2026, for a total of 15 (Ontario Health, 2026a). Program rules change often, so the nurse checks the current rules in the patient's own province or territory (Figures 9.2 and 9.3).

Table 9.1 Cancer screening in Canada at a glance (Bacchus et al., 2016; Canadian Task Force on Preventive Health Care, 2013, 2016; Klarenbach et al., 2018; Ontario Health, 2024, 2025, 2026; Ontario Health [Cancer Care Ontario], n.d.-a; Ontario Ministry of Health, 2025); check your province or territory

Cancer	Test	Who and how often (Canadian Task Force)	Ontario program (as of 2026)	Nursing role
Breast	Mammography	2018 guideline: ages 50 to 74, every 2 to 3 years; ages 40 to 49, not routinely, with the choice left to the person after discussing benefits and harms. A 2024 draft update was never finalized.	Ontario Breast Screening Program: ages 40 to 74, every 2 years; self-referral from age 40 since October 8, 2024; High Risk program for ages 30 to 69 with yearly mammogram and MRI	Explain benefits and harms; support decisions at ages 40 to 49; help people book; ask about family history that may mean higher risk
Cervical	HPV test (cells collected from the cervix by a clinician)	2013 guideline: ages 25 to 69, every 3 years; written before HPV-based screening	Ontario Cervical Screening Program: HPV testing since March 3, 2025; from age 25 for anyone with a cervix who has ever had sexual contact; most people every 5 years; most can end screening at 65 to 69 after a negative result	Include trans men and nonbinary people with a cervix; explain that HPV-vaccinated people still need screening; offer a trauma-informed approach
Colorectal	Fecal immunochemical test (FIT); colonoscopy for higher risk	2016 guideline: ages 50 to 74, a stool test (FIT or guaiac) every 2 years or a flexible sigmoidoscopy once every 10 years; colonoscopy not used as the first screening test	ColonCancerCheck: FIT every 2 years, ages 50 to 74, average risk; colonoscopy for people with a parent, sibling or child with colorectal cancer, beginning at age 50, or 10 years earlier than the age at which the relative was diagnosed, whichever comes first	Teach FIT collection; stress follow-up colonoscopy after an abnormal FIT; send people with symptoms for diagnosis, not screening
Lung	Low-dose CT	2016 guideline: ages 55 to 74 with at least 30 pack-years who currently smoke or stopped within the past 15 years, yearly for up to 3 years, only where expert care is available; no chest X-ray screening	Ontario Lung Screening Program: ages 55 to 80 who have smoked daily for at least 20 years (not necessarily in a row); eligibility set by a risk assessment (2% or higher over 6 years); clinician or self-referral; 15 sites	Take a smoking history; refer for cessation support; explain that the scan is part of a program with follow-up

Equity in Cancer Care

Cancer outcomes in Canada are shaped by where people live, their income, their language and how they are treated by the health system (Chapter 2). First Nations, Inuit and Métis have each described their own priorities for cancer care. The *Canadian Strategy for Cancer Control 2019–2029* includes three priorities identified by First Nations, Inuit and Métis: culturally appropriate care closer to home, peoples-specific and self-determined cancer care, and research and data systems governed by First Nations, Inuit or Métis (CPAC, 2019). Actions differ by people: for Inuit, for example, they include care closer to home and better medical travel policies. Gaps in outcomes reflect structural causes, including colonial policies, underfunded community services and racism in health care, not individual choices or biology. When First Nations data are used, the First Nations principles of OCAP® (ownership, control, access and possession) guide how they are collected and shared. The nurse builds on community strengths, such as Indigenous navigators where available and traditional healing practices the patient chooses, and practises cultural safety (Chapter 2).

Other groups face barriers too:

- **Rural, remote and northern residents:** radiation and specialized treatment are offered in a limited number of centres, so people may travel long distances or stay away from home for weeks. The *Canadian Strategy* calls for rural and remote communities to have the resources to serve their people (CPAC, 2019). The nurse asks about travel, lodging, cost and who will support the person.
- **Newcomers and people who speak neither English nor French:** they may not know that screening exists or is free. The nurse uses professional interpreters, not family members, and offers translated material.

- **2SLGBTQI+ people:** Ontario's screening programs explicitly include Two-Spirit, trans and nonbinary people (Ontario Health, 2024, 2025). The nurse asks which organs a person has rather than assuming from gender, uses the person's name and pronouns, and recognizes that past mistreatment may make an exam frightening.
- **People with disabilities:** mammography and cervical screening may need accessible equipment, positioning help, extra time or communication supports. The nurse plans these ahead so the person is not turned away.

9.3 Cancer Treatments

Surgery

Surgery remains a core cancer treatment, and it serves several purposes:

- **Diagnostic and staging:** a biopsy, or removal of lymph nodes to see whether cancer has spread.
- **Curative:** removal of the whole tumour with a margin of normal tissue.
- **Debulking:** removal of as much tumour as is safely possible when it cannot all be removed, so that other treatments work better.
- **Reconstructive:** restoring form or function, as in breast reconstruction.
- **Palliative:** relieving symptoms such as bowel obstruction, bleeding or pain when cure is not possible.
- **Risk-reducing:** removing an organ at very high risk, as some people with a harmful *BRCA* variant choose to do.

Surgery is often combined with other treatments. **Neoadjuvant** therapy is given before surgery to shrink a tumour; **adjuvant** therapy is given after surgery to destroy cancer cells that may remain. Perioperative nursing care is covered in Chapter 7.

Figure 9.4 A radiation therapist marks a custom mesh mask fitted to a patient model. For radiation to the head or neck, the mask holds the head in the same position for each treatment.

Radiation Therapy

Radiation therapy uses high-energy radiation to damage the DNA of cancer cells. Cells whose DNA damage cannot be repaired stop dividing or die. The effect is not immediate: damage builds over days to weeks of treatment, and cancer cells keep dying for weeks or months after treatment ends (NCI, n.d.-f). Treatment is usually given in many small daily sessions over several weeks.

External beam radiation is delivered by a machine, usually a linear accelerator, that aims radiation at the tumour from outside the body. The patient lies still for a few minutes and feels nothing. Because no radioactive source is placed in the body, a person treated with external beam radiation is not radioactive afterward and can safely be close to other people (NCI, n.d.-d). **Brachytherapy** places a sealed radioactive source, such as seeds, ribbons or capsules, inside or next to the tumour. While a source is in place, the patient gives off radiation. Some radiation is given as an unsealed liquid, by mouth or intravenously, and for a time the patient's body fluids are radioactive (NCI, n.d.-f). For sealed and unsealed sources, the nurse follows the hospital's radiation safety policy and the radiation safety officer's instructions, which apply the principles of limiting time near the source, keeping distance and using shielding (Figure 9.4).

Radiation affects normal tissue in the treatment area, so most effects are local:

- **Fatigue:** common, builds as treatment goes on and may take weeks or months to resolve (NCI, n.d.-f).
- **Skin reactions:** redness, dryness, itching and peeling in the treated area usually appear 1 to 4 weeks after treatment starts and are often worst 2 to 3 weeks after the last treatment (Alberta Health Services, 2026).
- **Site-specific effects:** mouth sores and dry mouth with head and neck treatment, painful swallowing with chest treatment, and diarrhea or bladder irritation with pelvic treatment.

Late effects can appear months or years later and depend on the area treated, so survivorship care plans include follow-up for them (section 9.6).

PATIENT EDUCATION

Preparing for Radiation Therapy

- **What to expect:** a planning visit comes first, then short daily treatments, usually on weekdays. The machine does not touch you, and after external beam treatment you are not radioactive.
- **Skin care in the treated area:** follow your treatment team's instructions. Wash daily with lukewarm water and a mild cleanser, and pat dry with a soft towel. Use the moisturizer your team suggests; unscented, water-based products are usual.
- **Avoid heat and friction:** skip hot tubs, saunas and steam rooms. Wear loose clothing made of soft, natural fabric.
- **Sun protection:** keep the treated skin out of the sun; cover it, and use sunscreen with a sun protection factor (SPF) of 30 or higher when your team says it is safe to apply.
- **Shaving and deodorant:** use an electric razor and avoid waxing. Ask before using deodorant on the treated area.
- **Fatigue:** plan rest, keep up light activity and accept help.
- **When to call:** open, weeping or very painful skin; fever, foul odour, pus or redness spreading beyond the treated area. Skin reactions may peak 2 to 3 weeks after treatment ends, so keep caring for the area.

(Alberta Health Services, 2026; NCI, n.d.-f, n.d.-h)

Chemotherapy

Chemotherapy uses cytotoxic drugs that kill cancer cells or slow their growth, along with other rapidly dividing cells (NCI, n.d.-c). Some drugs act mainly at one phase of the cell cycle; others damage cells at any phase. Drugs are often combined, and they are usually given in **cycles**: a period of treatment followed by a rest period that lets healthy cells recover (NCI, n.d.-c).

Because chemotherapy cannot fully tell cancer cells from healthy cells that divide quickly, its common adverse effects arise in those tissues. Damage to the bone marrow causes **myelosuppression**, a fall in white blood cells, red blood cells and platelets. Each count drops to its lowest point, the **nadir**, at a time after treatment that varies with the drug, and then recovers. A low neutrophil count leaves the person open to serious infection; fever may be the only sign, and febrile neutropenia is an emergency (section 9.4 and Chapter 4). Damage to the lining of the mouth and gut causes **mucositis**, nausea and diarrhea, and damage to hair follicles causes **alopecia** (hair loss) (NCI, n.d.-c). Fatigue is the most common effect of all (NCI, n.d.-c).

Chemotherapy can be given by mouth, intravenously, by injection into muscle or under the skin, into the spinal fluid (intrathecal), into the abdomen (intraperitoneal), into an artery or onto the skin (NCI, n.d.-c). Some intravenous drugs are **vesicants**, which can blister and destroy tissue if they leak out of the vein, and others are irritants; extravasation is covered in section 9.4 and safe handling in section 9.5. Drug classes include alkylating agents, antimetabolites, anthracyclines, taxanes and platinum agents. Regimens and doses are set by the oncology team and are beyond the scope of this text.

The common adverse effects of systemic therapy, and the related nursing care, are summarized below (Table 9.2).

Table 9.2 Common adverse effects of systemic therapy and nursing care (Cancer Care Ontario, 2012, 2018; Herrstedt, Clark-Snow, et al., 2024; Loprinzi et al., 2020; NCI, n.d.-c, n.d.-e; Ontario Health [Cancer Care Ontario], n.d.-b; Schneider et al., 2021)

Effect	Why it happens	What the nurse assesses	Nursing care and teaching

Effect	Why it happens	What the nurse assesses	Nursing care and teaching
Myelosuppression: neutropenia	Treatment damages rapidly dividing bone marrow cells	Temperature, signs of infection (which may be subtle), neutrophil count, timing since last treatment	Teach hand hygiene and infection avoidance; teach the person to check their temperature when unwell and to call the cancer centre or go to emergency at once for a fever at the level in their written instructions; report fever immediately (section 9.4)
Myelosuppression: anemia	Fewer red blood cells are produced	Fatigue, shortness of breath, dizziness, pallor (check conjunctivae and nail beds on darker skin), hemoglobin	Pace activity, prevent falls, report breathlessness or chest pain; transfusion as prescribed (Chapter 20)
Myelosuppression: thrombocytopenia	Fewer platelets are produced	Bruising, petechiae (easier to see in the mouth and conjunctivae on darker skin), bleeding gums, blood in urine or stool, platelet count	Use a soft toothbrush and an electric razor; avoid injury; report bleeding promptly
Nausea and vomiting	Treatment acts on the gut and on the brain's vomiting pathways; risk depends on the drugs	Nausea, vomiting, intake, hydration, weight, anticipatory nausea	Give preventive antiemetics on schedule as prescribed, chosen by the treatment's emetic risk; small frequent meals; report vomiting that prevents keeping fluids or medicines down
Mucositis	Treatment damages the fast-renewing lining of the mouth and gut	Mouth at each visit (redness, ulcers, white patches), pain, ability to eat and swallow	Brush gently with a soft brush after meals and at bedtime; rinse often with a bland salt and baking soda rinse; avoid alcohol-based mouthwash, tobacco, alcohol and spicy, acidic or hard foods; manage pain
Diarrhea or constipation	Gut lining damage; some targeted and immune therapies; antiemetics, opioids and inactivity cause constipation	Stool frequency and form, hydration, abdominal pain, blood in stool	Fluids; follow the team's bowel plan; report diarrhea that is new or severe, especially with immunotherapy
Fatigue	Effects of cancer and treatment, anemia, poor sleep, low mood	Severity, impact on daily life, possible treatable causes	Balance rest with regular light activity; plan priorities; screen for anemia, depression and poor sleep
Alopecia	Treatment damages hair follicles	Feelings about hair loss and body image	Prepare the person ahead; offer head coverings and resources; protect the scalp from sun and cold; hair usually regrows after treatment
Peripheral neuropathy	Some drugs, such as taxanes and platinum agents, damage peripheral nerves	Numbness, tingling or pain in hands and feet; balance; fine motor skills	Report early so the team can consider changing treatment; teach fall prevention and foot inspection; test water temperature by another means
Skin and nail changes	Targeted therapies and some chemotherapy affect skin and nail cells	Rash, dryness, itching, nail and cuticle changes, signs of infection	Gentle cleansing, moisturizers, sun protection; report spreading or painful rash
Immune-related adverse events	Immune checkpoint inhibitors let the immune system attack healthy organs	New diarrhea or abdominal pain, cough or breathlessness, yellowing of skin or eyes, rash, severe fatigue, headache, dizziness	Teach the person to report any new symptom early, even months after treatment ends; report the same day; treatment may be held and corticosteroids started

Targeted Therapy, Immunotherapy and Hormone Therapy

Targeted therapy acts on specific proteins that drive the growth and spread of cancer cells. Most people need biomarker testing of the tumour to show that it carries the target (NCI, n.d.-g). Small-molecule drugs, such as kinase inhibitors, enter cells and are usually taken by mouth. Monoclonal antibodies are laboratory-made proteins that attach to targets on cancer cells and are usually given

intravenously. Common adverse effects include diarrhea, liver problems, rash and dry skin, nail changes, high blood pressure and problems with clotting and wound healing (NCI, n.d.-g). Oral anticancer drugs are handled at home as hazardous drugs, and the nurse checks how the person stores them, takes them and disposes of them (section 9.5).

Immunotherapy helps the immune system fight cancer. **Immune checkpoint inhibitors** block the signals that cancer cells use to switch off T cells. Because they take the brakes off the immune system, they can cause an **immune-related adverse event**, an inflammatory reaction in a healthy organ. Common examples are colitis (diarrhea), pneumonitis (cough, breathlessness), hepatitis, endocrine disorders affecting the thyroid, pituitary or adrenal glands, and rash (Schneider et al., 2021). These reactions can begin at any time, can progress quickly and may appear months after treatment stops (Cancer Care Ontario, 2018). Depending on severity, the team may hold the drug and start corticosteroids (Schneider et al., 2021). The nurse teaches the person to report any new symptom early and to tell every health care provider, including in the emergency department, that they have received immunotherapy.

Hormone therapy slows or stops the growth of cancers that depend on hormones, mainly breast and prostate cancers. Some drugs block the body's production of a hormone; others block its action (NCI, n.d.-e). Examples are tamoxifen and aromatase inhibitors for breast cancer and androgen deprivation therapy for prostate cancer. Adverse effects include hot flashes, sexual changes, mood changes, fatigue and, with some drugs, weakened bones (NCI, n.d.-e).

Chimeric antigen receptor (CAR) T-cell therapy collects the patient's own T cells, engineers them in a laboratory to recognize cancer cells and infuses them back; it is used for certain blood cancers. Its serious effects include **cytokine release syndrome**, a surge of inflammatory signals causing high fever and a sharp drop in blood pressure that can be fatal, and neurologic toxicity with confusion or trouble speaking (NCI, n.d.-b). Hematopoietic stem cell transplant is described in Chapter 20. Both are delivered in specialized centres.

LIFESPAN CONSIDERATIONS

Older Adults With Cancer

Most cancers in Canada are diagnosed in older adults, yet age alone says little about how a person will tolerate treatment. The American Society of Clinical Oncology recommends a **geriatric assessment** for people aged 65 and older receiving chemotherapy, because it finds problems that routine oncology assessment misses (Mohile et al., 2018). At a minimum it covers function, other illnesses, falls, depression, cognition and nutrition. Tools such as the Cancer and Aging Research Group (CARG) and Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) scores estimate the risk of severe chemotherapy toxicity. The results should shape a plan that addresses both the cancer and other health problems, and they are shared with the person and their caregivers (Mohile et al., 2018).

- **Frailty:** frail older adults may need adjusted treatment and early supportive care (Chapter 8).
- **Polypharmacy:** the nurse reviews all medicines, including non-prescription and natural products, for interactions with oral anticancer drugs.
- **Cognition:** the nurse uses teach-back, gives written instructions and involves a support person with the patient's consent.
- **Caregivers:** older spouses who are caregivers may have health needs of their own; the nurse asks about them.

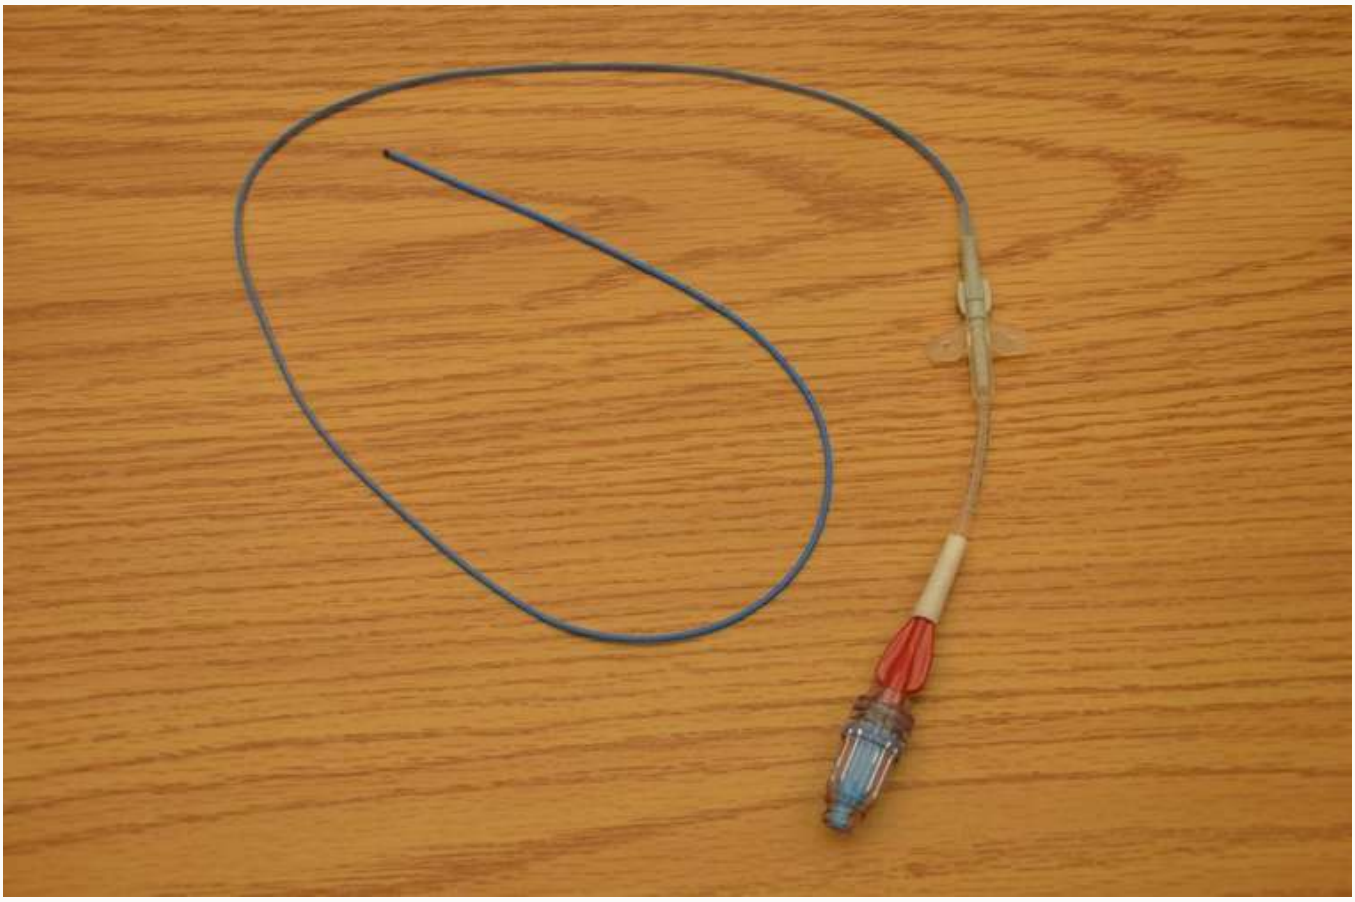

Figure 9.5 A single-lumen peripherally inserted central catheter (PICC) before insertion. (credit: “Peripherally inserted central catheter (PICC) with one lumen” by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

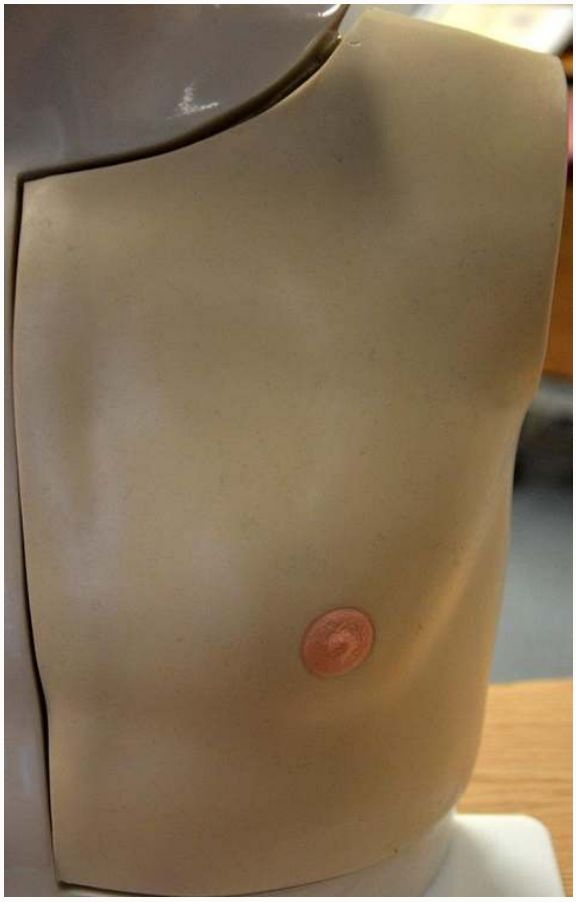

Figure 9.6 An implanted port under the skin of the upper chest, shown on a training manikin. (credit: "Chest with ICVC inserted" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Vascular Access for Treatment

Repeated intravenous treatment, blood sampling and the use of vesicants often call for a central venous access device. An **implanted port** is a small reservoir placed under the skin of the chest or arm, joined to a catheter that ends in a large central vein; it is reached through the skin with a special non-coring needle. A **peripherally inserted central catheter (PICC)** is inserted in an arm vein and threaded to a central vein (Figures 9.5 and 9.6). The care of these devices is taught in Chapter 3.

Before each use, the nurse assesses the site for redness, swelling, tenderness or drainage, looks for swelling of the arm, neck or face that could signal a clot, and confirms that the device flushes easily and gives a blood return. Fever in a person with a central line may mean a line infection and is reported at once. Accessing an implanted port and giving cancer drugs through any device require specific education and employer authorization. The nurse follows employer policy, which differs between settings and provinces or territories; in Ontario, provincial standards name the RN as the nurse who gives systemic cancer treatment (section 9.5).

9.4 Oncologic Emergencies

An **oncologic emergency** is a sudden, life-threatening problem caused by cancer or its treatment. Some come from the treatment itself, such as infection when white blood cells are low. Others come from the tumour pressing on a vital structure or releasing substances into the blood. Each one can worsen within hours, so the nurse must know the early cues, act at once and escalate. The main emergencies are compared in Table 9.3.

Febrile Neutropenia

Febrile neutropenia is fever in a person whose neutrophils are low, most often after chemotherapy. Neutrophils are the white blood cells that fight bacteria first, and myelosuppressive treatment lowers them most at the nadir (section 9.3). The **absolute neutrophil**

count (ANC) is the number of neutrophils per litre of blood. Definitions differ slightly from one guideline to another, so the nurse uses the hospital's own definition. In Ontario, people receiving cancer treatment are told to contact their team or go to the nearest emergency department if their oral temperature is above 38.3 °C at any time, or above 38.0 °C for at least 1 hour (Ontario Health [Cancer Care Ontario], n.d.-b). Other Canadian guidance is similar. Health PEI (2025), for example, defines fever as a single oral temperature of 38.3 °C, or a temperature of 38.0 °C or higher that lasts over 1 hour, and neutropenia as an ANC at or below 0.5×10^9/L, or below 1.0×10^9/L and expected to fall below 0.5×10^9/L within 48 hours. Alberta's guideline uses a neutrophil threshold of below 0.5×10^9/L (Alberta Health Services [AHS], 2014), and the American Society of Clinical Oncology (ASCO) and Infectious Diseases Society of America (IDSA) guideline uses nearly the same fever thresholds (Taplitz et al., 2018).

An Ontario guideline panel describes fever during systemic cancer treatment as common, potentially serious and in need of prompt assessment (Krzyzanowska et al., 2016). With few neutrophils, the body cannot mount its usual inflammatory response. Pus, redness, swelling and infiltrates on a chest X-ray may be faint or absent, so fever may be the only sign of a serious infection (see Chapter 4, section 4.2). A patient may also simply feel unwell, have chills or seem newly confused.

Febrile neutropenia is a medical emergency. The ASCO and IDSA guideline advises assessment within about 15 minutes of triage and the first dose of empirical antibiotics within 1 hour of triage (Taplitz et al., 2018). Health PEI (2025) likewise sets a target of antibiotics within 1 hour of presentation and warns against waiting for test results. The nurse:

- measures a full set of vital signs, checks level of consciousness and looks for a source, including the mouth, skin, perianal area and every line site;
- notifies the physician or nurse practitioner (NP) at once and uses the unit's febrile neutropenia order set if one exists;
- draws blood cultures before antibiotics without delaying them: one set from each lumen of a central line plus one peripheral set, or two peripheral sets (Health PEI, 2025), with urine and other cultures as ordered;
- starts the ordered broad-spectrum intravenous (IV) antibiotic and records the time.

Febrile neutropenia can progress to sepsis and septic shock. Falling blood pressure, rising heart and breathing rates, a high lactate level or new confusion call for the sepsis response and first-hour care in Chapter 4, section 4.6, and escalation in Chapter 6.

Prescribers estimate the risk of serious complications with a validated score such as the **Multinational Association for Supportive Care in Cancer (MASCC) risk index**; a few low-risk patients may be treated as outpatients in experienced centres (AHS, 2014; Taplitz et al., 2018). The nurse is not expected to calculate the score. Alberta's guideline advises against a rectal examination in neutropenic patients (AHS, 2014), so the nurse follows unit policy before using the rectal route for any purpose.

Teaching begins before the first treatment. Patients keep a working thermometer at home and know whom to call at any hour. They call at once for a temperature that meets the threshold their cancer centre gives, or for chills or feeling unwell, rather than waiting until morning (Taplitz et al., 2018).

CLINICAL JUDGMENT

A Fever Ten Days After Chemotherapy

Names and details are fictional; this is a composite story.

Mr. Hamid Rahimi, 66, was admitted to a medical unit with dehydration 10 days after his second cycle of chemotherapy for lymphoma.

- **Recognize cues:** At 0200 he says he feels cold and shaky. His temperature is 38.5 °C, heart rate 108 beats/min, blood pressure 112/68 mm Hg and respiratory rate 22 breaths/min. That afternoon his ANC was 0.3×10^9/L. He has a port in his chest. The nurse finds no redness at the port, no cough and no sore mouth, so there is no obvious source.
- **Analyze cues:** He is at his expected nadir. A fever above the threshold with an ANC this low meets the definition of febrile neutropenia.
- **Prioritize hypotheses:** Infection that could progress to sepsis comes first. A drug or transfusion reaction is less likely; he has received neither tonight.
- **Generate solutions:** Antibiotics within 1 hour; cultures first if they cause no delay; a search for the source; closer monitoring.
- **Take action:** The nurse calls the physician on call with an SBAR report (Chapter 6), starts the febrile neutropenia order set, draws blood cultures from both lumens of his port and a peripheral vein and hangs the ordered antibiotic at 0240.

- **Evaluate outcomes:** At 0330 his blood pressure is 108/66 mm Hg and he is alert. The nurse checks vital signs often, watches for signs of sepsis (Chapter 4, section 4.6) and hands over the time the antibiotic started. The next morning the nurse checks that the team has reviewed the culture results and that the next antibiotic dose is given on time. Mr. Rahimi is reminded to report chills at once.

Tumour Lysis Syndrome

Tumour lysis syndrome (TLS) is a group of metabolic problems that occurs when many cancer cells break open at once and spill their contents into the blood faster than the kidneys can clear them. It usually follows the start of treatment, but it can happen on its own in a fast-growing tumour (Enríquez Enríquez, 2024).

Risk is highest with a large tumour burden and with cancers that respond quickly to treatment, such as some acute leukemias and high-grade lymphomas. Other risk factors include a very high white blood cell count, a high lactate dehydrogenase level, bulky disease and kidney disease before treatment (Enríquez Enríquez, 2024).

The typical pattern is high potassium, high phosphate, high uric acid, low calcium and a rising creatinine level. The mechanism and the formal criteria are in the Going Deeper box. Many patients have no symptoms at first. Cues include nausea, muscle cramps or twitching, palpitations or an irregular pulse, falling urine output and new confusion or seizures.

Prevention is planned before treatment begins. The team orders generous IV hydration to keep urine flowing and a drug that lowers uric acid. **Allopurinol** blocks the enzyme that makes uric acid. **Rasburicase** is an enzyme that turns uric acid into a substance the kidneys excrete easily; it must not be given to people with glucose-6-phosphate dehydrogenase (G6PD) deficiency, because it can cause hemolysis (Enríquez Enríquez, 2024).

The nurse monitors intake and output closely, weighs the patient daily and reports falling urine output at once. The nurse also follows laboratory results, which may be ordered every 4 to 6 hours at first, and places the patient on a cardiac monitor as ordered. Potassium and calcium imbalances and their treatment are taught in Chapter 3, sections 3.5 and 3.6.

GOING DEEPER

Tumour Lysis Syndrome

Required for RN students; optional for PN students.

When cancer cells break apart, they release potassium, phosphate and nucleic acids into the blood. The body breaks the nucleic acids down to xanthine, which the enzyme xanthine oxidase converts to uric acid (Enríquez Enríquez, 2024).

Each product causes harm in a different way:

- **Potassium:** A high level makes heart cells unstable. Electrocardiogram (ECG) changes and dangerous dysrhythmias, including cardiac arrest, can follow.
- **Phosphate:** Phosphate binds calcium. Blood calcium falls, causing tingling, muscle cramps, tetany, seizures and dysrhythmias. Calcium phosphate crystals also form in tissues, including the kidneys.
- **Uric acid:** Uric acid and xanthine crystals, with calcium phosphate, block the kidney tubules. Reduced blood flow to the kidneys and inflammation add to the injury (Enríquez Enríquez, 2024).

The result can be **acute kidney injury**. As the kidneys fail, they clear even less potassium and phosphate, so the levels rise further.

The **Cairo–Bishop criteria** are widely used to define TLS (Cairo & Bishop, 2004). Laboratory TLS means two or more of these changes in the period that runs from 3 days before until 7 days after the start of treatment: high uric acid, high potassium, high phosphate or low calcium, each either beyond a set limit or changed by 25% from baseline. Clinical TLS means laboratory TLS plus kidney injury (creatinine at least 1.5 times the upper limit of normal), a dysrhythmia or sudden death, or a seizure (Cairo & Bishop, 2004; Enríquez Enríquez, 2024).

The RN reviews each laboratory result as it arrives, compares it with baseline and reports trends early. The RN also watches the cardiac monitor for changes linked to high potassium, such as peaked T waves (Chapter 3, section 3.5), and checks urine output hourly when ordered.

Hypercalcemia of Malignancy

Hypercalcemia of malignancy is the most common metabolic complication of cancer (El-Hajj Fuleihan et al., 2023). It occurs most often with breast, lung and kidney cancers and multiple myeloma. There are three main causes:

- many tumours release **parathyroid hormone–related peptide (PTHrP)**, which drives bone breakdown even with no bone metastases;
- cancer in the bone breaks down bone directly;
- some lymphomas make active vitamin D, which raises calcium absorption from the gut (El-Hajj Fuleihan et al., 2023).

Cues develop gradually and are easy to blame on cancer or its treatment. Mild hypercalcemia can cause fatigue, constipation and trouble thinking. Higher or fast-rising levels cause polyuria, thirst and kidney failure (El-Hajj Fuleihan et al., 2023). Polyuria causes dehydration, which raises the calcium further. The nurse reports these cues and checks the calcium result, corrected for albumin or as an ionized value (Chapter 3, section 3.6).

Treatment is led by the team. IV fluids come first. An IV bisphosphonate such as zoledronic acid, or denosumab, then slows bone breakdown (El-Hajj Fuleihan et al., 2023). The nurse gives fluids as ordered, monitors intake and output, lung sounds and weight for fluid overload, and keeps the confused patient safe from falls.

Malignant Spinal Cord Compression

Malignant spinal cord compression occurs when a tumour in the spine, usually a metastasis, presses on the spinal cord or the nerve roots below it. The pressure can cause weakness, loss of sensation and loss of bladder and bowel control.

Back pain is often the first cue. Pain that is severe and unrelenting, keeps getting worse, increases with coughing, sneezing or straining, or wakes the person at night suggests spinal metastases in anyone with current or past cancer (National Institute for Health and Care Excellence [NICE], 2023). Cues of cord compression include limb weakness, difficulty walking, numbness or tingling, pain that radiates along a nerve, and new bladder or bowel problems (NICE, 2023).

NICE (2023) treats new neurological cues in a person with cancer as an oncological emergency, with an MRI without delay and no later than 24 hours after the cues appear. The nurse reports these cues at once and does not wait for the next round. The team may give a corticosteroid such as dexamethasone to reduce swelling while planning radiation or surgery. The nurse:

- assesses strength, sensation, gait and bladder and bowel function, and compares them with baseline;
- keeps the spine aligned and limits movement as ordered until the team has assessed spinal stability;
- nurses the patient lying flat if ordered, since this lowers weight bearing on the spine (NICE, 2023);
- reports any new or worsening weakness or numbness at once;
- manages pain (Chapter 5) and prevents pressure injury (Chapter 35) and venous thromboembolism (VTE; Chapter 7).

Superior Vena Cava Syndrome

Superior vena cava syndrome occurs when a tumour or a clot narrows the superior vena cava, which carries blood from the head, neck and arms to the heart. Most cases are caused by cancer, especially lung cancer and lymphoma. The rest are mostly linked to central lines or pacemaker leads (Chow et al., 2024).

Blood backs up in the upper body. Cues include a feeling of fullness in the head, swelling of the face, neck and arms, and shortness of breath. The neck and chest-wall veins may stand out as collateral veins enlarge. These veins are easier to see on lighter skin; on darker skin, the nurse looks for swelling, a tight collar or rings, and asks about changes the patient has noticed. Symptoms often worsen when the patient lies flat or bends forward (Chow et al., 2024).

Severe swelling of the larynx, blockage of the central airway and swelling of the brain are the life-threatening complications (Chow et al., 2024). The nurse helps the patient sit up, gives oxygen as ordered and escalates any new noisy breathing, change in voice or decline in consciousness at once. The team confirms the diagnosis and may treat with stenting, radiation or systemic therapy (Chow et al., 2024).

Extravasation

Extravasation is the leakage of an IV drug out of the vein into the surrounding tissue. A **vesicant** is a drug that can cause blistering, ulcers and tissue death if it leaks. An **irritant** causes pain or inflammation at the site or along the vein, usually without lasting tissue damage. Some irritants behave like vesicants, and a 2025 guideline from the Oncology Nursing Society (ONS) and ASCO treats them the same way (Thomas et al., 2025).

Extravasation seems to occur more often with peripheral IV lines than with central venous access devices (Thomas et al., 2025). Early cues include pain, swelling and redness at the site; on darker skin, redness may be hard to see, so the nurse compares the site with the other arm and asks about pain, tightness and warmth. Later, blistering, ulcers and tissue death can develop (Thomas et al., 2025). The nurse checks the site before and often during every vesicant infusion and teaches the patient to report any discomfort at once. The steps that follow are in the Clinical Safety box.

CLINICAL SAFETY

Extravasation

Act at the first sign, following the organization's policy and the drug's protocol (Thomas et al., 2025):

- Stop the infusion at once. Leave the needle or catheter in place.
- Try to withdraw as much drug as possible with a syringe through the device, then disconnect the tubing.
- Notify the prescriber. Give an antidote only if one is ordered for that drug.
- Apply cold or warm compresses only as the drug's protocol directs. Cold suits some drugs and warmth others, so never guess.
- Elevate the limb.
- Mark the edges of the area and photograph the site if policy calls for it.
- Document the drug, the estimated amount, the time, the site's appearance, the actions taken and the patient's response, and complete an incident report.
- Teach the patient to keep the site clean and dry, avoid tight clothing and report increasing pain, blistering or fever. Arrange follow-up of the site over the following days and weeks.

Table 9.3 Oncologic emergencies: cues and first nursing actions (AHS, 2014; Chow et al., 2024; El-Hajj Fuleihan et al., 2023; Enríquez Enríquez, 2024; NICE, 2023; Thomas et al., 2025; Taplitz et al., 2018)

Emergency	Who is at risk	Cues	First nursing actions
Febrile neutropenia	People receiving myelosuppressive treatment, especially near the nadir	Temperature meeting the fever threshold; chills; feeling unwell; new confusion; few signs of infection	Assess within minutes; notify the prescriber; cultures, then IV antibiotics within 1 hour; watch for sepsis
Tumour lysis syndrome	Large, fast-growing, treatment-sensitive cancers such as some leukemias and lymphomas; kidney disease	Often none at first; nausea; cramps or twitching; palpitations; low urine output; seizures	Hydrate as ordered; give uric acid–lowering drugs; strict intake and output; cardiac monitoring; report lab changes
Hypercalcemia	Breast, lung and kidney cancers, myeloma, bone metastases	Fatigue; constipation; confusion; polyuria; thirst	Report cues; check calcium; IV fluids as ordered; watch for fluid overload; fall safety
Spinal cord compression	Cancers that spread to bone	New or worsening back pain; weakness; numbness; difficulty walking; bladder or bowel changes	Report at once; neurological checks; keep spine aligned; prepare for urgent MRI
Superior vena cava syndrome	Lung cancer, lymphoma, central lines	Swelling of face, neck and arms; head fullness; dyspnea; visible chest veins; worse lying flat	Sit patient up; oxygen as ordered; assess airway; escalate any breathing or consciousness change
Extravasation	Vesicant or irritant infusions, especially through peripheral lines	Pain, swelling, redness at the site; later blistering	Stop infusion; aspirate through the device; notify; follow the drug's protocol; document

9.5 Safe Handling of Hazardous Drugs

Nurses protect themselves, their co-workers and patients' families from exposure to hazardous drugs. Small, repeated exposures through the skin or by breathing in drug particles are the main concern.

What Makes a Drug Hazardous

A **hazardous drug** is a drug that can harm the people who handle it. Ontario's safe handling guideline uses the National Institute for Occupational Safety and Health (NIOSH) definition: a drug is hazardous if it has any one of six features (Kennedy et al., 2022):

- it damages genetic material (genotoxicity);
- it can cause cancer (carcinogenicity);
- it can cause birth defects (teratogenicity);
- it impairs fertility or harms reproduction;
- it damages organs at low doses;
- its structure and toxicity resemble drugs already known to be hazardous.

Exposure can happen at any step: unpacking deliveries, preparing and giving the drug, cleaning a spill, and handling waste, linen and body fluids (Kennedy et al., 2022). Many antineoplastic drugs meet this definition. The definition is not limited to cancer drugs, so the nurse checks the organization's hazardous drug list rather than assuming that only cancer drugs need precautions.

Protecting Staff

The Ontario Health (Cancer Care Ontario) guideline on safe handling of hazardous drugs sets out how staff should be protected at each step, from receiving the drug to disposing of waste (Kennedy et al., 2022). Its main points for nurses are:

- **Gloves:** Use powder-free gloves tested for use with chemotherapy, not vinyl. Wear two pairs to give IV, subcutaneous and liquid oral hazardous drugs; one pair is enough for solid tablets. Change gloves at once if they tear or are contaminated, and every 30 minutes unless the manufacturer states otherwise.
- **Gowns:** Wear a disposable, low-permeability gown with long sleeves, tight cuffs and a back closure. Remove gloves and gown without touching their outer surfaces, so the skin is not contaminated.
- **Eye and face protection:** Use face protection, such as a face shield, whenever splashing is possible. Ordinary eyeglasses, and even side-shielded safety glasses, do not give the eyes enough protection from splashes.
- **Closed-system drug-transfer devices:** A **closed-system drug-transfer device (CSTD)** is a device that connects drug containers and tubing so that drug cannot escape into the air or onto the skin. CSTDs reduce contamination but do not replace other precautions.
- **Labelling:** Hazardous drugs, their containers and their waste carry the "Cytotoxic" symbol or word, as legislation requires.
- **Spills:** Spill kits must be available wherever hazardous drugs are stored, carried, given or used, including the home. All staff who handle these drugs are trained to use them; a large spill calls for the organization's emergency code.
- **Waste:** Hazardous waste goes into labelled cytotoxic containers, never into regular biomedical waste.
- **Training:** Only trained staff carry, give and dispose of hazardous drugs, and training is repeated and documented each year.

Staff who are pregnant, breastfeeding or chestfeeding, or trying to conceive must be told about the reproductive risks. The guideline advises organizations to consider alternative duties for them (Kennedy et al., 2022). Occupational health and employer policy guide the process.

Body Fluids After Treatment

Many hazardous drugs and their by-products leave the body in urine, stool, vomit and other fluids. Ontario guidance asks staff handling these fluids, soiled linen or equipment from a patient who received a hazardous drug to wear two pairs of gloves and a gown, plus face protection if splashing is possible. These precautions apply for at least 48 hours after the drug is given, and longer

for some drugs, such as cyclophosphamide (Kennedy et al., 2022). Soiled incontinence products go into cytotoxic waste. Contaminated linen goes into a sealed bag and is washed separately.

Patients often receive treatment as outpatients, so families may handle body fluids at home. Organizations are expected to have a process for hazardous waste from the home that includes teaching patients and caregivers (Kennedy et al., 2022). The nurse reviews the cancer centre's written home instructions with the patient and family. These usually cover wearing gloves to clean up body fluids, washing soiled laundry separately and contacting the centre about a spill.

SCOPE IN PRACTICE

Who Gives Cancer Treatments

Scope rests on **authority, competence and context** (Chapter 1, section 1.3).

- **Authority:** Giving chemotherapy and immunotherapy needs an order and the employer's authorization. Employer policy and the province or territory decide which nurses may do so.
- **Competence:** Specialized education is required. The Canadian Association of Nurses in Oncology (CANO/ACIO) publishes standards and competencies for RNs who care for people receiving systemic therapy (Canadian Association of Nurses in Oncology, 2023). In Ontario, the Ontario Health (Cancer Care Ontario) competence standards state that "the RN is the appropriate nurse role to administer systemic treatment" (Ontario Health [Cancer Care Ontario], n.d.-c). The RN completes a recognized chemotherapy and immunotherapy course, shows competence on the provincial skills checklist and then completes a competency maintenance course every 24 months. A nurse who has not yet finished the course receives added training and supervised practice from the employer, and nurses use only the skills in which they have shown competence.
- **Context:** Practice settings differ. Rules and roles vary by province or territory and by organization, so the nurse follows the employer's policy.

Whatever the setting, RNs and RPNs both monitor patients during and after treatment, teach and handle hazardous drugs safely. The RPN consults the RN as the patient's needs change. Any nurse who notices deterioration, such as fever in a patient with neutropenia, acts and escalates at once.

9.6 Living With Cancer: Support and Survivorship

Cancer affects every part of a person's life, often for years. Nurses screen for symptoms and distress, support self-care during treatment and help people move into life after treatment.

Distress and Symptom Screening

Distress is an unpleasant emotional experience, with psychological, social, spiritual, practical or physical causes, that can make it harder to cope with cancer. It ranges from normal sadness and worry to disabling depression or anxiety (CPAC, 2012). CPAC describes distress as the sixth vital sign, to be monitored as routinely as temperature, pulse, blood pressure, breathing and pain (CPAC, 2012).

Distress screening is the routine use of a short standard tool to find patients who need more assessment or support. CPAC (2012) recommends screening every person with cancer at entry to care and at key points: diagnosis, the start and end of treatment, recurrence, advanced disease and other life transitions. Two tools form the core:

- The **Edmonton Symptom Assessment System–revised (ESAS-r)** asks the patient to rate nine common symptoms, such as pain, tiredness, nausea, anxiety and depression, on a scale from 0 (none) to 10 (worst possible) (Watanabe et al., 2011).
- The **Canadian Problem Checklist** asks about emotional, practical and physical concerns that a symptom scale misses (CPAC, 2012).

In Ontario, patients are encouraged to complete the ESAS-r through **Your Symptoms Matter** before each visit to the cancer centre, or when their team suggests (Ontario Health [Cancer Care Ontario], n.d.-d). A score is the start of a conversation, not a diagnosis. The nurse asks about high or rising scores, assesses further, agrees on a plan with the patient and refers to the right service, such as social work, psychosocial oncology, a dietitian or spiritual care (CPAC, 2012).

Nutrition, Fatigue and Exercise

Cancer-related fatigue is a distressing, lasting sense of physical, emotional or mental exhaustion that is out of proportion to recent activity and gets in the way of daily life (AHS, 2017). Rest does not fix it. The nurse screens for fatigue with the ESAS-r tiredness score and looks for causes that can be treated, such as anemia, pain, poor sleep, depression, infection, thyroid problems and medications (AHS, 2017).

Activity helps. Canadian guidance advises encouraging every patient to stay as active as they safely can during and after treatment. Walking suits most people, and a mildly fatigued patient can build up gradually toward 150 minutes of activity a week. More severe fatigue needs screening by a qualified exercise professional, or medical clearance, first (AHS, 2017). Energy conservation, pacing and occupational therapy also help.

Poor appetite, taste changes, mouth sores and nausea can all lead to weight loss. When a patient reports poor appetite with weight loss or reduced intake, the nurse uses a validated malnutrition screening tool and refers to a registered dietitian (AHS, 2017). Preventing nausea is covered in the Medications box.

MEDICATIONS

Preventing Chemotherapy-Induced Nausea and Vomiting

Nausea and vomiting are easier to prevent than to treat. Each treatment is classed by its emetic risk (how likely it is to cause vomiting), and the prescriber orders scheduled antiemetics to match (Herrstedt, Celio, et al., 2024). For treatments with the highest emetic risk, the Multinational Association for Supportive Care in Cancer (MASCC) and the European Society for Medical Oncology (ESMO) recommend four drugs together (Herrstedt, Celio, et al., 2024):

- a **5-HT3 receptor antagonist**, such as ondansetron;
- a **neurokinin-1 (NK1) receptor antagonist**, such as aprepitant;
- a **corticosteroid**, dexamethasone;
- **olanzapine**.

Nursing points:

- Give preventive antiemetics on schedule, before treatment and on the days that follow, not only when nausea starts.
- Ask about nausea, vomiting and intake each shift. Report breakthrough nausea promptly so the prescriber can add a drug from another class.
- Teach patients to take home antiemetics as prescribed and to call if they cannot keep fluids down.
- Check the product monograph for each drug's adverse effects and interactions.

Sexual Health and Fertility

Cancer and its treatment can affect fertility, sexual function and body image. ASCO advises that people with cancer be assessed and counselled about risks to their fertility at diagnosis and during survivorship (Su et al., 2025). **Fertility preservation** means storing sperm, eggs, embryos or reproductive tissue, or protecting reproductive organs, so that a person may have biological children later. The options should be discussed before cancer treatment starts, and anyone interested or unsure should be referred promptly to a reproductive specialist (Su et al., 2025). Sperm, egg and embryo freezing are well established. Some time to act is often available, so the nurse makes sure the conversation happens and the referral is made early.

Sexual changes are common and often go unspoken. Scars, hair loss, weight change, vaginal dryness, low desire and erection problems can all affect intimacy (Canadian Cancer Society [CCS], 2025b). The nurse asks about sexual health in a private, matter-of-fact way, uses inclusive language and offers referral to a counsellor or sex therapist. Patients follow the team's advice on contraception during treatment, because many cancer drugs can cause birth defects (Kennedy et al., 2022).

Survivorship

More people now live for years after a cancer diagnosis. Ontario Health's (2026) quality standard on cancer survivorship calls for:

- a regular, at least yearly, assessment of each survivor's needs;
- an individualized care plan that is kept up to date;

- coordinated transitions between the cancer team and primary care;
- psychosocial support for survivors and their care partners;
- education about follow-up and late effects;
- accessible, equitable care that is culturally and linguistically responsive.

A **survivorship care plan** is a written summary of the person's diagnosis and treatment plus a plan for follow-up. It lists scheduled visits and tests, signs of recurrence to report, possible late and long-term effects and advice on staying well (CCS, 2025b). Follow-up often moves from the oncologist to the family physician or NP over time. The plan helps that handover.

Late effects can appear months or years after treatment. Examples include fatigue, lymphedema, nerve damage, bone loss, memory changes and early menopause (CCS, 2025b). **Fear of recurrence** is common, especially in the first year and around follow-up visits. For most people it eases with time, but for some it disrupts sleep or daily life (CCS, 2025b). Most survivors who can work go back to their jobs, often gradually, and employers must make reasonable accommodations (CCS, 2025b).

The nurse links patients and caregivers with supports: patient navigators, including Indigenous patient navigators (Chapter 2); the Canadian Cancer Society's Cancer Information Helpline (1-888-939-3333) and online community; and local peer support groups (CCS, 2025b). Caregivers carry heavy loads and are screened and supported too (Ontario Health, 2026b).

> **PRACTICE STORY**
>
> **"Just a Little Fever"**
>
> *Names and details are fictional; this is a composite story.*
>
> Nurse: Tessa Morin, RPN. Years in practice: 6. Setting: medical unit, community hospital, Ontario.
>
> Mr. Halvorsen, 68, came back to our unit four days after his chemotherapy for lymphoma with diarrhea and dehydration. By day 9 he was eating better and talking about going home. At 1500 I brought his afternoon pills. He smiled and said, "I'm just a little warm, nothing to fuss over. My wife worries enough."
>
> His temperature was 38.4 °C. His heart rate was 104, up from 82 at noon. I looked at the morning bloodwork: neutrophils 0.4 × 10^9/L. Nine days after chemotherapy, a low count, and now a fever. I had learned that a fever might be the only sign of a serious infection in someone with almost no neutrophils.
>
> I went straight to Kwame, the RN on my team that day, instead of rechecking in an hour as I might for someone else. He agreed and paged the physician while I repeated the vitals and looked at Mr. Halvorsen's PICC site, mouth and skin. The physician ordered the febrile neutropenia order set. Kwame drew blood cultures from the PICC and a peripheral vein, and the first antibiotic was running at 1540, well within the hour.
>
> That evening Mr. Halvorsen's blood pressure dipped to 98/60. Because we had started early, the team was already watching. He needed IV fluids and several days of antibiotics, and his cultures grew a bacterium in his blood.
>
> I think about how easy it would have been to accept "just a little warm." He did not want to be a bother. Now I teach my patients that calling about a fever after chemotherapy is never a bother.
>
> Reflect: How did Tessa's knowledge of the chemotherapy nadir change what she did with an ordinary-sounding complaint? Using authority, competence and context, which actions were Tessa's own, and why was consulting the RN at once the right step?

Chapter 9 Summary

Introduction

- About 2 in 5 people in Canada are expected to develop cancer in their lifetime, and cancer is the leading cause of death in Canada.
- Nurses meet people with cancer on every unit; this chapter covers biology, prevention and screening, treatment, safe handling, emergencies and survivorship.

9.1 Cancer Biology

- Cancer develops as changes accumulate in proto-oncogenes, tumour suppressor genes and DNA repair genes; most changes are acquired, and up to about 10% of cancers are linked to inherited variants such as *BRCA1/2* or Lynch syndrome.
- The hallmarks framework describes the shared capabilities cancer cells acquire, several of which are targets of newer treatments.
- Malignant tumours invade and metastasize by lymphatic spread, blood-borne spread and seeding; a metastasis keeps the identity of the primary cancer.
- Grade describes how abnormal the cells look; stage, often TNM-based, describes extent and strongly predicts survival.
- Biopsy confirms the diagnosis; tumour markers mainly help monitor treatment and recurrence and are poor screening tools.

9.2 Cancer in Canada: Risk, Prevention and Screening

- *Canadian Cancer Statistics 2025* estimated 254,800 new cases and 87,400 deaths in 2025; lung, breast, prostate and colorectal cancers make up almost half of diagnoses.
- Between 33% and 37% of cancers in adults aged 30 and older in 2015 were attributable to modifiable risk factors, led by tobacco; radon, alcohol, UV radiation and infections are other targets for prevention.
- Screening finds cancer earlier but carries harms, including overdiagnosis; recommendations weigh both and support shared decisions.
- The Canadian Task Force ended its mandate on March 31, 2026, and a new National Advisory Committee on Preventive Health Services was announced on June 10, 2026; provincial programs, such as Ontario's, set the rules people actually use, so nurses check their own province or territory.
- Inequities in cancer outcomes for First Nations, Inuit and Métis, rural residents, newcomers, 2SLGBTQI+ people and people with disabilities have structural causes; nurses reduce barriers and practise cultural safety.

9.3 Cancer Treatments

- Surgery can diagnose, stage, cure, debulk, reconstruct, palliate or reduce risk, and it is often combined with neoadjuvant or adjuvant therapy.
- Radiation damages cancer cell DNA; external beam does not make the patient radioactive, while sealed and unsealed sources require radiation safety precautions.
- Chemotherapy harms fast-dividing normal cells, causing myelosuppression, mucositis, nausea, alopecia and fatigue; fever during neutropenia is an emergency.
- Targeted therapy, immune checkpoint inhibitors and hormone therapy have distinct adverse effects; immune-related adverse events can appear months after treatment and must be reported early.
- Implanted ports and PICCs are assessed before each use, and accessing them or giving cancer drugs requires education and employer authorization; in Ontario, provincial standards name the RN as the nurse who gives systemic cancer treatment.

9.4 Oncologic Emergencies

- Febrile neutropenia is fever with a very low neutrophil count. In Ontario, people on cancer treatment seek care for an oral temperature above 38.3 °C at any time or above 38.0 °C for at least 1 hour; definitions vary slightly, so follow the hospital's definition. Fever may be the only sign of infection.
- Assess at once, draw cultures without delay and give the first IV antibiotic within 1 hour of triage; watch for sepsis (Chapter 4, section 4.6).
- Tumour lysis syndrome causes high potassium, phosphate and uric acid, low calcium and kidney injury; prevention is hydration and uric acid–lowering drugs, with close monitoring of urine output, laboratory results and heart rhythm.
- Hypercalcemia causes fatigue, constipation, confusion, polyuria and thirst; IV fluids come first.
- New or worsening back pain in a person with cancer may be the first cue of spinal cord compression; neurological changes are an emergency needing MRI within 24 hours.

- Superior vena cava syndrome causes swelling of the face, neck and arms with dyspnea; sit the patient up and escalate. For extravasation, stop the infusion, aspirate through the device, notify and follow the drug's protocol.

9.5 Safe Handling of Hazardous Drugs

- Hazardous drugs can damage genes, cause cancer or birth defects, harm fertility or damage organs; they include many antineoplastic drugs and some others.
- For IV administration, wear two pairs of chemotherapy-tested gloves and a protective gown, with face protection if splashing is possible; use CSTDs, labelling, spill kits and cytotoxic waste as policy directs.
- Precautions with body fluids continue for at least 48 hours after a hazardous drug, longer for some drugs; teach families the cancer centre's home instructions.
- Giving cancer treatments requires specialized education and employer authorization; in Ontario, provincial competence standards name the RN as the appropriate nurse role, and every nurse monitors, teaches and escalates.

9.6 Living With Cancer: Support and Survivorship

- Distress is the sixth vital sign; screen with the ESAS-r and Canadian Problem Checklist, then talk, assess and refer.
- Cancer-related fatigue is not relieved by rest; look for treatable causes and encourage safe activity; screen nutrition and refer to a dietitian.
- Prevent nausea with scheduled antiemetics matched to emetic risk.
- Discuss fertility risks and preservation before treatment and refer early; ask about sexual health and body image.
- Survivorship care plans, transition to primary care, attention to late effects, fear of recurrence and return to work, and support for caregivers help people live well after treatment.

Key Terms (48)

absolute neutrophil count (ANC): The number of neutrophils per litre of blood, reported in × 10^9/L.

adjuvant therapy: treatment given after surgery to destroy cancer cells that may remain.

apoptosis: orderly, programmed cell death that removes damaged or unneeded cells.

brachytherapy: radiation therapy in which a sealed radioactive source is placed inside or next to a tumour.

Cairo–Bishop criteria: A widely used set of laboratory and clinical criteria that define tumour lysis syndrome.

Canadian Problem Checklist: A screening checklist of emotional, practical and physical concerns used with the ESAS-r.

cancer-related fatigue: A distressing, persistent sense of physical, emotional or mental exhaustion, out of proportion to activity and not relieved by rest.

carcinogen: an agent, such as a chemical, radiation or a virus, that can damage DNA and cause cancer.

carcinogenesis: the multistep process by which a normal cell becomes a cancer cell.

chemotherapy: treatment with cytotoxic drugs that kill cancer cells or slow their growth, along with other rapidly dividing cells.

closed-system drug-transfer device (CSTD): A device that connects drug containers and tubing so that hazardous drug cannot escape into the air or onto the skin.

cytokine release syndrome: a surge of inflammatory signals after some immune therapies, such as CAR T-cell therapy, causing high fever and low blood pressure.

distress: Emotional, social, spiritual, practical or physical suffering that makes coping with cancer harder; called the sixth vital sign.

distress screening: Routine use of a short standard tool to identify people with cancer who need further assessment or support.

Edmonton Symptom Assessment System–revised (ESAS-r): A tool in which patients rate nine common symptoms from 0 to 10.

external beam radiation: radiation delivered from a machine outside the body and aimed at the tumour; the patient does not become radioactive.

extravasation: Leakage of an IV drug out of the vein into the surrounding tissue.

fear of recurrence: Worry that cancer will return, common after treatment and sometimes severe enough to disrupt daily life.

febrile neutropenia: Fever in a person with a low neutrophil count, usually after chemotherapy; a medical emergency treated with IV antibiotics within 1 hour.

fertility preservation: Storing sperm, eggs, embryos or reproductive tissue, or protecting reproductive organs, before or after cancer treatment so that a person may have biological children later.

grade: a description of how abnormal cancer cells look under a microscope, reflecting how well differentiated they are.

hazardous drug: A drug that can harm people who handle it because it may damage genes, cause cancer or birth defects, harm fertility, damage organs at low doses, or resembles drugs with these effects.

hormone therapy: cancer treatment that blocks the production or action of hormones that some cancers need to grow.

hypercalcemia of malignancy: A high blood calcium level caused by cancer, often through parathyroid hormone–related peptide or bone metastases.

immune checkpoint inhibitor: a drug that blocks signals cancer cells use to switch off T cells, allowing the immune system to attack the cancer.

immune-related adverse event: an inflammatory reaction in a healthy organ caused by immune checkpoint inhibitor therapy, such as colitis, pneumonitis, hepatitis, endocrine disorders or rash.

irritant: A drug that causes pain or inflammation at the IV site or along the vein, usually without lasting tissue damage.

malignant spinal cord compression: Pressure on the spinal cord or nerve roots from cancer in the spine, causing pain and possible loss of strength, sensation and bladder or bowel control.

metastasis: spread of cancer from its primary site to a distant site, where it forms a new tumour.

mucositis: inflammation and ulceration of the lining of the mouth or gastrointestinal tract caused by cancer treatment.

Multinational Association for Supportive Care in Cancer (MASCC) risk index: A validated score prescribers use to estimate the risk of serious complications in febrile neutropenia.

myelosuppression: reduced production of blood cells by the bone marrow, causing neutropenia, anemia and thrombocytopenia.

nadir: the lowest point that a blood count reaches after a cancer treatment.

neoadjuvant therapy: treatment given before surgery to shrink a tumour.

oncologic emergency: A sudden, life-threatening problem caused by cancer or its treatment that needs immediate recognition and action.

overdiagnosis: detection through screening of a cancer that would never have caused symptoms or death.

parathyroid hormone–related peptide (PTHrP): A substance released by some tumours that increases bone breakdown and raises blood calcium.

proto-oncogene: a normal gene that promotes cell growth and division and can become a cancer-driving oncogene when mutated.

screening: testing people without symptoms to find cancer or precancerous changes early.

stage: a description of the size and extent of a cancer in the body, including spread to lymph nodes or distant sites.

superior vena cava syndrome: Swelling of the face, neck and arms with shortness of breath caused by narrowing of the superior vena cava by a tumour or clot.

survivorship care plan: A written summary of a person's cancer diagnosis and treatment with a plan for follow-up, signs to report, late effects and wellness.

targeted therapy: treatment that acts on specific proteins that drive the growth and spread of cancer cells.

TNM: an international staging system describing the primary tumour (T), regional lymph nodes (N) and distant metastasis (M).

tumour lysis syndrome (TLS): Metabolic imbalances (high potassium, phosphate and uric acid, low calcium) and possible kidney injury caused by the rapid breakdown of many cancer cells.

tumour marker: a substance made by cancer cells, or by the body in response to cancer, that can be measured to help monitor the disease.

tumour suppressor gene: a gene that normally slows cell division, repairs DNA or triggers apoptosis; loss of its function allows uncontrolled growth.

vesicant: a drug that can blister and destroy tissue if it leaks out of a vein.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Marisol Ferreira (Questions 1–4): Marisol Ferreira, 52, has stage III colon cancer and will start outpatient intravenous chemotherapy at a regional cancer centre next week. She lives with her husband and two teenagers and works as a bookkeeper. The nurse meets with her and her husband for pre-treatment teaching.

1. [CORE] Ms. Ferreira asks what she should do if she feels unwell at home between treatments. Which instruction is most appropriate?

a. "Take acetaminophen for any fever, rest at home, and call the clinic during office hours if the fever lasts more than 2 days."

b. "If you feel unwell, check your temperature, and for a fever at the level in your written instructions, call the cancer centre or go to emergency at once."

c. "Fever is expected for the first few days after each treatment, so you only need to call if you also develop a rash."

d. "Wait until your next scheduled blood test, because your neutrophil count will show whether a fever needs any treatment at all."

Answer: b — Neutropenia can make fever the only sign of a serious infection, so the person checks her temperature when unwell and seeks care at once for a fever at the threshold her cancer centre gives (section 9.3; febrile neutropenia in section 9.4). Treating the fever and waiting (a) masks the sign and delays urgent care. Fever is not an expected effect to tolerate at home (c). Waiting for a scheduled blood test (d) delays assessment and treatment of a possible emergency.

2. [CORE] The nurse teaches Ms. Ferreira how to prevent and manage mouth sores. Which plan reflects current guidance?

a. Rinse several times a day with a store-bought alcohol-based mouthwash so the mouth stays as free of germs as possible.

b. Stop brushing the teeth during treatment and use only mouthwash until treatment ends.

c. Rinse with club soda several times a day and choose tart fruits and juices to keep the mouth moist.

d. Brush gently with a soft toothbrush after meals and at bedtime, and rinse often with a bland salt and baking soda rinse.

Answer: d — Gentle brushing with a soft brush and frequent bland salt and baking soda rinses keep the mouth clean without irritating it (section 9.3). Alcohol-based mouthwash (a) dries and irritates tissue that is already fragile. Stopping brushing (b) allows plaque and infection to build up. Club soda is acidic, and tart or acidic foods irritate the mouth, so both are avoided (c).

3. [CORE] Ms. Ferreira is given prescriptions for antiemetics to take on a schedule for several days after treatment. She says, "I don't like taking pills, so I'll take them only if I feel sick." Which response is best?

a. "These medicines work best when taken on the schedule you were given, even if you feel well, because they are meant to prevent nausea."

b. "That is a good plan, since nausea after treatment is usually mild and does not need treatment."

c. "You can stop eating and drinking for a day after each treatment instead, so there is nothing to bring up."

d. "If you vomit, take a double dose of your antiemetic with your next meal."

Answer: a — Antiemetics are chosen according to the emetic risk of the treatment and are meant to prevent nausea, so they are taken as scheduled (section 9.3). Waiting until nausea starts (b) makes it harder to control. Withholding food and fluids (c) risks dehydration and does not prevent nausea. Changing doses on her own (d) is unsafe; she should call the cancer centre if she cannot keep fluids or medicines down.

4. [CORE] Ms. Ferreira's husband asks how to protect the family at home after each treatment. Which instruction is appropriate?

a. "Family members should avoid hugging or kissing her, and sleep in a separate room, until her course of treatment is finished."

b. "She should use disposable dishes and cutlery for the whole course of treatment."

c. "For about 48 hours after each treatment, she should close the toilet lid and flush twice, and anyone cleaning up her body fluids should wear disposable gloves."

d. "Her clothing and bedding should be thrown away if they touch her skin during the first week after each treatment."

Answer: c — Cancer drugs remain in body fluids for about 48 hours (longer for some drugs), so precautions focus on toilet use, gloves for cleaning up body fluids and washing soiled laundry separately (Easty et al., 2015; Waterloo Regional Health Network Cancer Centre, 2025; safe handling in section 9.5). Hugging and kissing are safe, and separate rooms are not needed (a). Disposable dishes are not needed (b). Linens are washed separately, not discarded (d).

5. [CORE] A nurse is teaching a community group about cancer prevention. Which of the following are modifiable risk factors for cancer? Select all that apply.

a. Smoking cigarettes

b. An inherited harmful *BRCA2* variant

c. Living in a home with a high radon level that has not been tested

d. Being 70 years of age

e. Physical inactivity

f. Drinking alcohol

Answer: a, c, e, f — Tobacco, physical inactivity and alcohol are modifiable risk factors linked to many cancers, and radon exposure can be found by testing and reduced (section 9.2). An inherited variant (b) cannot be changed, although risk can be managed through screening and risk-reducing options. Age (d) is the strongest risk factor, but it cannot be modified.

6. [CORE] A patient says, "The doctor told me my cancer is high grade, so that means it has spread everywhere." Which response by the nurse best explains the difference between grade and stage?

a. "Grade and stage mean the same thing; both describe how far the cancer has spread through the body."

b. "High grade means the cancer is in its earliest stage and has not spread."

c. "Grade tells how many lymph nodes are involved, and stage tells how fast the cells divide."

d. "Grade describes how abnormal the cells look under the microscope; stage describes the size of the tumour and whether it has spread."

Answer: d — Grade reflects how differentiated the cancer cells are, and stage, often expressed with TNM, describes the extent of the cancer in the body (section 9.1). They are separate measures (a). A high grade says nothing about early stage (b). Option c reverses and confuses the two: lymph node involvement is part of stage, and growth rate relates to grade.

7. [CORE] A patient receiving external beam radiation to the chest asks how to care for the skin in the treatment area. Which instruction is appropriate?

a. Apply a heating pad to the area each evening to relieve tightness.

b. Wash the area daily with lukewarm water and a mild cleanser, and pat it dry with a soft towel.

c. Scrub off the skin markings and any dry skin with a loofah each day.

d. Leave the area uncovered in direct sun to help the skin heal.

Answer: b — Gentle daily washing with lukewarm water and a mild cleanser, followed by patting dry, protects irritated skin (section 9.3). Heat (a) and friction (c) worsen radiation skin reactions, and the team's markings must be kept. Treated skin must be protected from the sun (d).

8. [CORE] A patient finished their last dose of an immune checkpoint inhibitor 3 months ago. They call the clinic to report five or six watery stools a day for 2 days and mild abdominal cramping. Which response by the nurse is most appropriate?

a. "Take an over-the-counter antidiarrheal, drink extra fluids, and call back if the diarrhea continues for another week."

b. "This cannot be related to your treatment, because it ended 3 months ago."

c. "This could be a reaction to your immunotherapy; I am letting the oncology team know now so you can be assessed today."

d. "Diarrhea is an expected effect of immunotherapy, so increase your fibre and fluids and it should settle on its own."

Answer: c — Immune-related colitis can begin months after the last dose and can progress quickly, so new diarrhea is reported and assessed the same day; the team may hold treatment and start corticosteroids (section 9.3). Self-treating and waiting (a, d) delays care for a potentially serious inflammatory reaction. Option b is incorrect because immune-related adverse events can appear long after treatment stops.

9. [CORE] On a medical unit in Ontario, the charge nurse asks a registered practical nurse (RPN) to hang a patient's scheduled intravenous chemotherapy because the oncology nurses are busy. Hospital policy, following provincial standards, authorizes only RNs who have completed chemotherapy education to give these drugs. What is the RPN's best action?

a. Decline, explain that hospital policy limits chemotherapy to RNs with this education, and tell the charge nurse so an authorized RN can be found.

b. Give the chemotherapy, because it has been ordered and any nurse on the unit may give a medication that has been ordered for the patient.

c. Ask an experienced RPN colleague to watch and coach while the RPN hangs the chemotherapy for the first time.

d. Delay the treatment until the next day without telling anyone, so that an oncology nurse can give it in the morning.

Answer: a — Under CNO's Scope of Practice standard, nurses accept only the activities they have the authority, competence and context to perform. In Ontario, Ontario Health (Cancer Care Ontario) competence standards name the RN, with recognized education and validated skills, as the nurse who gives systemic cancer treatment, and employer policy sets who is authorized; other provinces, territories and employers may differ (Ontario Health [Cancer Care Ontario], n.d.-c; sections 9.3 and 9.5; Chapter 1, section 1.3). Option b ignores the authority and competence required. A colleague who is not authorized either (c) cannot supply the missing authority or competence. Delaying treatment without communicating (d) is unsafe; the RPN informs the charge nurse so care can be arranged.

Case: Ms. Lucie Arsenault (Questions 10–15): Ms. Lucie Arsenault, 58, comes to the emergency department at 1410 with chills. She had her third cycle of chemotherapy for breast cancer 9 days ago. At triage her temperature is 38.7 °C, heart rate 114 beats/min, blood pressure 102/64 mm Hg, respiratory rate 24 breaths/min and SpO_2 95% on room air. She has an implanted port. A point-of-care count later shows neutrophils 0.2×10^9/L.

10. [CORE] Which finding is most important for the triage nurse to recognize as a cue to possible febrile neutropenia?

a. Her blood pressure of 102/64 mm Hg at triage

b. Her temperature 9 days after chemotherapy

c. Her SpO_2 of 95% on room air

d. The presence of an implanted port

Answer: b — A temperature at or above the threshold during the expected nadir after chemotherapy is the key cue to febrile neutropenia (section 9.4). Blood pressure (a) is lower than ideal but is not, by itself, a cue to neutropenia. An SpO_2 of 95% (c) is acceptable and points to no specific problem. A port (d) is a possible infection source, but it is not the cue that signals neutropenia.

11. [CORE] The nurse reviews the results: temperature 38.7 °C and neutrophils 0.2×10^9/L. How should the nurse analyze these cues?

a. They suggest a viral illness that needs rest and fluids.

b. They are expected after chemotherapy and need no action.

c. They show a transfusion reaction.

d. They meet the definition of febrile neutropenia.

Answer: d — A temperature of 38.7 °C with an ANC of 0.2×10^9/L meets every Canadian definition of febrile neutropenia, a medical emergency (section 9.4). A viral illness (a) cannot be assumed, and treating it as minor would delay antibiotics. Low counts are expected at the nadir, but fever with them is never "no action" (b). She has received no transfusion (c).

12. [CORE] Which hypothesis should the nurse place first?

a. Infection that may progress to sepsis
b. Dehydration from poor oral intake
c. Anxiety about starting her next cancer treatment
d. Expected fatigue from chemotherapy

Answer: a — With almost no neutrophils, fever means probable infection, which can quickly become sepsis; it is the most life-threatening possibility (section 9.4; Chapter 4, section 4.6). Dehydration (b) may add to her tachycardia but does not explain the fever. Anxiety (c) and fatigue (d) do not cause fever and would be dangerous explanations to accept.

13. [CORE] Which plan best matches Canadian and ASCO/IDSA guidance for Ms. Arsenault?

a. Hold antibiotics until blood culture results confirm a bacterial infection.
b. Give acetaminophen now and recheck her temperature in one hour before calling.
c. Draw blood cultures and give the first IV antibiotic within 1 hour of triage.
d. Arrange discharge home with an oral antibiotic once her temperature comes down.

Answer: c — Guidance calls for prompt assessment, blood cultures that do not delay treatment and the first antibiotic dose within 1 hour of triage (section 9.4). Waiting for culture results (a) delays treatment by days. Treating the fever and rechecking (b) hides the cue and loses time. Outpatient care (d) is only for selected low-risk patients after assessment, and she is already showing signs of instability.

14. [CORE] At 1450, before the antibiotic is hung, her blood pressure is 84/48 mm Hg, heart rate 128 beats/min and lactate 3.6 mmol/L. What should the nurse do first?

a. Recheck the blood pressure manually in 15 minutes.
b. Escalate at once and start the sepsis response, including IV fluids and the antibiotic as ordered.
c. Document the change carefully in the chart and report it to the oncology team at the next shift handover.
d. Encourage her to drink more fluids.

Answer: b — Hypotension, rising heart rate and a high lactate signal possible septic shock. The nurse escalates immediately and starts first-hour sepsis care (section 9.4; Chapter 4, section 4.6; Chapter 6). Waiting to recheck (a) and reporting at handover (c) delay care. Oral fluids (d) are too slow and not enough for shock.

15. [CORE] After IV fluids and antibiotics, which finding best shows that Ms. Arsenault is responding?

a. Her neutrophil count is still 0.2×10^9/L.
b. She says she feels "a bit better" but is now drowsy and hard to rouse.
c. Her temperature is 38.9 °C and her heart rate has risen to 120 beats/min.
d. Her blood pressure is 108/66 mm Hg; she is alert; lactate is falling.

Answer: d — A higher blood pressure, normal alertness and a falling lactate show improved perfusion (section 9.4; Chapter 4, section 4.6). Neutrophils (a) recover over days and do not reflect the response to fluids and antibiotics. New drowsiness (b) is a warning sign, not improvement. Ongoing fever and tachycardia (c) show no response.

16. [CORE] A patient with a high-grade lymphoma started chemotherapy yesterday. Which finding should the nurse report as a possible cue to tumour lysis syndrome?

a. Blood pressure 138/84 mm Hg, up slightly from 130/80 mm Hg yesterday
b. Mild hair thinning
c. Urine output of 15 mL/h for the past 3 hours and muscle twitching
d. A temperature of 37.4 °C

Answer: c — Falling urine output and muscle twitching suggest kidney injury and low calcium, both part of tumour lysis syndrome (section 9.4). This blood pressure (a) is mildly high but not a specific cue. Hair thinning (b) is an expected effect of chemotherapy. A temperature of 37.4 °C (d) is normal.

17. [CORE] A patient with breast cancer and bone metastases has new constipation, increased thirst, frequent urination and confusion. Which problem should the nurse suspect?

a. Hypercalcemia of malignancy
b. Superior vena cava syndrome
c. Febrile neutropenia
d. Extravasation

Answer: a — Constipation, thirst, polyuria and confusion are classic cues of hypercalcemia, which is common with breast cancer and bone metastases (section 9.4). Superior vena cava syndrome (b) causes swelling of the face and arms and dyspnea. Febrile neutropenia (c) needs a fever and low neutrophils. Extravasation (d) is a problem at an IV site.

18. [CORE] A patient with prostate cancer says his mid-back pain has been getting worse for two weeks, wakes him at night and is worse when he coughs. His leg strength is normal today. What is the nurse's best action?

a. Give the ordered analgesic and reassess the pain at the next scheduled round of checks.
b. Encourage him to walk more to loosen his back muscles.
c. Tell him that back pain is common with age.
d. Report the pain promptly as a possible early cue of spinal cord compression.

Answer: d — Progressive back pain that disturbs sleep or worsens with coughing in a person with cancer may be the first cue of spinal metastases, before weakness appears; it needs prompt reporting and urgent assessment (section 9.4). Analgesia (a) is appropriate but does not replace reporting. Walking more (b) could be unsafe if the spine is unstable. Blaming age (c) ignores a serious cue.

19. [CORE] A patient with lung cancer has new facial and neck swelling and is short of breath. Which nursing action is the priority?

a. Lay the patient flat in bed so that the patient can rest comfortably.
b. Help the patient sit up, give oxygen as ordered and escalate.
c. Start an IV in the patient's right arm.
d. Apply cool compresses to the face.

Answer: b — These cues suggest superior vena cava syndrome; symptoms worsen lying flat and the airway can be threatened, so the nurse sits the patient up, gives oxygen as ordered and escalates (section 9.4). Lying flat (a) worsens symptoms. Starting an IV (c) is not the priority while the airway may be at risk. Cool compresses (d) do not treat the obstruction.

20. [CORE] During a peripheral infusion of a vesicant, the patient reports pain and the nurse sees swelling at the site. What should the nurse do first?

a. Remove the IV catheter at once.

b. Slow the infusion rate and observe the site closely for 15 minutes.

c. Stop the infusion and leave the catheter in place.

d. Apply a warm compress to the site.

Answer: c — The first step is to stop the infusion and leave the catheter in place so that drug can be withdrawn through it (section 9.4). Removing the catheter first (a) loses the chance to aspirate. Slowing the infusion (b) lets more vesicant reach the tissue. Warm or cold compresses (d) are used only as the specific drug's protocol directs, and only after the first steps.

21. [CORE] The nurse is preparing to give an IV hazardous drug. Which personal protective equipment does Ontario guidance recommend?

a. Two pairs of chemotherapy-tested gloves and a protective gown

b. One pair of vinyl gloves

c. A surgical mask and eyeglasses only

d. One pair of nitrile gloves and a clean, long-sleeved cloth laboratory coat

Answer: a — For IV administration, Ontario's guideline recommends two pairs of chemotherapy-tested gloves and a low-permeability gown, plus face protection if splashing is possible (section 9.5). Vinyl gloves (b) are not recommended. A mask and eyeglasses (c) do not protect the skin, and glasses do not protect the eyes from splashes. One pair of gloves is not enough for IV administration, and a cloth coat (d) is not a low-permeability gown.

22. [CORE] A patient received IV chemotherapy 12 hours ago. A personal support worker asks how to handle the patient's soiled incontinence brief. What should the nurse tell them?

a. Place it in the regular garbage with bare hands.

b. No special precautions are needed, since they apply only during the infusion itself.

c. Place it in the biomedical waste bin while wearing one pair of disposable gloves.

d. Wear two pairs of gloves and a gown, and place it in the cytotoxic waste container.

Answer: d — For at least 48 hours after a hazardous drug, staff wear two pairs of gloves and a gown to handle body fluids, and soiled briefs go into cytotoxic waste (section 9.5). Regular garbage and bare hands (a) expose staff. Precautions continue after the infusion (b). Biomedical waste (c) is the wrong stream, and one pair of gloves is not enough.

23. [CORE] A patient's Your Symptoms Matter report shows an anxiety score of 8 out of 10, up from 3 last month. What is the nurse's best response?

a. File the report in the chart for the oncologist's next visit.

b. Discuss the score with the patient, assess further and refer if needed.

c. Tell the patient that anxiety is normal with cancer.

d. Ask the patient to complete the tool again next month.

Answer: b — A screening score opens a conversation; a high or rising score calls for further assessment, a shared plan and referral if needed (section 9.6). Filing it (a) or waiting a month (d) leaves the need unmet. Dismissing it as normal (c) ignores real distress.

24. [CORE] A 29-year-old patient newly diagnosed with Hodgkin lymphoma is scheduled to start chemotherapy next week. Which action reflects current guidance on fertility?

a. Plan the fertility discussion for after treatment ends, when the patient is less overwhelmed.

b. Advise the patient that fertility cannot be preserved once a cancer diagnosis is made.

c. Discuss fertility risks and options before treatment and refer promptly if interested or unsure.

d. Wait for the patient to raise the topic, so the discussion respects their privacy and readiness.

Answer: c — ASCO advises counselling about fertility risks at diagnosis and discussing preservation before treatment starts, with prompt referral to a reproductive specialist (section 9.6). Waiting until after treatment (a) may close options. Established methods exist (b). Waiting for the patient (d) means many people are never offered a choice.

25. [CORE] A patient finishing treatment for colorectal cancer asks what a survivorship care plan is for. Which reply is best?

a. "It summarizes your treatment and plans your follow-up, including signs to report and late effects."

b. "It lists the chemotherapy treatments you will need over the coming year."

c. "It is only needed if your cancer comes back and you need more treatment later on."

d. "It replaces your follow-up visits with your health care team, so you won't need to come in."

Answer: a — A survivorship care plan summarizes treatment and lays out follow-up, signs of recurrence, late effects and wellness advice, supporting the transition to primary care (section 9.6). It is not a treatment schedule (b). It is for every survivor, not only after recurrence (c). It guides visits; it does not replace them (d).

26. [CORE] On an Ontario medical unit, an RPN is caring for a patient receiving IV chemotherapy. The RPN notes a temperature of 38.5 °C. Which action best reflects scope and escalation?

a. Wait until the RN returns from break, then decide together what to do next.

b. Recheck the temperature in 4 hours.

c. Start the febrile neutropenia order set alone, without telling anyone on the team.

d. Consult the RN at once and make sure the prescriber is notified without delay.

Answer: d — Every nurse who notices a cue of deterioration acts at once and escalates; the RPN consults the RN as the patient's needs change (section 9.5; Chapter 1, section 1.3). Waiting (a, b) delays antibiotics in a possible emergency. Acting alone without informing the team (c) breaks communication and may exceed the RPN's authority under employer policy.

27. [RN] A patient is on day 2 of induction chemotherapy for acute leukemia. Which laboratory pattern is consistent with tumour lysis syndrome?

a. Low potassium, low phosphate, high calcium, low uric acid

b. Low uric acid, high calcium, low creatinine, low potassium

c. High potassium, high phosphate, high uric acid, low calcium

d. High sodium, high glucose, low potassium

Answer: c — Dying cells release potassium, phosphate and nucleic acids (which form uric acid), and phosphate binds calcium, so calcium falls (section 9.4, Going Deeper). Option a is nearly the reverse. Option b shows none of the expected rises. Option d describes changes unrelated to cell lysis.

28. [RN] Why does calcium fall in tumour lysis syndrome?

a. Released phosphate binds calcium, and the complex deposits in tissues.

b. Uric acid crystals block the absorption of calcium from the gut.

c. Potassium released from dying cells pushes calcium into healthy cells.

d. The kidneys excrete extra calcium in the urine.

Answer: a — High phosphate binds calcium, lowering blood calcium and forming calcium phosphate deposits, including in the kidneys (section 9.4, Going Deeper). Uric acid (b) does not block calcium absorption. Potassium (c) does not move calcium into cells. Kidney injury in TLS lowers excretion; it does not increase calcium loss (d).

29. [RN] Which mechanism best explains acute kidney injury in tumour lysis syndrome?

a. Antibodies made against tumour proteins attack the glomeruli.

b. Low blood calcium constricts the renal arteries and cuts blood flow.

c. High potassium directly destroys the cells of the renal tubules.

d. Uric acid and calcium phosphate crystals block the kidney tubules.

Answer: d — Crystals of uric acid, xanthine and calcium phosphate obstruct the tubules, and reduced renal blood flow and inflammation add to the injury (section 9.4, Going Deeper). TLS is not an antibody process (a). Low calcium (b) is not the main cause of kidney injury. High potassium (c) threatens the heart, not the tubules.

30. [RN] A patient with tumour lysis syndrome has a potassium of 6.4 mmol/L. Which risk is the RN most concerned about?

a. Seizures caused by a low sodium level

b. A life-threatening cardiac dysrhythmia

c. Hyperglycemia from reduced insulin release

d. Respiratory alkalosis from rapid breathing

Answer: b — High potassium makes heart cells unstable and can cause dangerous dysrhythmias and cardiac arrest, so the RN watches the cardiac monitor and reports at once (section 9.4, Going Deeper; Chapter 3, section 3.5). Sodium (a) is not the issue here. Hyperglycemia (c) and respiratory alkalosis (d) are not caused by high potassium.

10 Palliative and End-of-Life Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain the palliative approach to care and how it differs from specialist palliative care and end-of-life care.
2. Support advance care planning and goals-of-care conversations, applying Ontario law on substitute decision-makers and noting how other provinces differ.
3. Assess and manage common symptoms in serious illness: pain, dyspnea, nausea, constipation, delirium, fatigue and respiratory secretions.
4. Describe Canada's medical assistance in dying law, its eligibility criteria and safeguards, and nurses' roles and rights, including conscientious objection.
5. Recognize the signs that death is approaching and provide comfort care to the patient and family.
6. Provide culturally safe care after death, including coroner notification and tissue and organ donation requirements.
7. Support grieving families and care for one's own wellbeing.
8. Distinguish RN, RPN and NP roles in palliative care and medical assistance in dying using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 3, 5	Clinician; Scholar	Foundations of Practice
2, 4, 8	Advocate; Professional; Communicator	Legal Practice; Ethical Practice
6, 7	Advocate; Collaborator	Ethical Practice; Collaborative Practice

Introduction

For most people, death now comes at the end of a progressive illness, such as cancer, heart failure, chronic lung disease or dementia, rather than suddenly (Murray et al., 2005). The Canadian Institute for Health Information (CIHI) reported that 58% of people who died in 2021–2022 in Ontario, Alberta, British Columbia and Yukon were identified in CIHI's data as receiving palliative care; of those who received some form of palliative care, 61% received it in hospital only (CIHI, 2023). Medical-surgical nurses therefore care for dying patients and their families on every adult unit, not only on palliative care units.

Every nurse gives palliative care: easing breathlessness, asking a family what matters most and making sure a patient's wishes reach the team are all palliative care. Section 10.1 explains palliative care and how it is organized in Canada. Section 10.2 covers advance care planning and goals of care, and section 10.3 the common symptoms of serious illness. Sections 10.4 to 10.6 address medical assistance in dying (MAID), care in the last days and after death, and grief and nurse self-care. Related topics live elsewhere: consent and substitute decision-makers (Chapter 1), pain and opioids (Chapter 5), delirium and dementia (Chapter 8), cancer (Chapter 9), chronic obstructive pulmonary disease (COPD) (Chapter 14) and heart failure (Chapter 18).

10.1 The Palliative Approach

What Palliative Care Is

The World Health Organization (WHO) describes palliative care as an approach that aims to raise the quality of life of patients and their families facing a life-threatening illness. It works by identifying problems early, assessing them carefully and treating pain and other physical, psychosocial and spiritual concerns (WHO, 2020). Health Canada's *Framework on Palliative Care in Canada* adopts

this definition and applies it to people of all ages (Health Canada, 2018). In this book, **palliative care** means care that aims to relieve suffering and improve quality of life for people who have a life-limiting illness and for those close to them.

The patient and family together are the unit of care, and care can begin at diagnosis, alongside treatments meant to control the disease. The Canadian Hospice Palliative Care Association (CHPCA) model places the patient and family at the centre of eight domains of possible suffering: disease management, physical, psychological, social, spiritual, practical, end-of-life care and death management, and loss and grief (CHPCA, 2013). The domains work as an assessment checklist: a patient whose pain is controlled may still be worried about money or struggling with questions of meaning.

End-of-life care is the part of palliative care given when death is expected in the near future. In Canada, "hospice care" and "palliative care" refer to the same thing; **hospice** is often used for care given in the community, and a hospice residence is one setting for care near the end of life (CHPCA, n.d.).

The *Framework* also describes a **palliative approach** to care: the core elements of palliative care are built into everyday care by providers who are not palliative specialists, early in the illness and in every setting. All providers, regulated or not, are expected to have foundational palliative skills, with specialists supporting them as needed (Health Canada, 2018). **Specialist palliative care** is given by interprofessional teams with advanced training, such as consult teams, palliative care units and hospice programs. The medical-surgical nurse provides the palliative approach and asks for a specialist consult when symptoms or distress remain hard to control.

Illness Trajectories

An **illness trajectory** is the usual pattern of a person's function over time as a serious illness progresses. Lynn and Adamson (2003) described three common patterns, and Murray et al. (2005) linked them to palliative care planning:

- **Short period of evident decline (typical of cancer):** Function stays fairly good for a long time, then falls steeply over the final weeks.
- **Long-term limitation with intermittent exacerbations (typical of heart failure and COPD):** Serious flare-ups bring the person to hospital over years, each may leave them weaker, and death can come suddenly during one.
- **Prolonged dwindling (typical of frailty and dementia):** Function declines slowly from a low level, often over many years.

The trajectories matter for timing. In cancer, the decline is fairly predictable but fast, so conversations should not wait for it. In organ failure, any exacerbation might be the last, so goals of care are discussed early and revisited after each admission. In frailty and dementia, the person may lose capacity long before death, so advance care planning happens while they can still share their wishes, and caregivers need support over many years (Lynn & Adamson, 2003). Trajectories give patients and families a broad sense of what lies ahead, which can help them feel more in control (Murray et al., 2005).

Access in Canada

CIHI's 2023 report used data from Ontario, Alberta, British Columbia and Yukon (CIHI, 2023):

- In 2021–2022, 58% of people who died (about 89,000) were identified in CIHI's data as receiving palliative care, up from 52% in 2016–2017 (Ontario and Alberta only).
- Of those, 61% received it in hospital only and 36% received palliative home care. Overall, 13% of all deaths took place at home with the support of palliative home care.
- Half of patients died within 22 days after CIHI's data first identified them as palliative, so identification often comes late.
- People with palliative home care spent fewer days in hospital in their last year (an average of 18 versus 28 days).
- 77% of people with cancer were identified as palliative, while people with dementia were the least likely to receive palliative care in their last year of life (39%); people aged 85 and older were less likely than younger people to receive it.

Palliative needs are often recognized too late, especially in people without cancer. Noticing them earlier is part of the palliative approach.

CANADIAN CONTEXT

A National Framework for Palliative Care

In December 2017, Parliament passed the *Framework on Palliative Care in Canada Act*, which required the federal Minister of Health to develop a national framework in consultation with the provinces, territories and palliative care providers (Health Canada, 2023). The *Framework on Palliative Care in Canada* was tabled on December 4, 2018. Its vision is that everyone in Canada who has a life-limiting illness can live well right up to the end of life, and it sets four priority areas: education and training for providers and caregivers, support for providers and caregivers, research and data, and equitable access (Health Canada, 2018).

The *Action Plan on Palliative Care* (2019) followed, with five goals: public awareness of palliative care and advance care planning; better skills and supports for providers, families and communities; better data and research; better access for underserved populations; and better access to culturally sensitive palliative care in Indigenous communities (Health Canada, 2019).

For nurses, the most direct effects are educational. The *Framework* supports developing mandatory palliative care courses in undergraduate health provider programs and expects every provider to have skills in the palliative approach, and the *Action Plan* called for a national interdisciplinary competency framework (Health Canada, 2018, 2019).

Equity and Culturally Safe Palliative Care

Access to palliative care is not equal, and the causes are mostly structural. CIHI (2023) cites Canadian research suggesting that people of colour and recent immigrants may have poorer access and that many First Nations people lack access to palliative care programs. Because CIHI's data lack details such as race, religion and language, these gaps cannot be fully measured.

First Nations, Inuit and Métis peoples. For many Indigenous Peoples, dying and death are a social and spiritual event honoured collectively, with roles for family, Elders, Knowledge Carriers and healers (Canadian Partnership Against Cancer [CPAC], 2022). Colonization and the residential school system continue to shape health and trust in health care (CPAC, 2022). Receiving care, and dying, at home is a central part of culturally safe end-of-life care, yet high transportation costs and inflexible travel policies can keep many Inuit from being with their families at the end of life (CPAC, 2024). The nurse uses a distinctions-based approach, asks the patient and family what they need, and supports Indigenous-led and community-based care. In Ontario, for example, Indigenous Navigators support and advocate for First Nations, Inuit, Métis and urban Indigenous patients with cancer and their families, including coordinating access to palliative and supportive care and attending to cultural and spiritual needs (Ontario Health, n.d.). Elders and Knowledge Carriers can be involved where available and when the patient wishes (Chapter 2).

Rural and remote communities. Rural palliative patients were more often admitted to hospital mainly for palliative care than urban patients (36% versus 29%) (CIHI, 2023). Early planning for home supports, medications and after-hours crises can help a person stay home if they wish.

People experiencing homelessness. A Canadian study described barriers to end-of-life care for people who are poor or unhoused: the daily struggle to survive, the normalizing of early death, lack of identification, providers' risk concerns and siloed services (Stajduhar et al., 2019). CIHI (2023) found that palliative patients experiencing homelessness were more likely to have longer hospital stays and to wait longer for discharge to a more suitable setting.

2SLGBTQI+ people and chosen family. Many people rely on partners, friends or chosen family. In Ontario, these people can act as substitute decision-makers only if they rank highest in the legal hierarchy or are named in a power of attorney for personal care (Hospice Palliative Care Ontario [HPCO], n.d.). The nurse asks every patient who they consider family and encourages planning that names the right person.

Newcomers and language. Serious news needs a professional interpreter, not a family member (Chapter 1, section 1.7), and the nurse asks how the patient prefers to receive information.

10.2 Advance Care Planning and Goals of Care

Three Different Conversations

Ontario's guidance separates three conversations that are often blurred together (HPCO, n.d.):

- **Advance care planning (ACP):** a voluntary process in which a capable person confirms or chooses their future substitute decision-maker and shares their wishes, values and beliefs about future care. It can happen at any age and in any state of health.
- **Goals of care:** a discussion, when a person is seriously ill, about their current illness, its likely course and what matters most to them, so that treatment options can be matched to their goals. It involves the patient or, if the patient is incapable, the substitute decision-maker, and it often takes more than one conversation.
- **Informed consent:** a decision about a specific treatment, made at the time it is proposed, by the capable patient or, if the patient is incapable of that decision, by the substitute decision-maker.

The distinction matters because, in Ontario, wishes are not consent. Wishes guide the substitute decision-maker but cannot replace a decision by a person; a written form alone is not consent, apart from limited emergencies under the *Health Care Consent Act, 1996* (HPCO, n.d.). Wishes apply only if the person becomes incapable and should be reviewed after any major change in health. Chapter 1, section 1.5, explains capacity, the hierarchy and the emergency exception.

Substitute Decision-Makers and Powers of Attorney

A **substitute decision-maker (SDM)** is the person who makes health care decisions for a patient who is incapable of making a particular decision. In Ontario, a person who wants someone other than the highest-ranked relative to be their SDM prepares a **power of attorney for personal care**, a legal document under the *Substitute Decisions Act, 1992* that names an attorney to make personal care decisions, including health care, if the person becomes incapable (HPCO, n.d.). To make one, the person must be at least 16 years old and mentally capable, and it must be signed in front of two eligible witnesses (Government of Ontario, 2025; Ontario Ministry of the Attorney General, 2020). It is used only while the person is incapable, and for treatment decisions a health practitioner must first find the person incapable of that decision. The term "living will" is not used in Ontario law, although people may write down their wishes, including inside the power of attorney (Ontario Ministry of the Attorney General, 2020).

An SDM does not decide on the basis of their own preferences. They must follow the wishes the person expressed while capable that apply to the situation, unless following them is impossible. If no applicable wish is known, the SDM decides in the person's best interests, considering their values, beliefs and well-being (HPCO, n.d.; Ontario Ministry of the Attorney General, 2020). The **Consent and Capacity Board** is an independent Ontario tribunal that hears disputes about capacity and substitute decisions, including disputes about withdrawing life-sustaining treatment (College of Physicians and Surgeons of Ontario [CPSO], 2023a).

Other provinces and territories use different laws and terms. In Alberta, a **personal directive** names an agent who will make personal decisions that are not financial, and it takes effect only after the person is found to lack capacity (Government of Alberta, 2025). In British Columbia, a representation agreement names a representative, and an advance directive gives health care instructions that providers must follow when they address the care needed (Government of British Columbia, 2025). The nurse learns the law and employer policy where they practise.

Serious Illness Conversations

A **serious illness conversation** is a planned discussion with a seriously ill person about their understanding of the illness, their prognosis, their goals and fears, and the trade-offs they would or would not accept. The Serious Illness Conversation Guide, developed by Ariadne Labs and adopted by the BC Centre for Palliative Care, gives a structure that many Canadian teams use (Ariadne Labs, 2017). In plain terms, the clinician:

- **Sets up the conversation:** explains its purpose and asks permission to talk.
- **Explores understanding:** asks what the person knows about their illness and how much information they want.
- **Shares information:** gives an honest outlook that holds both hope and worry, then pauses to let the person react.
- **Explores what matters:** goals, worries and fears, what gives the person strength, abilities so important that life without them would be unacceptable, trade-offs they would make for more time, and how much their family knows.
- **Closes and documents:** summarizes, recommends a plan that fits the person's priorities, affirms ongoing support, and records the conversation where other providers can find it.

Nurses often hear the first cues: a patient who says "I never want to go back to intensive care" or a daughter who asks "Is he dying?" The nurse responds with curiosity, starts or invites a conversation about values, prepares the patient and family for a team meeting,

sits in to clarify and support, and follows up. In Ontario, physicians are expected to begin goals-of-care discussions for patients with a significant illness who are at risk of deterioration, including explaining prognosis and treatment options (CPSO, 2023b); nurses support that discussion within their scope (Chapter 1, section 1.3). A professional interpreter is used whenever language is a barrier. Cultural safety means asking, not assuming: some patients want every detail, while others prefer that information go through family (Chapter 2). The nurse documents what was discussed, the patient's own words where helpful, and who took part.

Resuscitation Decisions

Cardiopulmonary resuscitation (CPR) is far less successful than many people expect. Only about 12% to 25% of patients who have a cardiac arrest in hospital survive to discharge, even with prompt CPR and defibrillation (Ottawa Hospital Research Institute, 2019). A Canadian-led systematic review and meta-analysis found that active cancer and chronic kidney disease (high-certainty evidence) and age 60 or older (low-certainty evidence) were associated with lower odds of survival (Fernando et al., 2019).

In Ontario, the CPSO policy *Decision-Making for End-of-Life Care* states that a physician may write an order not to provide CPR when they judge that its risk of harm outweighs its potential benefit. Because the decision is not considered a treatment, the patient's or SDM's consent is not required (CPSO, 2023b); the CPSO's companion *Advice to the Profession* links this position to a 2019 Ontario Superior Court decision, *Wawrzyniak v. Livingstone* (CPSO, 2023a). The physician must still consider the patient's wishes and values, tell the patient or SDM that the order will be written, explain the diagnosis, prognosis and reasons, and describe the care that will continue. If the patient or SDM disagrees, the physician may still write the order but must make reasonable efforts to support them, for example by identifying the reason for the disagreement, offering supportive services and, where available, a second opinion or an ethics consultation (CPSO, 2023b). Withdrawing other life-sustaining treatments is handled differently: the CPSO notes that in *Cuthbertson v. Rasouli* (2013), the Supreme Court of Canada affirmed that the Consent and Capacity Board is the appropriate body to decide disagreements between physicians and SDMs about withdrawing such treatment (CPSO, 2023a).

The nurse's role is practical and protective:

- Know each patient's code status at the start of every shift, and confirm that the written order matches what was discussed.
- Clarify at once with the physician or nurse practitioner (NP) when the order is missing, unclear or conflicts with what the patient or family says.
- Explain that a no-CPR order does not mean "no care": assessment, symptom relief and treatments that fit the goals continue.
- Include code status in every handover and transfer.

10.3 Managing Symptoms

Assessing Symptoms

Symptoms are best assessed regularly and systematically, using the patient's own report whenever possible (Hui et al., 2021). The revised Edmonton Symptom Assessment System (ESAS-r), described in Chapter 9, rates common symptoms on a 0 to 10 scale. The Palliative Performance Scale (PPS) is often used alongside it to describe function. When a patient cannot self-report, the nurse uses an observational tool, such as the Pain Assessment in Advanced Dementia (PAINAD) scale for pain (Chapter 5) or the Respiratory Distress Observation Scale for breathlessness (Hui et al., 2021). Skin colour changes such as cyanosis or pallor are harder to see on darker skin, so the nurse also checks the lips, oral mucosa and nail beds and relies on the patient's report and breathing pattern (Chapter 12).

Cicely Saunders, who trained as a nurse, social worker and physician, observed that dying patients' pain often opened onto other kinds of suffering. She called this **total pain**: suffering with physical, psychological, social, emotional and spiritual parts (Clark, 1999). A patient whose pain "won't settle" may also be afraid, grieving or worried about their family. The nurse assesses all these parts and involves social work, spiritual care and other team members.

Pain

Pain is one of the most feared symptoms of serious illness. Its assessment and its treatment with non-opioids, opioids and adjuvant analgesics are covered in Chapter 5. WHO (2020) describes opioids as essential for managing pain and notes that they can also ease

breathlessness. Started at a low dose, adjusted to the patient's response and monitored, opioids are a safe, standard treatment. Patients and families often worry about addiction, about "saving" opioids for later or about opioids hastening death; the Going Deeper box in section 10.5 examines these fears. Whenever an opioid is started, a laxative plan is started too (Chapter 5). The nurse reassesses pain after each dose, reports pain that stays uncontrolled, and remembers that unrelieved pain may also be total pain, needing more than an analgesic.

Dyspnea

Dyspnea is the subjective experience of breathing discomfort. In serious illness it may come from the disease itself (lung tumour, pleural effusion, advanced COPD or heart failure), from a new problem such as pneumonia, anemia or pulmonary embolism, or from anxiety, which both causes and worsens breathlessness. Reversible causes are treated when treatment fits the patient's goals (Hui et al., 2021). Because breathlessness is subjective, the nurse asks the patient to rate it, for example on a 0 to 10 scale, and asks what triggers it and what it stops them from doing; oxygen saturation and respiratory rate alone do not show how distressing it is (Hui et al., 2021).

Non-drug measures come first and continue throughout:

- **Airflow:** A fan directed at the face, specifically the cheek, is recommended by the American Society of Clinical Oncology (ASCO) guideline, based on evidence of intermediate quality (Hui et al., 2021).
- **Position:** Sitting upright or leaning forward on a table.
- **Breathing and relaxation:** Pursed-lip breathing, relaxation and distraction may help, although the evidence is weaker (Hui et al., 2021).
- **Presence:** A calm nurse who stays, speaks slowly and explains each step can ease the fear that feeds breathlessness.

When these are not enough, systemic opioids are the drug class that the ASCO guideline recommends for dyspnea in advanced cancer, with close monitoring (Hui et al., 2021). Oxygen should be available for breathless patients who are hypoxemic (oxygen saturation of 90% or less on room air); when saturation is above 90%, the same guideline does not recommend oxygen, and a fan is offered instead. Benzodiazepines are not first-line treatment for dyspnea; they may be considered for anxiety related to breathlessness when opioids and non-drug measures are not enough (Hui et al., 2021). COPD and heart failure are discussed in Chapters 14 and 18.

Nausea, Vomiting and Constipation

Nausea and vomiting in advanced illness usually have identifiable causes, and several can occur together. Causes can be grouped as chemical or metabolic (drugs such as opioids, hypercalcemia, kidney or liver failure, infection), gastrointestinal (slow gastric emptying, bowel obstruction, constipation), cerebral (raised intracranial pressure, anxiety) and vestibular (nausea triggered by movement) (Cancer Care Ontario, 2010). The prescriber chooses an antiemetic that matches the likely cause; for example, a prokinetic drug for slow gastric emptying or a corticosteroid for raised intracranial pressure (Table 10.1). For persistent nausea, the antiemetic is usually given regularly rather than only as needed, and a second drug acting on a different receptor may be added (Cancer Care Ontario, 2010). Bowel obstruction must be ruled out. Nursing measures include small, frequent, bland meals; cool or room-temperature foods; removing strong smells; fresh air; and mouth care after vomiting (Cancer Care Ontario, 2010).

Constipation is defined largely by the patient's experience, and it can cause pain, nausea, delirium and great distress (Larkin et al., 2008, 2018). Causes include opioids and many other drugs, immobility, weakness, low food and fluid intake, metabolic problems and lack of privacy. Because almost every patient taking an opioid needs a laxative, laxatives are started preventively, usually a softening agent with a stimulant; bulk-forming fibre is generally avoided in frail, seriously ill patients because it can worsen obstruction when fluid intake is low (Larkin et al., 2008). A peripherally acting opioid-receptor antagonist may be used when opioid-induced constipation does not respond to laxatives (Larkin et al., 2018). The nurse assesses bowel patterns every day, offers privacy and a commode rather than a bedpan where possible, and reports no bowel movement for more than 3 days, or as the unit's bowel protocol directs.

Delirium, Fatigue, Anorexia and Cachexia

Delirium is common in serious illness and is covered in Chapter 8. Its causes are sought and treated when that fits the patient's goals. In the last days of life, delirium may be part of dying and not reversible; this **terminal delirium** is managed for comfort and safety, as described in section 10.5. Fatigue is also nearly universal. The nurse looks for treatable contributors, such as anemia, poor sleep, depression or medications, and helps the patient spend limited energy on what matters most to them (Chapter 9 discusses cancer-related fatigue).

Loss of appetite (anorexia) distresses families as much as patients. **Cachexia** is a syndrome of ongoing loss of skeletal muscle, with or without loss of fat, driven by reduced intake and abnormal metabolism; it cannot be fully reversed by usual nutritional support and leads to steadily worsening function (Fearon et al., 2011). An ASCO guideline suggests dietitian counselling, does not recommend routine tube feeding or parenteral nutrition in advanced cancer, and supports a brief trial of a corticosteroid or a progesterone analogue for patients with loss of appetite or weight (Roeland et al., 2020). The nurse offers small portions of preferred foods without pressure and helps families find other ways to show care.

Artificial nutrition and hydration (tube feeding and intravenous or subcutaneous fluids) near the end of life is a medical treatment. Starting, continuing or stopping it is a values-based decision made through goals-of-care discussions and informed consent from the patient or SDM. Thirst and hunger near death are often brief, and mouth care eases dryness (Lam & Lam, 2014).

Respiratory Secretions

In the last hours or days of life, some patients develop **respiratory secretions** that cause a noisy, rattling sound with each breath, often called the "death rattle." It occurs when saliva and secretions pool in the upper airway because the person can no longer swallow or cough effectively; it is reported in about half of dying patients (Moons et al., 2024). In an observational study of 71 dying patients, those with a rattle showed no more signs of respiratory distress than those without it (Campbell & Yarandi, 2013). Families, however, often find the sound very distressing (Moons et al., 2024).

Care focuses on comfort and on the family:

- Reposition the patient on their side, with the head raised slightly, to help secretions drain.
- Give gentle mouth care. Deep suctioning is generally avoided because it can cause discomfort and rarely helps for long.
- Explain to the family that the sound is a natural part of dying and that, based on current evidence, it does not appear to cause the patient distress. Invite them to sit close, hold the person's hand and keep talking to them.
- Watch for true respiratory distress, such as grimacing, restlessness or laboured breathing, and treat it.

Anticholinergic (antisecretory) drugs may be ordered. They seem to work best when started early, and they often do not quiet breathing once the rattle is established (Campbell & Yarandi, 2013; Moons et al., 2024).

Table 10.1 Common symptoms in serious illness: causes, comfort measures and drug classes (Cancer Care Ontario, 2010; Hui et al., 2021; Larkin et al., 2008; Moons et al., 2024; Roeland et al., 2020)

Symptom	Common causes	Comfort measures	Drug classes the team may use
Pain	Tumour growth, bone or nerve involvement, procedures, immobility, constipation; psychological, social and spiritual distress (total pain)	Repositioning, supportive surfaces, relaxation, presence; attention to fears and spiritual needs	Non-opioid analgesics, opioids and adjuvant analgesics (Chapter 5)
Dyspnea	Lung tumour, pleural effusion, advanced COPD or heart failure, pneumonia, anemia, pulmonary embolism, anxiety	Fan directed at the face, upright or forward-leaning position, pursed-lip breathing, relaxation, calm presence	Opioids; oxygen if hypoxemic; a benzodiazepine for related anxiety when other measures fail; treatment of reversible causes
Nausea and vomiting	Opioids and other drugs, hypercalcemia, kidney or liver failure, slow gastric emptying, bowel obstruction, constipation, raised intracranial pressure, anxiety, motion	Small frequent bland meals, cool foods, no strong odours, fresh air, mouth care after vomiting	Chosen by cause: dopamine antagonists (including prokinetics), antihistamines, corticosteroids, serotonin (5-HT3) antagonists, benzodiazepines for anticipatory nausea

Symptom	Common causes	Comfort measures	Drug classes the team may use
Constipation	Opioids and other drugs, immobility, weakness, low intake, metabolic problems, lack of privacy	Daily bowel assessment, privacy, commode rather than bedpan, fluids and activity as tolerated	Softening (osmotic) and stimulant laxatives, often together; rectal measures if needed; peripherally acting opioid-receptor antagonists for opioid-induced constipation that does not respond
Delirium	Drugs, infection, dehydration, metabolic changes, hypoxia, urinary retention, constipation, the dying process	Calm, well-lit room by day, reorientation, family presence, glasses and hearing aids, safety measures (Chapter 8)	Treatment of reversible causes when it fits the goals; antipsychotics for distressing symptoms in selected patients (Chapter 8)
Fatigue	Disease progression, anemia, poor sleep, depression, drugs, cachexia	Energy conservation, rest periods, planning activities that matter most	Treatment of contributing causes, such as anemia or depression (Chapter 9)
Anorexia and cachexia	Tumour-related metabolic change, nausea, mouth problems, taste changes, constipation, low mood	Small portions of preferred foods, no pressure to eat, mouth care, dietitian referral, family teaching	Brief trial of a corticosteroid or a progesterone analogue in some patients with advanced cancer
Respiratory secretions	Saliva and secretions pooling in the upper airway when the person can no longer swallow or cough	Side-lying position, gentle mouth care, explanation and support for the family; deep suctioning generally avoided	Anticholinergic (antisecretory) drugs, which seem to work best when started early

CLINICAL JUDGMENT

Breathless at Night

Names and details are fictional; this is a composite story.

Gerald Bouchard, 78, has advanced COPD and is on a medical unit after his third admission this year. With his wife present, he has agreed with the team on goals of care focused on comfort, and he has a no-CPR order. At 0200, he presses the call bell, sitting slumped low in bed.

- **Recognize cues:** He speaks in three-word phrases, uses his neck muscles to breathe and rates his breathlessness 8 out of 10. His respiratory rate is 30, he is afebrile and his oxygen saturation is within the range ordered for him. He says, "I'm scared I'll suffocate."
- **Analyze cues:** His breathlessness is being worsened by his position and by panic. Nothing points to a new cause such as fever, chest pain or a sudden change in his chest sounds.
- **Prioritize hypotheses:** Relieving distressing dyspnea comes first, while watching for any new, reversible problem.
- **Generate solutions:** Sit him upright and leaning forward, direct a handheld fan at his face, coach pursed-lip breathing and stay with him. Give the as-needed opioid ordered for breathlessness.
- **Take action:** The nurse does all of this, speaking slowly and calmly, and dims the lights.
- **Evaluate outcomes:** After 30 minutes, he rates his breathlessness 4 out of 10, his respiratory rate is 22 and he is easy to rouse. The nurse continues to monitor his sedation and breathing (Chapter 5). If his symptoms had not eased, or if new signs had appeared, the nurse would notify the physician or NP at once; comfort-focused goals do not remove the duty to escalate (Chapter 6). He asks the nurse to call his wife in the morning. The nurse documents the episode and the response and adds a fan to his care plan.

LIFESPAN CONSIDERATIONS

Palliative Care for Older Adults and People Living With Dementia

Older adults, and people with dementia in particular, are less likely to receive palliative care. CIHI found that people aged 85 and older were less likely than younger adults to receive palliative care in their last year of life, and that people with dementia were the least likely to receive palliative care (39%), whereas 77% of people with cancer were identified as palliative (CIHI, 2023). Pain is often missed in people who cannot describe it, so the nurse uses an observational tool such as PAINAD (Chapter 5). Eating difficulties are part of the natural course of advanced dementia. In one large cohort, 85% of people with advanced dementia had them. Choosing Wisely Canada advises against recommending feeding tubes in advanced dementia and suggests offering oral feeding instead; careful hand-feeding appears to be as good as tube feeding for complications and survival (Lam & Lam, 2014).

> These choices are best discussed with the person while they can still take part, and with their SDM well before a crisis admission; in one trial, a video decision aid gave SDMs more knowledge and less distress about feeding choices (Lam & Lam, 2014). Chapter 8 covers dementia, delirium and frailty.

10.4 Medical Assistance in Dying

Medical assistance in dying (MAID) is legal across Canada. Under the Criminal Code, it takes one of two forms, both at the person's request: a physician or NP gives the person a substance that causes death (**clinician-administered MAID**), or a physician or NP prescribes or provides a substance that the person takes themselves (**self-administered MAID**) (College of Nurses of Ontario [CNO], 2025). This book does not describe methods, drugs or doses. This section describes the law as of October 25, 2026. Because the law is changing, the nurse checks the current Criminal Code and CNO guidance before relying on any detail here.

The Law in Canada

In February 2015, the Supreme Court of Canada's decision in *Carter v. Canada* required Parliament to change the Criminal Code's prohibition on assisted dying (Department of Justice Canada, 2026). Bill C-14 received royal assent in June 2016 and placed the rules for MAID in sections 241.1 to 241.4 of the Criminal Code. After a Quebec court ruled in 2019 (*Truchon*) that limiting MAID to people whose natural death was reasonably foreseeable was unconstitutional, Bill C-7, in force in March 2021, removed that limit and created two sets of safeguards (CNO, 2025; Department of Justice Canada, 2026).

Aiding a person to die by suicide remains an offence. Physicians and NPs who provide MAID, and anyone who helps them, are exempt only when they act in accordance with section 241.2 (Criminal Code, 1985, s. 241). Ontario follows the federal eligibility rules and safeguards (Government of Ontario, 2024). Quebec also has its own statute, the *Act respecting end-of-life care* (CQLR, c. S-32.0001), which adds provincial rules.

Eligibility

A person must meet every one of these criteria (Criminal Code, 1985, s. 241.2(1)):

- qualify for publicly funded health services in Canada, or would qualify apart from a minimum period of residence or waiting period;
- be 18 or older and capable of making decisions about their own health;
- have a grievous and irremediable medical condition;
- make a voluntary request that is not the result of outside pressure;
- give informed consent after learning about the ways their suffering could be relieved, including palliative care.

A **grievous and irremediable medical condition** has three parts, all of which must be present: an illness, disease or disability that is serious and incurable; an advanced, irreversible decline in capability; and enduring physical or psychological suffering that the person finds intolerable and that cannot be relieved in a way they consider acceptable (Criminal Code, 1985, s. 241.2(2)). Since 2021, a **reasonably foreseeable natural death** is no longer an eligibility criterion; it decides which safeguards apply. The request and consent must come from the person. A substitute decision-maker cannot request or consent to MAID for someone else (see Chapter 1, section 1.5).

Under section 241.2(2.1), a mental illness does not count as an illness, disease or disability for eligibility, so a person whose mental illness is their only underlying medical condition is not eligible. The exclusion does not cover neurocognitive or neurodevelopmental disorders (Department of Justice Canada, 2026). Bill C-62 (S.C. 2024, c. 1), which received royal assent on February 29, 2024, extended the exclusion until March 17, 2027. On October 7, 2026, Justice Minister Sean Fraser said that the government would not go ahead with the expansion and intends to introduce legislation later in the fall of 2026 to keep the exclusion in place indefinitely (Rana, 2026). As of October 25, 2026, no such bill had been introduced. Students should check the current law, because this part may change soon.

Safeguards

Health Canada's reports call the two pathways **Track 1** (natural death is reasonably foreseeable) and **Track 2** (natural death is not reasonably foreseeable). Both require a written request signed before an independent witness, two independent assessments and the chance to withdraw; Track 2 adds further steps (Table 10.2). The witness must be an adult who understands the request and does not benefit from the death or run the facility. A paid health or personal care worker, including a nurse, may act as witness unless they are assessing or providing MAID (Criminal Code, 1985, s. 241.2(5), (5.1); CNO, 2025).

In Track 2, at least 90 clear days must pass between the start of the first assessment and the day MAID is provided. The period may be shortened only when both assessments are complete and both practitioners consider the person's loss of capacity imminent (Criminal Code, 1985, s. 241.2(3.1)). If neither assessor has expertise in the condition causing the suffering, they must consult someone who does. The person must also be told about counselling, mental health and disability supports, community services and palliative care.

Just before MAID is provided, the person must have the chance to withdraw and must confirm consent. In Track 1 only, a person at risk of losing capacity before the chosen date may arrange in writing for a **waiver of final consent**, often called Audrey's Amendment. The arrangement no longer applies if the person, after losing capacity, shows refusal or resistance through words, sounds or gestures; reflexes and other involuntary movements do not count (Department of Justice Canada, 2026).

Practitioners report MAID requests and assessments under federal monitoring regulations, which since January 1, 2023, also collect data on race, Indigenous identity and disability so that inequality can be studied (Department of Justice Canada, 2026). In Ontario, NPs also report every MAID death to the Office of the Chief Coroner (CNO, 2025).

Table 10.2 MAID eligibility and safeguards: Track 1 and Track 2 compared (Department of Justice Canada, 2026; Criminal Code, 1985)

Element	Track 1: natural death reasonably foreseeable	Track 2: natural death not reasonably foreseeable
Eligibility criteria	Same five criteria for both tracks: government-funded health services; 18 or older and capable; grievous and irremediable condition; voluntary request; informed consent. Mental illness as the sole underlying condition is excluded until March 17, 2027 (check for changes)	Same as Track 1
Written request and witness	Signed and dated request before one independent witness; the person is told they may withdraw at any time	Same as Track 1
Assessments	Two independent physicians or NPs each confirm in writing that the criteria are met	Two independent physicians or NPs; added discussion of means to relieve suffering and agreement that the person has seriously considered them
Minimum assessment period	None (the former 10-day reflection period was removed in 2021)	At least 90 clear days from the start of the first assessment to the day MAID is provided; shorter only if both assessments are complete and loss of capacity is imminent
Expertise consultation	Not required	Required if neither assessor has expertise in the condition causing the suffering
Final consent and waiver	Express consent just before provision; may be waived by written arrangement if loss of capacity is a risk	Express consent just before provision; no waiver
Reporting	Practitioners report under federal monitoring regulations; in Ontario, MAID deaths are reported to the Office of the Chief Coroner	Same as Track 1

MAID in Numbers

Health Canada's *Sixth Annual Report on Medical Assistance in Dying in Canada* describes 2024 (Health Canada, 2025). That year, 16,499 people received MAID, which was 5.1% of all deaths in Canada and 6.9% more than in 2023. Of these, 15,767 (95.6%) were Track 1 and 732 (4.4%) were Track 2. Cancer was the most common underlying condition in Track 1 (63.6%), while neurological

and "other" conditions were cited most often in Track 2. In both tracks, the most commonly reported source of suffering was loss of the ability to take part in meaningful activities. NPs made up 6.8% of the 2,266 practitioners who provided MAID.

Nurses and MAID

Only physicians and NPs may assess eligibility and provide MAID. An NP who provides MAID also reports it and ensures that unused medication is safely disposed of (CNO, 2025). RNs and RPNs may not assess eligibility or give the substance. They may help the physician or NP, for example by inserting an intravenous line when ordered, and they teach, comfort and support the patient and family before, during and after MAID. The Criminal Code protects anyone who helps a physician or NP provide MAID lawfully (Criminal Code, 1985, s. 241(3)).

Counselling a person to die by suicide remains a criminal offence. However, a health care professional who gives information about the lawful provision of MAID commits no offence (Criminal Code, 1985, s. 241(5.1)). Nurses who give information must not encourage or pressure a patient to choose MAID (CNO, 2025). When a patient raises MAID, the nurse listens, explores what lies behind the question, answers factually and tells the NP or physician so that all options, including palliative care, can be offered. In Ontario, the provincial **Care Coordination Service** gives information about MAID and other options at the end of life and accepts self-referrals as well as referrals from clinicians (Government of Ontario, 2024).

No one can be compelled to provide or assist with MAID (Criminal Code, 1985, s. 241.2(9)). A nurse who declines for reasons of conscience is making a **conscientious objection**. CNO (2025) expects the nurse not to share the objection with the patient or express moral judgments, to transfer the patient's care to another nurse or provider (the employer can help find one), and to keep giving all other nursing care until a replacement takes over. The patient is never abandoned. Physicians and NPs who object must refer the patient in a timely manner to another physician or NP who provides MAID (CNO, 2025; Government of Ontario, 2024).

The nurse documents care, teaching and the patient's own words about any request (Chapter 1, section 1.5). The nurse uses neutral terms such as "MAID", avoids language that judges the person's choice and respects every patient and family, whatever they decide. MAID can affect nurses deeply, whatever their views; debriefing and peer support help (section 10.6).

> **SCOPE IN PRACTICE**
>
> **Nurses' Roles in MAID and Pronouncing Death**
>
> CNO's Scope of Practice standard asks every nurse to consider authority, competence and context (Chapter 1, section 1.3).
>
> - **Authority:** The Criminal Code allows only physicians and NPs to assess eligibility and provide MAID. RNs and RPNs may aid them, give information and give care, and may act as an independent witness, but may never give the substance (CNO, 2025).
> - **Competence:** The nurse takes part only in activities they have the knowledge, skill and judgment to do safely, such as intravenous (IV) insertion, family support and teaching.
> - **Context:** Employer policy may narrow these roles, and the law and regulator guidance differ by province and territory.
> - **Conscientious objection:** Hand care over to another nurse or provider (the employer can help), say nothing judgmental, and keep giving other care until a replacement takes over.
> - **Pronouncing death:** In Ontario, no legal requirement bars RNs or RPNs from pronouncing death; the nurse checks the employer's policy on who may do it (CNO, n.d.-a). **Pronouncement of death** is different from certifying death.
> - **Certifying death:** NPs may complete the medical certificate of death in broad circumstances, including in hospitals. Since July 1, 2025, RNs (General Class) may certify certain expected deaths, but not in public hospitals and never after MAID (CNO, n.d.-b). Physicians also certify death.

10.5 The Last Days and Care After Death

In the last days of life, care focuses fully on comfort, dignity and the people at the bedside. This section builds on the goals-of-care conversations in section 10.2 and the symptom management in section 10.3. It describes how the nurse recognizes that death is near, gives comfort care, and acts when death occurs.

Recognizing That Death Is Near

Some signs appear days or weeks before death, and others usually appear only in the last few days. The Registered Nurses' Association of Ontario (RNAO, 2011) lists common signs of imminent death. They include:

- sleeping much of the time, and a lower level of consciousness not explained by another cause;
- progressive weakness and being bedbound;
- difficulty swallowing and taking little food or fluid;
- changes in breathing pattern, including pauses (**apnea**) and **Cheyne-Stokes respiration**, a cycle of deepening and then shallower breaths followed by a pause;
- noisy breathing from secretions in the throat;
- cooling and mottling of the extremities;
- less urine, or darker urine;
- **delirium** with no reversible cause.

In a study of 357 people with advanced cancer in two palliative care units, reduced consciousness, low function and trouble swallowing liquids appeared early but did not predict the timing of death well. Five signs mostly appeared in the final 3 days of life and strongly predicted death within that time: no radial pulse, breathing with movement of the jaw, reduced urine output, Cheyne-Stokes breathing and noisy breathing from secretions, often called the "death rattle" (Hui et al., 2014). Noisy breathing affects about one in three dying people; across studies, death followed its onset after a median of 11 to 28 hours (Lokker et al., 2014).

Mottling is a patchy, lace-like discolouration of the skin caused by poor blood flow, often first seen over the knees. It can be hard to see on darker skin; one study of mottling excluded patients with dark skin because it could not be scored (Bourcier et al., 2017). The nurse does not rely on colour alone: they feel the hands, feet and knees for coolness and compare them with the trunk, look at the nail beds and lips, and ask the family what they have noticed (see Chapter 4, section 4.6).

Restlessness near death has many causes. **Terminal restlessness** is agitation or delirium in the last days that has no reversible cause. Before using that label, the nurse looks for causes that can be treated, such as pain, a full bladder, constipation or a medication effect (see section 10.3 and Chapter 8).

When these signs appear, the nurse tells the physician or NP and the family. The team then reviews orders so that they match the patient's goals.

Comfort Care

Comfort care keeps what helps and stops what does not. With the physician or NP, and as policy and orders allow, the team stops interventions that no longer serve the patient's goals. Examples include routine vital signs, blood tests, repositioning schedules designed to prevent problems in the future rather than to give comfort, and medications that no longer give a benefit. Interventions that relieve symptoms continue (Table 10.3).

- **Mouth care:** Moisten and clean the mouth and lips often; a dry mouth is common when a person breathes through the mouth and takes little fluid.
- **Positioning:** Turn the person for comfort, and place them on their side with the head slightly raised to help secretions drain.
- **Skin and eyes:** Keep skin clean and dry and use pressure-relieving surfaces; moisten dry eyes.
- **Medications:** Give them by a route the person can tolerate. When swallowing fails, the team often uses the **subcutaneous** route, as single doses or a continuous subcutaneous infusion, through a small indwelling needle or catheter.
- **Presence and privacy:** Offer a private room if possible, flexible visiting and a chair or bed for family.
- **Spiritual care:** Ask what matters to the patient and family, offer the chaplain or the family's own spiritual leader, and respect cultural and religious practices (RNAO, 2011; see Chapter 2).
- **Family teaching:** Explain what is happening and what to expect, and check what the family has understood (RNAO, 2011).

No studies have tested suctioning, repositioning or explanation for noisy breathing in the dying person (Lokker et al., 2014). Deep suctioning is invasive and is generally avoided. Gentle suction of the mouth only, repositioning and calm explanation are reasonable

comfort measures.

Table 10.3 Signs that death is approaching and comfort actions (Hui et al., 2014; Lokker et al., 2014; RNAO, 2011)

Sign	What the family may notice	Comfort actions
More sleep, less response	Hard to wake; may not open eyes or speak	Keep talking to the person gently; encourage the family to sit close, hold hands and speak to them
Little or no intake; trouble swallowing	Stops eating and drinking; coughs with sips	Stop oral intake that causes coughing; frequent mouth and lip care; explain that loss of appetite is part of dying
Breathing changes	Pauses in breathing; deep then shallow breaths; jaw moves with each breath	Raise head of bed; explain the pattern to the family; give opioid for distressing breathlessness as ordered
Noisy breathing from secretions	Gurgling or rattling sound with each breath	Turn onto side; gentle mouth suction only; give anticholinergic as ordered; explain that the sound probably does not distress the person
Cool, mottled skin	Hands, feet and knees cool, blotchy or darker; harder to see on dark skin	Light covers; avoid heating pads; check nail beds, lips and limb temperature
Less urine	Little urine; dark urine	Check for a full bladder; keep skin clean and dry; use pads or a catheter if more comfortable
Restlessness or agitation	Picking at covers, moaning, trying to get up	Look for pain or a full bladder; calm, quiet room; familiar voices; medication as ordered; tell the prescriber

MEDICATIONS

Anticipatory Medications at End of Life

Anticipatory medications are drugs ordered in advance, before symptoms arise, so that a dying person can get relief at any hour without waiting for a new order. Professionals believe the practice gives reassurance, controls symptoms and prevents crisis transfers to hospital, but a systematic review found the research evidence for these benefits inadequate (Bowers et al., 2019). They are typically ordered for five common symptoms: pain, breathlessness, nausea and vomiting, agitation, and noisy respiratory secretions (Bowers et al., 2023). The prescriber chooses a drug class for each (see section 10.3):

- an opioid for pain and for breathlessness;
- an antiemetic for nausea and vomiting;
- an antipsychotic, or sometimes a benzodiazepine, for terminal delirium or agitation, as the prescriber decides;
- an anticholinergic (antimuscarinic) for respiratory secretions; evidence that these drugs reduce noisy breathing is weak (Lokker et al., 2014).

Most are given subcutaneously. The nurse:

- assesses the symptom and looks for reversible causes first;
- gives the drug as ordered;
- evaluates and documents the effect;
- tells the prescriber if relief is inadequate;
- teaches the family what each drug is for.

When Death Occurs

When the patient dies, the nurse notes the time of death and follows policy on who pronounces death (see the Scope in Practice box in section 10.4). The nurse informs the physician or NP and the family, if they are not present, using the contact plan agreed on earlier (RNAO, 2011). Family members need time with the person. The nurse offers privacy, a chair and the chance to touch, hold or pray.

Some deaths must be reported to the coroner. In Ontario, these include deaths that occur suddenly and unexpectedly and deaths that appear to result from an accident, suicide or homicide (Government of Ontario, 2026). A coroner may also become involved when there are concerns about the care a person received before death. A death that appears to result from a fall, which is an accident, is

reported even when the patient was receiving palliative care. If a family member raises concerns about the care or treatment the person received, CNO advises nurses not to certify the death, and the threshold for involving the coroner is low (CNO, n.d.-b). The nurse escalates any doubt to the physician or NP and follows hospital policy.

Ontario hospitals designated under the *Gift of Life Act* (1990) must notify Ontario Health (Trillium Gift of Life Network) of patient deaths, and of patients who meet referral indicators before death. For patients who are not on a ventilator, these indicators include a planned discussion about withdrawing or limiting life-sustaining therapy, planned palliation and expected death within an hour. For these patients, notification after death is due within 1 hour. Some patients who cannot donate organs may still be able to donate tissue (Trillium Gift of Life Network, n.d.). Staff do not raise donation with the family before Trillium has checked eligibility and registered consent. If the family asks, the nurse offers to connect them with a donation specialist.

The care of the body follows hospital policy and the wishes of the patient and family. Practices differ widely, so the nurse asks rather than assumes. Some families want to wash or dress the body themselves or with members of their faith community. Some want a spiritual leader present, prayers said, or the body moved quickly so that burial can take place soon. Others want the body left undisturbed for a time. The nurse removes lines and tubes as policy allows; if the death is reportable to the coroner, the nurse checks policy first, because lines and tubes may need to stay in place. The nurse gently closes the eyes and mouth, and labels and documents the body and belongings carefully.

PATIENT EDUCATION

What Families Can Expect in the Last Days

- Your family member will sleep more and may be hard to wake. Keep talking to them gently; your voice and touch can still bring comfort.
- They will eat and drink very little. This is part of dying, not starvation. Small sips or mouth swabs keep the mouth moist.
- Breathing may change. There may be pauses, or deep breaths followed by shallow ones.
- A gurgling sound may come from saliva in the throat. Experts doubt that this sound distresses the dying person (Lokker et al., 2014), but it can upset those who hear it. Turning them onto their side may help.
- Hands and feet may feel cool and change colour. A light blanket is enough.
- They may become restless. Tell the nurse; there are things that help.
- Call the nurse at any time if you are worried. At home, keep the palliative team's 24-hour number close by.
- It is all right to rest, eat and step out. Some people die when their family has left the room for a moment, and that is no one's failure.

GOING DEEPER

Palliative Sedation and the "Double Effect" Myth

Required for RN students; optional for PN students.

Palliative sedation is the closely monitored use of medications to reduce consciousness, in proportion to need, so as to relieve refractory suffering in a person with a life-limiting disease (Surges et al., 2024). Refractory means it cannot be relieved by other means or is intolerable to the patient. Canadian palliative care physicians published a consensus framework for continuous palliative sedation (Dean et al., 2012); the revised European framework stresses these points:

- **Proportionality:** Drugs are titrated to the lowest dose that gives adequate relief, and lighter or intermittent sedation comes first where possible.
- **Monitoring:** Comfort and sedation are assessed with tools such as the Richmond Agitation-Sedation Scale–Palliative version, and the rationale and planned depth are documented.
- **Aim:** To ease suffering that nothing else relieves, never to end life sooner. This sets it apart from MAID, which ends life at a capable person's request.

Many people believe that end-of-life opioids or sedation hasten death. A systematic review found that palliative sedation, when properly indicated and used, was not associated with shorter survival (Maltoni et al., 2012). A review of opioids given to control symptoms in advanced cancer and the last days of life likewise found no link with survival (López-Saca et al., 2013). No randomized trials exist, so this evidence has limits.

The **principle of double effect** holds that an act aimed at a good effect can be acceptable despite a foreseen but unintended harmful effect. The harm must not be the means to the good, and the act must be proportionate. Some authors argue that the

> principle does not fit palliative sedation, because properly used sedation has not been shown to hasten death and intentions are often mixed (Faris et al., 2021; Maltoni et al., 2012). Fear of hastening death should not stop a nurse from giving ordered symptom relief.

10.6 Grief and Caring for Ourselves

Death ends one person's life and changes many others. Families grieve, and so do nurses. This section describes grief and bereavement, and how nurses care for themselves and one another.

Grief and Bereavement

Grief is the emotional, physical and spiritual response to loss. **Bereavement** is the state of having lost someone through death. **Anticipatory grief** begins before the death, as the patient and family face losses that are coming: abilities, roles, plans and, finally, life. Families may feel sadness, guilt, relief and exhaustion all at once. The nurse acknowledges these feelings as normal.

Grief usually brings intense sadness, longing, disturbed sleep and trouble concentrating for a time, and it eases gradually. Typical grief is not a disorder, and most people's grief lessens without treatment (American Psychiatric Association [APA], n.d.). In 2022, the APA added **prolonged grief disorder** to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, text revision (DSM-5-TR). It describes grief that stays intense and disabling long after a death: at least 12 months for adults (6 months for children and adolescents). Along with intense longing for, or preoccupation with, the person who died, the person has at least three of these symptoms nearly every day for at least the last month:

- a sense that part of themselves has died;
- strong disbelief about the death;
- avoiding reminders that the person has died;
- intense emotional pain;
- difficulty re-engaging with people and activities;
- emotional numbness;
- a sense that life is meaningless;
- intense loneliness.

The grief causes significant distress or impairment and lasts longer than the person's cultural, religious or social norms would lead others to expect. An estimated 4% to 15% of adults who are bereaved have persistent symptoms (APA, n.d.). Grief-focused psychotherapy can help. The nurse does not diagnose the disorder but can recognize grief that is not easing and suggest the person speak with their primary care provider.

Grief is expressed in many ways. Mourning rituals, the expression of emotion and beliefs about what happens after death vary across cultures, faiths and families, and suffering takes its meaning from these traditions (RNAO, 2011; see Chapter 2). Some families grieve openly and loudly; others grieve quietly or in private. Neither pattern shows more or less love, and the nurse asks rather than assumes.

At the bedside, the nurse supports families by explaining what is happening, inviting them to take part in care if they wish, and allowing time after the death. Before the family leaves, the nurse gives practical information on next steps and on bereavement resources, such as hospital or hospice bereavement programs and the Canadian Virtual Hospice (virtualhospice.ca).

Nurses' Wellbeing

Caring for dying patients is meaningful work, and it is also demanding. Nurses grieve patients they have known, especially after long admissions, sudden deaths or deaths that did not go as hoped. A death at work can also stir up a nurse's own past losses. RNAO (2011) encourages nurses to reflect on their own attitudes and feelings about death, because this self-awareness supports both their care and their own coping.

Moral distress was first described as knowing the right thing to do while institutional constraints make acting on it nearly impossible (Jameton, as cited in Morley et al., 2020). Researchers now describe it more broadly. It is psychological distress, such as anger, frustration, guilt or powerlessness, caused by a moral event: a constraint, a conflict, a dilemma, uncertainty or tension (Morley et al., 2020). In end-of-life care, it can arise when treatment seems to prolong suffering, when symptoms are poorly controlled, or when staffing prevents a nurse from being present. Unaddressed, it is linked to withdrawal from patients and to nurses leaving their jobs or the profession (Morley et al., 2020).

Compassion fatigue describes the emotions and behaviours that can result from repeatedly learning about, and caring for, other people's suffering and trauma. It overlaps with burnout and secondary traumatic stress. Heavy workloads, low resilience and long, intense stress raise the risk. Supportive colleagues, adequate staffing and a positive practice environment lower it (Noor et al., 2025).

RNAO (2011) recommends that nurses' education include self-care and coping strategies and reflection on death and dying, and that organizations recognize nurses' wellbeing as a critical part of quality end-of-life care. Helpful supports include:

- a brief team debrief or pause after a death;
- peer support and mentorship;
- the employer's employee and family assistance program;
- spiritual care staff;
- clear ethics consultation for moral questions;
- sleep, rest, exercise and time away from work.

A nurse who notices lasting sadness, numbness, irritability or dread about going to work is encouraged to speak with a manager, colleague or health professional.

> PRACTICE STORY
>
> **"We Sat With Her"**
>
> *Names and details are fictional; this is a composite story.*
>
> Nurse: Priya Raman, RN. Years in practice: 6. Setting: medical unit, community hospital, Ontario.
>
> Mrs. Halina Sobczak was 91, and her goals were comfort only. At 0200 her breathing became wet and noisy, and she began pulling at her blanket and calling out in Polish. Her only son lived in Calgary.
>
> I checked her first: no full bladder, no grimace when I moved her, a mouth that was very dry. I turned her onto her side, cleaned her mouth and gave the anticholinergic and the antipsychotic from her anticipatory orders. I paged the NP to say that she was now actively dying and that her son needed to know.
>
> Martin, the RPN on my team, stayed with her while I called her son. He asked if he could see her. Our unit had a tablet for video calls, and I booked a Polish interpreter by phone so that he could understand everything I said and ask his own questions. On the screen he said goodbye to her in Polish. Her hand moved on the sheet when she heard his voice. Afterward, he asked for one thing: that a rosary from her bag be placed in her hands and that someone pray with her. Martin found the rosary. The night chaplain came and prayed with her, and the interpreter stayed on the line so that her son could pray too.
>
> By 0400 she was calm and quiet. Martin and I took turns sitting with her between our other patients. She died at 0520 with my hand on her shoulder. I phoned her son, and the interpreter helped us through that call.
>
> Driving home, I cried. I had only known her for one night. At our huddle the next evening, our manager asked how the night had gone, and Martin said, "We sat with her." It helped to say it out loud.
>
> Reflect: How did the RN and the RPN share this patient's care, and which tasks fell within each nurse's scope? What supports would help you after a night like this?

Chapter 10 Summary

Introduction

- For most people in Canada, death follows a progressive illness, and many receive palliative care in hospital only (CIHI, 2023).
- Every nurse gives palliative care; this chapter covers the palliative approach, planning, symptoms, MAID, the last days and grief.

10.1 The Palliative Approach

- Palliative care relieves physical, psychological, social and spiritual suffering for patients and families, from diagnosis onward, not only at the end of life.
- The palliative approach builds palliative principles into everyday care by all providers, with specialists for complex needs.
- Three illness trajectories (cancer, organ failure, frailty and dementia) guide when to start and revisit conversations.
- CIHI found that 58% of people who died in 2021–2022 in four jurisdictions were identified as receiving palliative care, often late and, for most, in hospital only; people with dementia and those aged 85 and older were less likely to receive it.
- Equitable care is distinctions-based for First Nations, Inuit and Métis peoples and attends to rural residents, people experiencing homelessness, chosen family and language.

10.2 Advance Care Planning and Goals of Care

- In Ontario, advance care planning, goals-of-care discussions and informed consent are separate conversations; wishes are not consent.
- SDMs follow applicable wishes the person expressed while capable, otherwise the person's best interests; a power of attorney for personal care names a chosen SDM.
- Other provinces use instruments such as Alberta's personal directive and British Columbia's advance directive and representation agreement.
- Nurses notice cues, start and support serious illness conversations, use professional interpreters and document what matters to the patient.
- Under CPSO policy, a no-CPR order does not require consent, but the physician must inform, explain and support; the nurse confirms and clarifies code status.

10.3 Managing Symptoms

- Symptoms are assessed regularly with self-report tools such as ESAS-r, or observational tools when the patient cannot report, and with attention to total pain.
- For dyspnea, a fan to the face, positioning, breathing techniques and calm presence come first; opioids are the main drug class, and oxygen is for hypoxemia.
- Antiemetics are matched to the cause of nausea, and laxatives are started whenever an opioid is started.
- Cachexia cannot be fully reversed by feeding; artificial nutrition and hydration is a values-based treatment decision.
- Noisy respiratory secretions near death do not appear to distress the patient; repositioning, mouth care and family explanation are the core of care.

10.4 Medical Assistance in Dying

- MAID is legal across Canada under the Criminal Code (Bill C-14, 2016; Bill C-7, 2021). It may be clinician-administered or self-administered, and only physicians and NPs may assess and provide it.
- Eligibility: government-funded health services; 18 or older and capable; a grievous and irremediable condition; a voluntary request; and informed consent. Mental illness as the sole underlying condition is excluded until March 17, 2027, and the government announced on October 7, 2026, that it intends to extend the exclusion indefinitely. Check the current law.
- Track 1 (natural death reasonably foreseeable) and Track 2 (not reasonably foreseeable) both need a witnessed written request and two independent assessments. Track 2 adds expert consultation when needed, discussion of other means of relief and at least 90 clear days. Final consent may be waived only in Track 1.
- In 2024, MAID was provided to 16,499 people (5.1% of deaths in Canada); 4.4% were Track 2.
- RNs and RPNs may aid, inform and care, but never counsel or encourage MAID or give the substance. Nurses who object transfer care through the employer without abandoning the patient. Ontario's Care Coordination Service accepts self-referrals.

10.5 The Last Days and Care After Death

- Signs that death is near include more sleep, little intake, breathing pauses, noisy secretions, cool mottled skin, less urine and restlessness. Reduced urine output, Cheyne-Stokes breathing and noisy breathing strongly suggest death within about 3 days.
- Mottling is hard to see on darker skin, so check temperature, nail beds and lips as well.
- Comfort care stops interventions that no longer help and focuses on mouth care, positioning, subcutaneous medications, presence and teaching. Anticipatory medications are ordered in advance so that relief can be given at any hour.
- In Ontario, reportable deaths (for example, sudden, unexpected or accidental deaths) go to the coroner, and designated hospitals notify Trillium Gift of Life Network of deaths and of referral indicators. Ask the family about cultural and religious practices for care of the body.
- Palliative sedation is proportional and monitored, and it differs from MAID. Properly used opioids and sedation have not been shown to shorten life (Going Deeper).

10.6 Grief and Caring for Ourselves

- Anticipatory grief begins before death. Typical grief is not a disorder, and its expression varies across cultures and families.
- Prolonged grief disorder (DSM-5-TR) is disabling grief lasting at least 12 months in adults and exceeding cultural norms.
- Nurses experience grief, moral distress and compassion fatigue. Debriefing, peer support, employee assistance and self-care help, and organizations share responsibility for nurses' wellbeing.

Key Terms (43)

advance care planning (ACP): A voluntary process in which a capable person confirms or chooses a substitute decision-maker and shares wishes, values and beliefs about future care; in Ontario it is not consent.

anticipatory grief: Grief that begins before a death, as the patient and family face coming losses.

anticipatory medications: Drugs ordered in advance for expected end-of-life symptoms so that relief can be given at any hour.

apnea: A pause in breathing.

artificial nutrition and hydration: Nutrition and fluids given by tube or by the intravenous or subcutaneous route; a medical treatment that requires a values-based decision and consent.

bereavement: The state of having lost someone through death.

cachexia: A syndrome of continuing skeletal muscle loss (with or without loss of fat) that usual nutritional support cannot fully reverse and that steadily worsens function.

Care Coordination Service: Ontario's provincial service that gives information about MAID and other options at the end of life and connects people, including those who refer themselves, with physicians and NPs who provide MAID.

Cheyne-Stokes respiration: A cyclic breathing pattern of deepening and then shallower breaths followed by a pause.

clinician-administered MAID: The form of MAID in which a physician or NP gives the substance.

compassion fatigue: The emotions and behaviours that can result from repeatedly learning about, and caring for, other people's suffering and trauma.

conscientious objection: A health professional's refusal, for reasons of conscience or religion, to take part in a lawful service such as MAID; nurses must transfer care without abandoning the patient.

Consent and Capacity Board: An independent Ontario tribunal that hears disputes about capacity findings, substitute decision-making and withdrawal of life-sustaining treatment.

dyspnea: The subjective experience of breathing discomfort.

end-of-life care: The part of palliative care given when death is expected in the near future, focused on comfort, dignity and family support.

goals of care: A discussion during a serious illness about the illness, its likely course and what matters most to the person, used to match treatment options to the person's goals.

grief: The emotional, physical and spiritual response to loss.

grievous and irremediable medical condition: An illness, disease or disability that is serious and incurable, with an advanced, irreversible decline in capability and enduring, intolerable suffering that cannot be relieved under conditions the person considers acceptable.

hospice: In Canada, a term used interchangeably with palliative care and often applied to community-based care; a hospice residence is one setting for care near the end of life.

illness trajectory: The typical pattern of a person's function over time as a serious illness progresses, such as the patterns seen in cancer, organ failure and frailty or dementia.

medical assistance in dying (MAID): Under the Criminal Code, a physician or NP either giving a person, at their request, a substance that causes death, or prescribing or providing one that the person takes themselves.

moral distress: Psychological distress, such as guilt, anger or powerlessness, caused by a moral event such as a constraint, conflict, dilemma or uncertainty.

mottling: Patchy, lace-like discolouration of the skin caused by poor perfusion, often seen first around the knees; hard to see on darker skin.

palliative approach: The integration of core palliative care principles into everyday care by all providers, early in a serious illness and in every setting, with specialists supporting complex needs.

palliative care: Care that aims to prevent and relieve suffering and improve quality of life for people who have a life-limiting illness and for those close to them, from diagnosis onward.

palliative sedation: The closely monitored use of medications to reduce consciousness, in proportion to need, so as to relieve refractory suffering in a person with a life-limiting disease.

personal directive: In Alberta, a legal document naming an agent who will make personal decisions that are not financial; it takes effect only after the person is found to lack capacity.

power of attorney for personal care: In Ontario, a legal document under the Substitute Decisions Act, 1992 that names an attorney to make personal care decisions, including health care, if the person becomes incapable.

principle of double effect: The ethical principle that an act aimed at a good effect may be acceptable even if a harmful effect is foreseen but not intended, provided the harm is not how the good is achieved and the act is proportionate.

prolonged grief disorder: A DSM-5-TR diagnosis of intense, disabling grief lasting at least 12 months after a death in adults (6 months in children and adolescents) and exceeding cultural norms.

pronouncement of death: Determining and recording that a person has died; distinct from certifying the cause of death on the medical certificate of death.

reasonably foreseeable natural death: The test that decides which set of MAID safeguards applies; it is no longer an eligibility criterion.

respiratory secretions: Saliva and secretions that pool in the upper airway near death, causing noisy breathing (the "death rattle") when the person can no longer swallow or cough effectively.

self-administered MAID: The form of MAID in which the person takes a substance prescribed or provided by a physician or NP.

serious illness conversation: A structured discussion with a seriously ill person about understanding, prognosis, goals, fears, sources of strength and acceptable trade-offs, used to guide future care.

specialist palliative care: Care given by interprofessional teams with advanced palliative training, usually for patients with complex needs.

substitute decision-maker (SDM): The person who makes health care decisions for a patient who is incapable of making a particular decision.

terminal delirium: Delirium in the last days of life that is part of the dying process and usually not reversible; care focuses on comfort and safety.

terminal restlessness: Agitation or delirium in the last days of life that has no reversible cause.

total pain: Cicely Saunders's concept of suffering with physical, psychological, social, emotional and spiritual parts.

Track 1: The MAID pathway for a person whose natural death is reasonably foreseeable.

Track 2: The MAID pathway for a person whose natural death is not reasonably foreseeable; it adds consultation with an expert when neither assessor has expertise in the condition, discussion of other means of relief and at least 90 clear days from the first assessment to provision.

waiver of final consent: A written arrangement, available only in Track 1, that allows MAID to proceed on a set date if the person loses capacity, unless they refuse or resist by words, sounds or gestures; also called Audrey's Amendment.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Tomas Reyes (Questions 1–4): Tomas Reyes, 84, has advanced heart failure and lives alone in Kingston, Ontario. He was admitted to a medical unit 5 days ago and has become drowsy and confused; the physician has found him incapable of making treatment decisions. Two years ago, Mr. Reyes made a power of attorney for personal care naming his niece, Lena, as his attorney. He also has a son who lives in another province. The team has arranged a goals-of-care meeting with Lena.

1. [CORE] The physician proposes inserting a feeding tube for Mr. Reyes. From whom must the team obtain consent?

a. Mr. Reyes's son, because he is Mr. Reyes's closest living relative

b. No one, because Mr. Reyes wrote down his wishes when he was capable

c. Lena, because she is named as his attorney for personal care

d. The physician, who may decide in an incapable patient's best interests

Answer: c — In Ontario, consent for a treatment proposed for an incapable patient comes from the substitute decision-maker at the time of the decision, and a person named in a power of attorney for personal care ranks above relatives (section 10.2; Chapter 1, section 1.5). The son (a) ranks below the named attorney. Written wishes (b) guide the SDM but are not consent. The physician (d) proposes treatment but does not consent on the patient's behalf outside the limited emergency exception.

2. [CORE] At the meeting, Lena says, "I can't lose him. I want everything done, even a breathing machine." Last year Mr. Reyes told her he would not want to be kept alive on machines if he could no longer recognize his family. Which response by the nurse is most appropriate?

a. "This is hard. What do you think your uncle would want, based on what he told you when he was well?"

b. "As his attorney, you should decide based on what feels right to you as his closest family member."

c. "Because he told you his wishes, the team will make the decision and you will not have to choose."

d. "Perhaps his son should make this decision, since you are finding it too difficult to decide."

Answer: a — An SDM must follow wishes the person expressed while capable that apply to the situation, and decide in the person's best interests only when no applicable wish is known (section 10.2). Acknowledging her distress and asking what he would want guides Lena toward that duty (a). Her own preferences (b) are not the standard. The team does not take over the decision (c); wishes guide the SDM, who still gives or refuses consent. The son (d) does not replace the named attorney simply because the decision is difficult.

3. [CORE] Which action best reflects the nurse's role in Mr. Reyes's goals-of-care meeting?

a. Telling Lena how many weeks Mr. Reyes is likely to live before the physician joins the meeting

b. Asking Lena to sign a form agreeing to the no-CPR order so the team has her consent

c. Leaving the meeting to the physician because goals-of-care discussions are outside nursing practice

d. Sharing what the nurse has observed, checking Lena's understanding and exploring Mr. Reyes's values with her

Answer: d — Nurses support goals-of-care discussions by contributing observations, clarifying understanding, exploring values and following up (section 10.2). Prognosis and treatment options are explained by the physician or NP, so the nurse does not give a time estimate alone (a). Under the CPSO policy, a no-CPR order does not require consent, although the physician must inform and discuss it, so a consent form is not the nurse's task (b). Nurses have a central role in these conversations, so stepping away (c) is not appropriate.

4. [CORE] After the meeting, the physician's progress note says that a no-CPR order was discussed with Lena, but there is no order in the chart, and the unit board lists Mr. Reyes as "full code." What should the nurse do first?

a. Change the board to "no CPR," because the progress note documents the discussion

b. Contact the physician now to clarify and confirm the code status order

c. Wait until morning rounds to raise it, because Mr. Reyes is stable at the moment

d. Ask Lena to put Mr. Reyes's wishes about resuscitation in writing so the nurse can update the board

Answer: b — A missing or conflicting code-status order must be clarified at once with the physician or NP (b); the nurse then documents the clarification and includes code status in handover (section 10.2). The nurse cannot act on a progress note in place of an order (a). Waiting (c) leaves a mismatch that could lead to the wrong response in an arrest. A written statement from the SDM (d) is not an order and does not resolve the conflict.

5. [CORE] A patient with advanced lung cancer is short of breath at rest. Her oxygen saturation is 95% on room air. Which non-drug measures should the nurse include in her care? Select all that apply.

a. Direct a handheld fan toward her face.

b. Start oxygen at a high flow rate to relieve her breathlessness.

c. Help her sit upright, leaning forward on an over-bed table.

d. Coach her in pursed-lip breathing and relaxation.

e. Stay with her and speak in a calm, slow voice.

f. Lower the head of the bed so that she can rest flat.

g. Keep the room door closed and turn up the heat.

Answer: a, c, d, e — Airflow from a fan to the face, an upright or forward-leaning position, breathing and relaxation techniques and a calm presence are recommended comfort measures for dyspnea (section 10.3). Oxygen (b) is not recommended for breathlessness when saturation is above 90% on room air, and oxygen is a drug, not a non-drug measure. Lying flat (f) usually worsens breathlessness. A warm, closed room (g) reduces airflow and often worsens the sensation.

6. [CORE] Which statement best describes the palliative approach to care?

a. Transferring a patient to a palliative care unit once curative treatment has stopped

b. Building palliative care principles into everyday care by all providers, early in a serious illness

c. Caring for a patient during the last days of life, when death is expected within hours to days

d. Referring every patient with a life-limiting illness to a specialist palliative care team at diagnosis

Answer: b — The palliative approach brings the core elements of palliative care into care given by all providers, early and in every setting, with specialists supporting them as needed (section 10.1). Waiting until curative treatment stops (a) delays care the patient could already benefit from. Care in the last days (c) describes end-of-life care, only one part of palliative care. Referring everyone to specialists (d) is neither necessary nor possible; generalists provide most of the palliative approach.

7. [CORE] A patient with severe COPD has just been discharged after his third hospital admission this year. He has not talked with anyone about his future care. Based on his likely illness trajectory, which plan is most appropriate?

a. Delay advance care planning until his function declines steadily, because the timing of death in COPD is predictable.

b. Wait until he loses the capacity to make decisions, then hold a goals-of-care meeting with his family.

c. Focus on goals-of-care discussions only if he is diagnosed with lung cancer, because COPD is not a life-limiting illness.

d. Start advance care planning now and revisit it after each exacerbation, because any flare-up could be life-threatening.

Answer: d — Organ failure such as COPD typically follows long-term limitation with intermittent exacerbations, and death can come suddenly during one of them, so planning starts early and is revisited after each admission (section 10.1). The timing of death in COPD is hard to predict (a). Waiting until he loses capacity (b) removes his own voice from the planning. Advanced COPD is a life-limiting illness that warrants a palliative approach (c).

8. [CORE] A patient with advanced heart failure has an order for a low-dose opioid as needed for breathlessness. His daughter says, "I don't want him to have morphine. I'm afraid he'll get addicted, or that it will kill him." Which response by the nurse is best?

a. "Many families worry about that. With a low starting dose and careful monitoring, it is a safe, standard treatment. What worries you most?"

b. "There is no chance of any side effects at the low dose he has been ordered, so you do not need to worry about it."

c. "We will save the morphine until he is very close to death, because that is when it will help him the most."

d. "If you are worried, I will stop the morphine order right away, and we will use oxygen for his breathing instead."

Answer: a — The nurse acknowledges the fear, explains that low-dose opioids adjusted to the response and monitored are a safe, standard treatment for dyspnea, and invites further discussion (section 10.3). Claiming no side effects (b) is false; opioids cause effects such as constipation and need monitoring. Saving opioids for the end (c) leaves him breathless now and feeds a common myth. The nurse cannot cancel an order (d), and oxygen helps only if he is hypoxemic.

9. [CORE] An RPN in Ontario is caring for a patient with advanced cancer whose goals of care focus on comfort. The patient has been settled for 2 days. Now the patient has a new fever, a respiratory rate of 32 and sudden pain in one leg, and the family is upset. What is the RPN's best action?

a. Continue the current plan, because comfort-focused goals mean new findings do not need to be reported

b. Ask the family to decide whether the changes should be reported to the physician

c. Provide immediate comfort, consult the RN about the change in condition and notify the physician or NP according to policy

d. Transfer care of the patient to another RPN, because a palliative patient whose condition changes is outside RPN scope

Answer: c — Every nurse who notices a change acts at once and escalates, and the RPN consults the RN when a patient's needs change; employer policy sets how the physician or NP is notified (section 10.3; Chapter 1, section 1.3). Comfort-focused goals (a) do not remove the duty to report new findings, which may have a treatable or symptom-relieving response. The decision to report (b) belongs to the nurse, not the family. Caring for palliative patients is within RPN practice (d); what changes is the need to consult the RN as the patient's needs change.

Case: Mrs. Evelyn Baptiste (Questions 10–15): Mrs. Evelyn Baptiste, 88, has advanced lung cancer and is on a medical unit. Her goals of care are comfort only, and there is a do-not-resuscitate order. Anticipatory subcutaneous orders include an opioid, an antipsychotic and an anticholinergic, as needed. At 0300 her breathing is noisy and gurgling, with pauses of up to 20 seconds. She is moaning, picking at her sheets and trying to climb out of bed. She has taken nothing by mouth for 2 days and has not voided for 9 hours. Her feet and knees are cool. Her daughter, at the bedside, is crying and says, "She's choking. Please do something."

10. [CORE] Which findings are cues that Mrs. Baptiste may be in the last hours to days of life? Select all that apply.

a. Pauses in breathing of up to 20 seconds

b. Her daughter crying at the bedside

c. Cool feet and knees

d. No oral intake for 2 days

e. Noisy, gurgling breathing

f. A do-not-resuscitate order on the chart

Answer: a, c, d, e — Apnea, cool extremities, very low intake and noisy breathing from secretions are common signs that death is near (section 10.5; Table 10.3). The daughter's distress (b) is an important cue for family support, but it is not a sign of the patient's dying. A do-not-resuscitate order (f) reflects a decision about care, not a physical sign.

11. [CORE] The nurse analyzes Mrs. Baptiste's restlessness. Which finding most needs follow-up before the restlessness is attributed to the dying process?

a. Her age of 88 years

b. Pauses in her breathing

c. No urine output for 9 hours

d. Her lung cancer diagnosis

Answer: c — Terminal restlessness is a label used only after reversible causes are ruled out; a full bladder from urinary retention is a common, treatable cause of agitation (section 10.5). Less urine is also expected near death, but the nurse checks the bladder before deciding. Age (a) and diagnosis (d) do not explain new agitation. Breathing pauses (b) are a sign of dying, not a cause of restlessness.

12. [CORE] The nurse finds no distended bladder. Which concern has the highest priority now?

a. Distress from agitation that may include pain

b. Dehydration needing intravenous fluids

c. Aspiration pneumonia needing antibiotics

d. Low oxygen saturation needing frequent monitoring

Answer: a — Her goals are comfort, so relieving distress from agitation, which may include pain, comes first (sections 10.3 and 10.5). Intravenous fluids (b), antibiotics (c) and frequent oxygen monitoring (d) aim to treat or measure problems rather than relieve suffering. They do not match her goals, and some could add to her burden.

13. [CORE] Which interventions fit Mrs. Baptiste's goals of care? Select all that apply.

a. Deep suctioning through the nose every hour

b. Turning her onto her side with the head slightly raised

c. Giving the ordered anticholinergic for secretions

d. Checking vital signs every hour

e. Mouth care and moistening her lips

f. Starting a bolus of intravenous fluids

Answer: b, c, e — Side-lying, the ordered anticholinergic and mouth care are comfort measures for noisy breathing and a dry mouth (section 10.5; Table 10.3). Deep suctioning (a) is invasive, and no studies show that it helps. Hourly vital signs (d) and intravenous fluids (f) do not serve comfort-only goals, and fluids may add to secretions.

14. [CORE] The daughter says again, "She's choking." Which response by the nurse is best?

a. "Don't worry. She can't hear you or feel anything now, so there's no need to talk to her."

b. "I'll call the physician to come and suction her lungs so that she can breathe more easily."

c. "This sound means she is in pain, so I'll give her more of her medicine right away."

d. "The sound comes from saliva she can no longer clear. It probably doesn't distress her. Let's turn her onto her side together."

Answer: d — Explaining the cause and involving the family in comfort care eases distress, and evidence suggests the sound is unlikely to distress the dying person (section 10.5; Lokker et al., 2014). Option a is false reassurance and discourages the daughter from speaking to her mother. Deep suction (b) is invasive and has no evidence of benefit. Noisy breathing is not a sign of pain (c).

15. [CORE] One hour after the nurse's actions, which finding shows that the plan is working?

a. Her breathing is still gurgling, and she is still pulling at the sheets.

b. She is lying still with a relaxed face, and her daughter is holding her hand.

c. Her respiratory rate has risen to 28 breaths/min.

d. She has started to take sips of water.

Answer: b — Relief of agitation, a relaxed face and a family able to stay close show that the comfort goals are met (section 10.5). Continued agitation (a) and rapid breathing (c) show distress that calls for reassessment and a call to the prescriber. Sips of water (d) are not the goal and may cause coughing in a person who can no longer swallow safely.

16. [CORE] Under the Criminal Code as of October 25, 2026, which person meets one of the eligibility criteria for MAID?

a. A capable 17-year-old with a serious, incurable illness who asks for MAID

b. An adult whose substitute decision-maker requests MAID on the adult's behalf

c. An adult whose only underlying medical condition is major depression that has not improved with treatment

d. A capable adult with an incurable disease who is in an advanced state of irreversible decline

Answer: d — A grievous and irremediable condition includes an illness, disease or disability that is serious and incurable, with an advanced state of irreversible decline (section 10.4). The person must be at least 18 (a). The request must come from the person, not a substitute decision-maker (b). Mental illness as the sole underlying condition is excluded until at least March 17, 2027, and the government plans to extend that exclusion (c).

17. [CORE] A patient whose natural death is not reasonably foreseeable has made a written request for MAID. Which safeguard applies to this patient but not to a patient whose death is reasonably foreseeable?

a. A minimum of 90 clear days between the start of the first assessment and provision

b. A written request signed and dated in front of an independent witness

c. Two independent written assessments by physicians or NPs

d. A chance to withdraw consent immediately before MAID is provided

Answer: a — Track 2 requires at least 90 clear days for assessments, unless loss of capacity is imminent and both assessments are complete (section 10.4; Table 10.2). A witnessed written request (b), two independent assessments (c) and the chance to withdraw (d) apply in both tracks.

18. [CORE] A patient asks the RPN, "What is MAID, and could I get it?" Which response is most appropriate?

a. "You should think about MAID, given how much you are suffering."

b. "Nurses aren't allowed to talk about MAID. Please ask your doctor."

c. "I can tell you what MAID is. Can you tell me what's making you ask? I'll also let your NP know so that you can talk about all your options."

d. "You don't qualify, because your illness is not terminal."

Answer: c — Nurses may give factual information about lawful MAID, explore the question and inform the prescriber, without encouraging the patient (section 10.4). Option a encourages MAID, which CNO forbids and which may amount to counselling. Option b is inaccurate, because the Criminal Code allows health care professionals to give information. Only physicians and NPs assess eligibility, and a terminal illness is not required (d).

19. [CORE] An RN with a conscientious objection to MAID is assigned to a patient who is scheduled to receive MAID tomorrow. What should the RN do?

a. Tell the patient about the objection so that they understand why a different nurse will be caring for them.

b. Ask the charge nurse or manager to transfer the patient's care, and keep giving other care until another nurse takes over.

c. Refuse the assignment and leave the unit until a replacement is found.

d. Arrange for the patient to be assessed by a second NP.

Answer: b — CNO expects the nurse to hand care over to another nurse or provider, working with the employer as needed, and to keep giving all other care until a replacement takes over, without abandoning the patient (section 10.4). The objection must not be shared with the patient (a). Leaving the unit (c) abandons the patient. Ordering assessments (d) is not the RN's role.

20. [CORE] Which sign most strongly suggests that a patient with advanced cancer may die within the next 3 days?

a. Sleeping more during the day
b. Eating less than usual
c. Needing help to walk
d. Greatly reduced urine output

Answer: d — Reduced urine output was one of five signs that appeared mostly in the final 3 days of life and were highly specific for death within that time (section 10.5; Hui et al., 2014). More sleep (a), less eating (b) and weakness (c) often appear earlier, so they predict timing poorly.

21. [CORE] The nurse is assessing perfusion in a dying patient with dark skin. Which approach is best?

a. Feel the hands, feet and knees for coolness, compare them with the trunk, and check the nail beds and lips.
b. Document "no mottling" if no purple pattern is visible on the knees.
c. Use the pulse oximeter reading alone to judge perfusion.
d. Skip perfusion assessment, because colour changes cannot be seen on dark skin.

Answer: a — Mottling can be hard to see on darker skin, so the nurse adds temperature, comparison with the trunk, nail beds, lips and the family's observations (section 10.5). Relying on colour (b) may miss changes. Oximetry (c) does not show skin perfusion, and readings may be unreliable when perfusion is poor. Skipping the assessment (d) leaves the family without preparation.

22. [CORE] A palliative patient in an Ontario hospital dies 1 day after an unwitnessed fall in which she fractured her hip. What should the nurse do?

a. Remove all lines and tubes and prepare the body for the family.
b. Ask the family whether they would like an autopsy.
c. Notify the physician or NP so that the death can be reported to the coroner, and leave lines and tubes in place as policy directs.
d. Complete the medical certificate of death, because the death was expected.

Answer: c — A death that may have resulted from an accident is reportable to the coroner, even when the patient was receiving palliative care (section 10.5). Removing lines (a) may interfere with an investigation. Autopsy decisions (b) rest with the coroner in a reportable death. RNs cannot certify deaths in Ontario hospitals, and an RN may certify only expected deaths without unexpected events, so this death is not one a nurse may certify (d).

23. [CORE] An Ontario hospital patient who is not on a ventilator has a planned family meeting to discuss stopping life-sustaining treatment. The family has not mentioned donation. What is the nurse's responsibility?

a. Tell the family that their relative is too ill to donate organs or tissue.
b. Make sure the team notifies Trillium Gift of Life Network according to hospital policy before donation is discussed.
c. Ask the family to decide about donation before the meeting.
d. Wait to notify Trillium until the family raises the subject of donation.

Answer: b — Designated Ontario hospitals must notify Trillium Gift of Life Network when a patient meets one of its referral indicators, such as a planned discussion to withdraw life-sustaining therapy. Trillium checks eligibility before anyone raises donation with the family (section 10.5). Nurses do not decide eligibility (a) or raise donation first (c). Notification does not depend on the family raising it (d).

24. [CORE] A patient has just died. The family tells the nurse that their faith community has customs for the care of the body. What should the nurse do first?

a. Prepare the body according to the hospital's standard procedure.
b. Call the chaplain to explain the hospital's routines to the family.
c. Tell the family that customs can take place only at the funeral home.
d. Ask the family what they would like done and how the team can help.

Answer: d — Practices after death vary, so the nurse asks the family about their wishes and then works within policy to support them (section 10.5). Using standard procedure first (a) may break an important practice. A chaplain may help, but should not be there to explain routines in place of asking (b). Option c refuses requests that can often be met.

25. [CORE] Which statement about prolonged grief disorder is accurate?

a. In adults, it is diagnosed only when at least 12 months have passed since the death.
b. It is the expected response to the death of a spouse.
c. It is diagnosed when grief includes crying in the first month.
d. It is treated first with medications that target grief.

Answer: a — DSM-5-TR requires at least 12 months since the death for adults (6 months for children and adolescents), with disabling symptoms beyond cultural norms (section 10.6). Typical grief, even after a spouse's death, is not a disorder (b), and crying soon after a loss is normal (c). No medication specifically treats grief symptoms; grief-focused psychotherapy is used (d).

26. [CORE] After three patient deaths in one week, a nurse says she feels guilty and powerless because staffing kept her from being with a dying patient. Which response by the charge nurse is most helpful?

a. "You'll get used to it. Deaths are part of the job."
b. "Try not to think about it at work."
c. "That sounds like moral distress. Let's hold a team debrief, and here is the number for our employee assistance program."
d. "You should consider transferring to a unit with fewer deaths."

Answer: c — Guilt and powerlessness when constraints block what a nurse believes is right describe moral distress, and debriefing and employee assistance are recommended supports (section 10.6). Options a and b dismiss the distress, which, unaddressed, is linked to leaving the profession. A transfer (d) does not address what happened.

27. [RN] Which statement best distinguishes palliative sedation from MAID?

a. Palliative sedation is used only for psychological suffering.
b. Palliative sedation is intended to ease refractory suffering, not to shorten life.
c. Palliative sedation requires a 90-day assessment period.
d. Palliative sedation can be provided only by an NP.

Answer: b — Palliative sedation is the monitored, proportional lowering of consciousness to relieve refractory suffering, while MAID aims to end life at a capable person's request (section 10.5, Going Deeper). Refractory suffering may be physical, psychological or existential, and delirium is the most common reason for sedation (a). The 90-day period is a Track 2 MAID safeguard (c). Palliative sedation is not limited to NPs; the prescriber orders it, and nurses give it and monitor the patient (d).

28. [RN] A patient receiving palliative sedation for refractory delirium is calm and comfortable at a light level of sedation. Which action reflects the principle of proportionality?

a. Increase the infusion to reach deep sedation as soon as possible so that the delirium cannot return.

b. Stop all sedation to assess whether the delirium has resolved.

c. Hold the next dose until the patient is unresponsive.

d. Keep the current level of sedation, and keep monitoring comfort and sedation with a validated tool.

Answer: d — Proportionality means using the lowest level of sedation that gives adequate relief, with ongoing monitoring (section 10.5, Going Deeper). Deepening sedation without need (a) is not proportional. Abruptly stopping sedation (b) risks a return of suffering unless a planned interruption has been agreed on. Waiting for unresponsiveness (c) wrongly treats deep sedation as the goal.

29. [RN] A family member asks, "Will the morphine you're giving her speed up her death?" Which reply is consistent with the evidence?

a. "Studies of opioids used for symptoms at the end of life have not shown that they shorten life."

b. "Yes, it may shorten her life a little, but that is acceptable because it keeps her comfortable."

c. "Only if we give it more often than every 4 hours."

d. "We can stop it if you're worried, even though she is breathless."

Answer: a — Systematic reviews have found no link between opioids used for symptom control and shorter survival (section 10.5, Going Deeper). Option b repeats the myth. Option c invents a rule. Stopping effective symptom relief (d) leaves the patient suffering and does not follow her goals.

30. [RN] Which statement about the principle of double effect in end-of-life care is accurate?

a. It permits a nurse to give medication with the intent of ending the life of a patient who is suffering.

b. It is the legal basis for MAID in Canada.

c. It holds that an act aimed at a good effect may be acceptable even if a harmful effect is foreseen but not intended.

d. It requires the nurse to withhold opioids whenever any harmful effect, such as drowsiness, is possible.

Answer: c — Double effect distinguishes intended good effects from foreseen but unintended harms, and the harm must not be the means to the good (section 10.5, Going Deeper). It never permits intending death (a). MAID rests on the Criminal Code, not on double effect (b). The principle does not require withholding needed opioids (d), and properly titrated opioids have not been shown to hasten death.

11 Substance Use in Acute Care

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Describe substance use as a continuum, the Canadian picture of alcohol harms and the toxic drug crisis, and the structural causes of substance-related harm.
2. Use language and approaches that reduce stigma when caring for people who use substances.
3. Screen hospital patients for alcohol and other substance use, offer a brief intervention and support referral.
4. Recognize, monitor and respond to alcohol withdrawal and Wernicke encephalopathy, including escalation of severe withdrawal.
5. Recognize opioid toxicity and respond with ventilation and naloxone, and recognize and support the care of opioid withdrawal and opioid agonist treatment in hospital.
6. Describe the nursing care of patients with stimulant toxicity, cannabis-related problems and other substance-related presentations.
7. Apply harm reduction principles and plan safe transitions, including take-home naloxone, follow-up and culturally specific supports.
8. Distinguish RN, RPN and NP roles in substance use care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 3, 4, 5, 6	Clinician; Scholar	Foundations of Practice
2, 7	Advocate; Communicator; Educator	Ethical Practice; Collaborative Practice
5, 8	Professional; Collaborator; Coordinator	Legal Practice; Collaborative Practice

Introduction

Substance use is part of everyday care on medical-surgical units. The Canadian Institute for Health Information (CIHI) reports that about 540 people are hospitalized in Canada every day for harm from alcohol or other drugs, and that alcohol accounts for more than half of these hospital stays (CIHI, 2026). The count is conservative. It includes only stays for conditions wholly caused by substance use, such as poisonings and substance-related mental and behavioural conditions, and medical conditions caused by alcohol. Stays for conditions to which substance use only contributes, such as many cancers, strokes, respiratory diseases and injuries, are not counted, and neither are emergency department visits. Nurses therefore meet people who use alcohol and other drugs on every unit, whatever the reason for admission.

This chapter is the book's home for substance use in hospital. Section 11.1 explains the continuum of use, the Canadian picture, structural causes and the harm done by stigma. Section 11.2 covers screening and brief intervention, and section 11.3 alcohol withdrawal and Wernicke encephalopathy. Section 11.4 turns to opioid toxicity and the naloxone response, opioid withdrawal and opioid agonist treatment (OAT) in hospital; section 11.5 to stimulants, cannabis and other substances; and section 11.6 to harm reduction and safe transitions. Related topics live elsewhere: cultural safety and Indigenous health (Chapter 2), electrolytes (Chapter 3), pain care and opioid safety (Chapter 5), rapid response (Chapter 6), delirium (Chapter 8) and liver disease (Chapter 26).

11.1 Substance Use, Stigma and Health

A Continuum of Use

Substance use is not a single behaviour. It runs along a continuum, from no use, through occasional or lower-risk use, to use that raises the risk of harm, to a substance use disorder. A person can move along this continuum in either direction over a lifetime. Most people who drink alcohol or use other drugs do not have a disorder, yet their use can still matter in hospital, for example through drug interactions, injuries or withdrawal.

A **substance use disorder** is a health condition in which a person keeps using a substance despite significant problems linked to that use. Clinicians diagnose it with the criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, text revision (DSM-5-TR). The Canadian alcohol use disorder guideline summarizes the approach: a problematic pattern of use over 12 months that causes clinically significant impairment or distress, shown by at least 2 of 11 criteria (Wood et al., 2023). The criteria fall into four broad groups:

- **Impaired control:** using more or for longer than intended, failed efforts to cut down, much time spent getting, using or recovering, and craving.
- **Social impairment:** failing at major roles, continuing despite relationship problems, and giving up important activities.
- **Risky use:** use in physically hazardous situations, and continued use despite a physical or psychological problem it is making worse.
- **Pharmacological criteria:** tolerance and withdrawal.

Severity depends on the number of criteria met: 2 or 3 is mild, 4 or 5 is moderate and 6 or more is severe (Wood et al., 2023). Nurses do not make this diagnosis, but knowing its structure helps them recognize cues and describe what they observe.

Tolerance and withdrawal alone do not mean a person has a disorder. When a person takes a medicine such as an opioid only as prescribed and under medical supervision, these two criteria are not counted toward the diagnosis (Centers for Disease Control and Prevention [CDC], 2024). Chapter 5, section 5.4, explains tolerance and physical dependence.

The Canadian Picture

Alcohol is the substance behind most hospital stays for substance-related harm (CIHI, 2026). *Canada's Guidance on Alcohol and Health* (Canadian Centre on Substance Use and Addiction [CCSA], 2023) describes risk as rising steadily with the amount a person drinks each week; section 11.2 explains how nurses use it in screening.

Since 2016, Canada has also lived through a public health crisis of deaths from an **unregulated drug supply**: drugs made and sold outside any legal or quality control, often containing fentanyl and other toxic substances of unknown strength. Public health leaders reported 7,146 opioid-related deaths in 2024, an average of 20 people every day, which was 17% fewer than in 2023 (Public Health Agency of Canada [PHAC], 2025). In 2025, there were 5,608 opioid-related deaths, an average of 15 per day, a further 23% decrease. Leaders called this number unacceptably high and noted that the decrease did not happen everywhere: some jurisdictions and communities were still seeing increases in harm (PHAC, 2026). The Canadian Context box gives more detail.

CANADIAN CONTEXT

The Toxic Drug Crisis in Numbers

- **Total:** 57,509 apparent opioid toxicity deaths were reported in Canada from January 2016 to March 2026 (Substance-related Overdose and Mortality Surveillance Task Group on behalf of the Council of Chief Medical Officers of Health, 2026).
- **Early 2026:** From January to March 2026, there were 1,354 apparent opioid toxicity deaths. Most (96%) were accidental. Fentanyl analogues were involved in 70% of these deaths, fentanyl in 36% and a stimulant in 62%. Males accounted for 70%, and people aged 30 to 39 (25%) and 40 to 49 (26%) made up the largest age groups. British Columbia, Alberta and Ontario together accounted for 78% (Substance-related Overdose and Mortality Surveillance Task Group on behalf of the Council of Chief Medical Officers of Health, 2026). Figures for the latest four quarters are preliminary and could still be revised.
- **A changing supply:** Benzodiazepines contributed to 8% of opioid toxicity deaths in 2018 and 34% in 2024. In 2025, stimulant-related deaths outnumbered opioid-related deaths in seven provinces and territories, including Ontario (PHAC, 2026).

- **Unequal harms:** In British Columbia in 2024, the toxic drug death rate among First Nations people was 6.7 times that of other residents of the province (First Nations Health Authority [FNHA], 2025).

Causes Are Structural

Why a person uses substances, and how much harm follows, depends far more on their circumstances than on willpower. Health Canada explains that people develop addictions for many reasons, among them trauma and chronic stress, their surroundings, their mental well-being, and their genes and biology, and that recovery is possible (Health Canada, 2026c). Poverty, unstable housing, untreated pain and mental illness, and past trauma all raise risk. Stigma and unsafe drug supplies then turn risk into harm.

For some First Nations, Inuit and Métis communities, colonization is a root cause. The Truth and Reconciliation Commission called on governments to acknowledge that the current state of Indigenous health is a direct result of past government policies, including residential schools, and named addictions among the health gaps to be closed (Truth and Reconciliation Commission of Canada [TRC], 2015). A scoping review found that residential school attendance was linked with poorer health, including substance use, among survivors and the generations that followed (Wilk et al., 2017). The response begins from strength. The *First Nations Mental Wellness Continuum Framework* places culture at the foundation of wellness and describes mental wellness as a balance supported by hope, belonging, meaning and purpose (Health Canada & Assembly of First Nations, 2015). First Nations leaders in British Columbia frame the toxic drug response as grounded in culture, self-determination, community and kinship (FNHA, 2025). Chapter 2 explains cultural safety and trauma- and violence-informed care.

Stigma and Language

Stigma is a set of negative attitudes, beliefs and behaviours directed at a group because of their situation, expressed as stereotypes, prejudice and discrimination (Health Canada, 2026c). It works at three levels: in how people see themselves (self-stigma), in how others treat them (social stigma) and in rules and systems (structural stigma).

Stigma harms health. People who expect to be judged avoid or delay care and may hide their use or use alone, which raises the risk of dying (Health Canada, 2026c). In health care, stigma is linked with reduced empathy, lower-quality care and poorer treatment outcomes (PHAC, 2019). In a Vancouver study, people who use drugs who had left hospital against medical advice described emergency care in which they felt stigmatized and neglected and their pain and withdrawal were poorly managed; many became less willing to seek care again (Mayer et al., 2023). Chapter 5, section 5.5, covers pain care and patients who want to leave.

Words are one of the easiest places to start. Federal guidance asks health professionals to use **person-first language**, which names the person before the condition, and to avoid terms that frame substance use as a moral failing or a choice (PHAC, 2020). Table 11.1 gives examples.

Table 11.1 Choosing words that reduce stigma (based on Health Canada, 2026c; PHAC, 2019; and PHAC, 2020; original wording)

Instead of	Say	Why
Addict, user, junkie	Person who uses drugs; person with a substance use disorder	Puts the person first; slang labels carry blame
Alcoholic	Person with an alcohol use disorder	Names a treatable health condition, not an identity
Substance abuse, misuse	Substance use; substance use disorder	"Abuse" and "misuse" express judgment and imply wrongdoing
Clean or dirty (test)	Negative or positive test result	Uses clinical terms; "dirty" suggests the person is soiled
Clean (person)	Not currently using; in recovery	Avoids implying that use makes someone unclean
Relapse	Recurrence of substance use; return to use	Treats a return to use as part of a health condition, not a failure
Drug-seeking	Describe what the person said and did, and the need behind it	The label can lead to needed medicine being withheld; a description keeps the assessment open
Non-compliant	Chose not to receive this care; facing barriers to care	Moves attention to barriers the team can address

11.2 Screening and Brief Intervention in Hospital

Ask Everyone

Canada's alcohol guideline recommends routine screening of every adult and young person for drinking above low-risk levels; its 2026 update lists medical wards and emergency departments among the settings where alcohol problems often go undiagnosed (Wood et al., 2023, 2026). Canadian guidance for older adults names hospital admission as a key time to ask (Butt et al., 2020). Screening only patients who "look like" they drink misses many people and reinforces stereotypes, so the nurse asks every patient, in the same way, at admission.

Asking at admission matters for safety. A patient who drinks heavily every day may begin to withdraw within hours of arriving. A patient who uses benzodiazepines, opioids or other drugs not on the medication list may face dangerous interactions with sedating medicines given in hospital. Knowing what a person uses also helps the team plan pain care and offer treatment.

How the nurse asks shapes the answer. The nurse asks in private, explains why the question is asked of everyone, uses neutral words and accepts the answer without comment. A useful opening is: "I ask everyone about alcohol and other drugs, because it helps us keep you safe while you're here." Patients may worry that the information will be shared with police, employers or child welfare services. The nurse can explain how health information is protected and who on the team will see it (Chapter 1, section 1.5).

Screening Tools

Short tools help the nurse ask in a consistent way.

- **Weekly drinks and drinks per occasion:** In 2026, Canada's guideline replaced its earlier screening approach with simpler questions tied to *Canada's Guidance on Alcohol and Health*. The clinician asks how many standard drinks the person has in an average week and whether they now have more than 2 standard drinks on any one evening or occasion, then compares the answers with the guidance. If use is above low risk, a further question asks about difficulty controlling use or about significant problems at work, in relationships or with physical or mental health (Wood et al., 2026).
- **Single alcohol question:** The 2023 guideline began with a single question: how often in the past year the person has had 5 or more drinks in one day (men) or 4 or more (women) (Smith et al., 2009; Wood et al., 2023). A positive answer led to a longer tool. The 2026 update no longer recommends this two-step approach, but nurses may still see these tools on admission forms.
- **AUDIT-C:** The **AUDIT-C** is a short version of the 10-item Alcohol Use Disorders Identification Test (AUDIT) built from its questions about how often and how much a person drinks. The 2023 guideline grouped AUDIT-C scores of 0 to 4 as low risk, 5 to 7 as moderate risk and 8 or more as high risk (Wood et al., 2023).
- **Single drug question:** The clinician asks how often in the past year the person has used an illegal drug or taken a prescription medicine for non-medical reasons. Any answer of one or more times is positive (Smith et al., 2010).

Canada's Guidance on Alcohol and Health describes a continuum of weekly risk. Not drinking has benefits. People who have 2 standard drinks or fewer per week are likely to avoid alcohol-related harm. From 3 to 6 drinks, the risk of several cancers, including breast and colon cancer, rises. At 7 or more, the risk of heart disease and stroke rises significantly. Each additional drink increases risk further, and anyone who drinks more than 2 drinks a week is advised to have no more than 2 on any day. For a person who is pregnant or trying to become pregnant, no amount of alcohol is known to be safe (CCSA, 2023).

Brief Intervention and Referral

A positive screen leads to a conversation, not a lecture. **Brief intervention** is a short, structured conversation, based on motivational interviewing, that helps a person consider their use and decide on a change. Canada's guideline recommends offering it to everyone who screens positive; it can be delivered by many kinds of health professionals, and even one five-minute session can help (Wood et al., 2023). The nurse shares the result, links it to the person's health concern, asks what they think and supports the step they choose.

When use is above low risk with signs of a problem, the guideline recommends a full diagnostic assessment (Wood et al., 2026). Depending on the setting and employer policy, the nurse can suggest or help arrange:

- an **addiction medicine consult service**, where available, for assessment, withdrawal management and starting treatment;

- a **Rapid Access Addiction Medicine (RAAM) clinic** referral after discharge. Ontario has nearly 100 publicly funded RAAM clinics, supported by the META:PHI (Mentoring, Education, and Clinical Tools for Addiction: Partners in Health Integration) network; most see people without an appointment or referral and offer medication, counselling, harm reduction education and links to other services (META:PHI, n.d.);
- community counselling, withdrawal management and peer support;
- Indigenous-led and culturally specific supports, such as Indigenous patient navigators where available (Chapter 2).

11.3 Alcohol Withdrawal

Why Withdrawal Happens

Alcohol slows the brain. It boosts the effect of gamma-aminobutyric acid (GABA), the main calming messenger, and blocks glutamate, the main excitatory messenger, at N-methyl-D-aspartate (NMDA) receptors. With heavy daily drinking, the brain adapts to keep working: GABA activity falls and glutamate signalling increases. The person now needs alcohol to feel normal.

When the person stops drinking or cuts down sharply, the brakes are gone but the accelerator is still pressed. The nervous system becomes overexcited, which causes the tremor, sweating, fast heart rate, agitation and, in severe cases, seizures and delirium of **alcohol withdrawal** (Gortney et al., 2016). Withdrawal can begin while alcohol is still measurable in the blood, so a patient who arrives intoxicated can be withdrawing by the next shift.

Repeated cycles of heavy drinking and withdrawal leave lasting changes in the brain. Each episode tends to be worse than the last, a process called **kindling**. Kindling has also been linked with more craving and a weaker response to benzodiazepines (American Society of Addiction Medicine [ASAM], 2020). A history of severe or complicated withdrawal is therefore an important warning sign.

Timeline and Severity

Withdrawal ranges from mild discomfort to a life-threatening emergency. How severe it becomes depends on how much the person drinks, how long since the last drink and how many withdrawals they have had before (Gortney et al., 2016). Table 11.2 gives typical timing, although individual patients vary and stages can overlap.

- **Minor withdrawal** starts within hours of the last drink, with tremor, sweating, anxiety, palpitations, headache, nausea, poor appetite and insomnia.
- **Alcoholic hallucinosis** is hallucinations, most often visual but also auditory or tactile, in a person who otherwise remains oriented.
- A **withdrawal seizure** is a generalized tonic-clonic seizure, usually in the first two days.
- **Delirium tremens**, also called alcohol withdrawal delirium, is the most severe form: disorientation, fluctuating attention, hallucinations, agitation and autonomic overactivity such as fever, a fast heart rate and high blood pressure. Its mortality has been reported at 5% to 10% (Gortney et al., 2016).

Some cues look different across skin tones. Flushing and pallor are harder to see on darker skin, so the nurse also feels for warm, damp skin and looks for beads of sweat on the forehead, upper lip and palms. Tremor is best seen with the arms held out and fingers spread. Vital signs give objective evidence on every patient: a rising heart rate, blood pressure and temperature signal worsening withdrawal.

There is no single test for alcohol withdrawal; it is a clinical diagnosis. Blood work usually includes electrolytes, magnesium, glucose, liver tests and a complete blood count, and sometimes a blood alcohol level. ASAM advises that withdrawal treatment should not be delayed while results are pending (ASAM, 2020). The team also looks for other causes of the same signs. A seizure is blamed on withdrawal only when drinking recently stopped or decreased (ASAM, 2020); a fall can cause a head injury, and infection, low blood glucose or other drugs can mimic withdrawal.

Table 11.2 Alcohol withdrawal: timeline, cues and nursing actions (Gortney et al., 2016; ASAM, 2020)

Stage	Typical timing after last drink	Cues	Nursing actions
Minor withdrawal	6 to 12 hours	Tremor, sweating, anxiety, palpitations, headache, nausea, poor appetite, insomnia	Assess with the unit's withdrawal scale; give medicines as ordered; quiet room; fluids and food; reassess per protocol
Alcoholic hallucinosis	12 to 24 hours; usually resolves within 48 hours	Visual, auditory or tactile hallucinations; person usually oriented	Reassure and orient; keep the patient safe; report to the registered nurse (RN) or prescriber; reassess often
Withdrawal seizure	24 to 48 hours; can occur as early as 2 hours	Generalized tonic-clonic seizure	Seizure precautions; protect airway and prevent injury; call for help; report at once; closer monitoring afterward
Delirium tremens	48 to 72 hours; can last up to 5 days	Disorientation, mainly visual hallucinations, agitation, fever, tachycardia, high blood pressure, sweating	Call rapid response or the critical care team per policy; constant observation; safety; fluids and electrolytes as ordered

Predicting and Monitoring

Two different tools serve two different jobs. The **Prediction of Alcohol Withdrawal Severity Scale (PAWSS)** estimates, at admission, whether a patient is likely to develop complicated withdrawal: hallucinosis, seizures or delirium tremens. Its 10 items come from risk factors that research has linked with complicated withdrawal, and it was developed for medically ill patients in hospital (Maldonado et al., 2014). Canada's guideline recommends using the clinical history with PAWSS to choose a withdrawal management plan; a score of 4 or more signals high risk (Wood et al., 2023).

The **Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar)** measures how severe withdrawal is right now (Sullivan et al., 1989). The nurse scores 10 areas, some by observation, such as tremor and sweating, and some by asking the patient, such as nausea, anxiety and disturbances in what they see, hear or feel. Higher totals mean more severe withdrawal and guide medication under the unit's protocol (Gortney et al., 2016). In medical and surgical patients, a low score can usually be trusted, but a high score is interpreted with caution (ASAM, 2020).

The CIWA-Ar has important limits (ASAM, 2020):

- It is not a diagnostic tool. Pain, fever, infection, anxiety and other illnesses can raise the score.
- Because much of it depends on what the patient reports, it does not work well for a patient who cannot communicate, including one who is intubated or has a language barrier without an interpreter. Scales that rely more on objective signs are used instead.
- It is not recommended once a patient is delirious. A structured delirium tool is used instead (Chapter 8, section 8.2).

Reassessment follows the protocol. For moderate to severe withdrawal, ASAM (2020) suggests reassessing every 1 to 4 hours, extending the interval once the patient has been stable for a day. The nurse also reassesses after every dose and whenever the patient's condition changes.

Treatment

Canada's guideline is written mainly for primary care, so this section also draws on the ASAM guideline for hospital withdrawal management. **Benzodiazepines** are the first-line medicines for moderate and severe withdrawal, because they calm the overexcited nervous system and prevent seizures and delirium (ASAM, 2020). Longer-acting benzodiazepines are generally preferred because they give a smoother course. For patients with significant liver disease, a benzodiazepine that depends less on the liver is chosen, and older adults need close monitoring because long-acting drugs can build up (ASAM, 2020). Benzodiazepines are used only for the withdrawal period, not as ongoing treatment of alcohol use disorder (Wood et al., 2023).

In hospital, **symptom-triggered treatment** is preferred: medicine is given when the withdrawal score reaches the threshold in the order, rather than on a fixed schedule (ASAM, 2020). This approach usually means less medicine overall. It suits only patients whose symptoms can be assessed reliably, so fixed schedules are used when they cannot, for example right after surgery (Gortney et

al., 2016). Phenobarbital is an alternative only in experienced hands and closely monitored settings (ASAM, 2020). Alcohol itself should never be given to prevent or treat withdrawal (ASAM, 2020).

Supportive nursing care matters as much as medication:

- a quiet, well-lit room, a clock and calendar, and simple, calm explanations;
- fluids, food and help with eating;
- fall precautions and seizure precautions per policy;
- vital signs and sedation checks after each dose;
- monitoring magnesium, potassium and phosphate, which are often low and are replaced as ordered (Chapter 3, sections 3.5 and 3.6).

The nurse escalates promptly. Signs of delirium, a seizure, rising scores despite treatment, oversedation or unstable vital signs are reported at once to the most responsible practitioner (a registered practical nurse [RPN] also consults the RN), and the rapid response team is called per policy (Chapter 6, section 6.2). Severe withdrawal and withdrawal delirium often need critical care and constant one-to-one observation (ASAM, 2020).

Thiamine and Wernicke Encephalopathy

Heavy drinking often reduces how much **thiamine** (vitamin B1) a person takes in and absorbs. Thiamine deficiency can cause **Wernicke encephalopathy**, an acute brain disorder that is a medical emergency. Besides alcohol use disorder, other risk factors include malnutrition, bariatric and other gastrointestinal surgery, prolonged vomiting, cancer and chemotherapy, and malabsorption (Li & Xing, 2025).

The classic triad is confusion, unsteady gait (ataxia) and abnormal eye movements. Only about 10% to 16% of patients show all three, so most cases are missed if the nurse waits for the full picture (Li & Xing, 2025). In a patient at risk, any one of these signs is reported at once. Untreated, Wernicke encephalopathy can lead to coma and death. Many untreated patients develop **Korsakoff syndrome**, a lasting memory disorder in which the person cannot form new memories (Li & Xing, 2025).

Thiamine is given as ordered to everyone at risk. Canada's guideline offers it by mouth before and during withdrawal and by injection when Wernicke encephalopathy is suspected or the person has decompensated liver disease or is at risk of malnutrition (Wood et al., 2023); for inpatients, ASAM prefers the intravenous or intramuscular route, especially with poor nutrition or malabsorption (ASAM, 2020). Thiamine is given before any intravenous glucose, because glucose metabolism uses up the little thiamine that remains and can deepen the deficiency (Gortney et al., 2016; Li & Xing, 2025).

After Withdrawal

Withdrawal management is not treatment of alcohol use disorder. Without further care, many people return to drinking. Canada's guideline recommends naltrexone or acamprosate as first-line medicines for adults with moderate to severe alcohol use disorder (Wood et al., 2023). Naltrexone can support either stopping or reducing drinking; it cannot be used by a person who needs opioids, including for pain or OAT, or who has acute hepatitis. Acamprosate supports abstinence (Wood et al., 2023) and is not used in severe kidney impairment (Mylan Pharmaceuticals ULC, 2011). The guideline advises against antidepressants of the selective serotonin reuptake inhibitor class and antipsychotics as treatment for alcohol use disorder (Wood et al., 2023). An estimated less than 2% of people who could benefit receive evidence-based medicine for alcohol use disorder (BC Centre on Substance Use [BCCSU], n.d.), so hospital is an opportunity to start.

Medication works best alongside psychosocial treatment, such as counselling or family-based therapy (Wood et al., 2023). Before discharge, the nurse helps connect the patient with a RAAM clinic, primary care or community program, and confirms a follow-up plan the patient agrees with.

Patient and family teaching includes:

- Stopping heavy drinking suddenly can be dangerous. Anyone planning to stop or cut down should talk with a health care provider first. People at low risk can often withdraw safely at home with support, while those with a high PAWSS score, past complicated withdrawal or barriers to care in the community may need inpatient care (Wood et al., 2023).

- Warning signs that need urgent care: shaking that gets worse, confusion, seeing or hearing things that are not there, a seizure, or a fast heartbeat with fever.
- Thiamine and other medicines are taken as prescribed, and alcohol is not combined with sedating drugs.
- Any reduction in drinking brings health benefits (CCSA, 2023).

CLINICAL JUDGMENT

Tremor and Hallucinations on Day Two

Roger Thibault, 58, fell at home one evening and fractured his hip. He was admitted that night and had surgery the next morning. On the evening of postoperative day 2, about 3 days after he last drank, the nurse finds him sweating, with a coarse tremor of both hands. His heart rate is 124 beats/min and his blood pressure is higher than at baseline. He points at the window and asks who the people outside are; his room is on the sixth floor.

- **Recognize cues:** Tremor, sweating, tachycardia, high blood pressure and visual hallucinations. His wife now tells the nurse he drinks 8 to 10 beers every day; this was not recorded at admission.
- **Analyze cues:** The timing and signs fit alcohol withdrawal that may be progressing to delirium tremens. Other causes of acute confusion after surgery, such as hypoxia, infection, pain, low blood glucose and medications, must also be considered (Chapter 8, section 8.2).
- **Prioritize hypotheses:** Withdrawal delirium is life-threatening and comes first.
- **Generate solutions:** The nurse checks whether he can attend to questions. If he can communicate reliably, a CIWA-Ar is done per protocol; if he is disoriented, a delirium screen is used instead. Oxygen saturation, temperature and capillary blood glucose are checked.
- **Take action:** The nurse stays with him, keeps the bed low and the room calm, and reports to the most responsible practitioner using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6), calling the rapid response team per the unit's criteria. Thiamine is given before any glucose-containing fluid, and medicines are given as ordered.
- **Evaluate outcomes:** The nurse reassesses after each dose and documents his orientation, vital signs and sedation level.

LIFESPAN CONSIDERATIONS

Older Adults, Alcohol and Benzodiazepines

Alcohol use disorder in older adults is common but under-recognized and under-treated. Its signs, such as falls, poor mobility and memory problems, are easily mistaken for aging (Butt et al., 2020). Every older adult is asked about alcohol at admission, in the same way as younger adults.

Withdrawal may look atypical. Confusion may be the main sign, overlapping with delirium from other causes (Chapter 8, section 8.2), and symptoms may last longer than in younger adults (Gortney et al., 2016). Older adults are more sensitive to benzodiazepines and may clear long-acting drugs more slowly. Benzodiazepines raise the risk of delirium, falls and fractures (Conn et al., 2020), so the nurse checks sedation, orientation and mobility after every dose and puts fall precautions in place.

At discharge, *Canada's Guidance on Alcohol and Health* applies to all adults: less alcohol is better (CCSA, 2023). Older adults who are frail, live with several health conditions or take medicines that interact with alcohol are advised to drink even less or not at all (Butt et al., 2020).

11.4 Opioid Toxicity and Withdrawal

Opioids cause most of the toxic drug deaths described in section 11.1. This section covers the two opioid emergencies nurses meet most often in acute care: opioid toxicity, when too much opioid stops a person from breathing, and opioid withdrawal, when a person who is physically dependent goes without. It ends with starting or continuing OAT in hospital. Opioid pharmacology, respiratory depression from prescribed opioids and OAT during acute pain are covered in Chapter 5 (sections 5.4 and 5.5) and are not repeated here.

The Unregulated Drug Supply

Section 11.1 introduced the unregulated drug supply, also called the toxic drug supply. A person buying from it cannot know what a dose contains or how strong it is. The Council of Chief Medical Officers of Health (2026) describes the drugs in this market as

contaminated and highly toxic, so the risk of overdose is extremely high. Fentanyl and fentanyl analogues, which are chemically related compounds, are involved in most opioid toxicity deaths, and many of these deaths also involve a stimulant (section 11.1).

Non-opioid sedatives are increasingly mixed into the opioid supply. Benzodiazepines contributed to about a third of opioid toxicity deaths in 2024 (section 11.1). Health Canada's Drug Analysis Service identified xylazine, a veterinary sedative not approved for human use in Canada, in sharply rising numbers of seized samples, from 5 in 2018 to 1,350 in 2022, usually together with fentanyl (Health Canada, 2023b). Medetomidine, another veterinary sedative, has since appeared in the supply as well (Council of Chief Medical Officers of Health, 2026; Simcoe Muskoka District Health Unit, 2026).

These mixtures matter at the bedside. Naloxone works on opioids only. It does not reverse sedation from benzodiazepines, alcohol or other non-opioid drugs (Health Canada, 2024a), and an Ontario public health alert states that it does not reverse medetomidine (Simcoe Muskoka District Health Unit, 2026). A person may therefore start breathing again after naloxone yet stay deeply sedated. Ontario public health alerts advise that naloxone is still given whenever opioid exposure is suspected, because medetomidine is almost always found with fentanyl (Simcoe Muskoka District Health Unit, 2026; York Region Public Health, 2026).

Recognizing Opioid Toxicity

Opioid toxicity, often called an opioid overdose or poisoning, is a life-threatening depression of breathing and consciousness caused by opioids. The nurse looks for this cluster of cues (Government of Ontario, 2026; Health Canada, 2024a):

- **Consciousness:** cannot be woken, or does not respond to a loud voice or a firm shake of the shoulders; the body may be limp.
- **Breathing:** slow, shallow or absent, sometimes with snoring or gurgling sounds as the airway obstructs.
- **Pupils:** very small (pinpoint).
- **Skin and colour:** pale, cold or clammy skin; blue, grey or purple lips and nail beds.
- **Other cues:** vomiting; slow or absent pulse.

Cyanosis is a late sign and can be harder to see on darker skin. The nurse checks the lips, gums, nail beds and the inside of the lower eyelids, and does not wait for a colour change before acting (Chapter 12).

Opioid toxicity also happens in hospital. In interviews with 24 people in Toronto and Ottawa who used drugs and were living with human immunodeficiency virus (HIV) or hepatitis C, many said they had used non-prescribed substances while admitted, to cope with withdrawal, untreated pain, boredom or loneliness, and most tried to hide this use (Strike et al., 2020). Hidden use often happens alone, behind a closed bathroom door. A patient who has been in the bathroom for a long time, or who is found with drug equipment and deep sleepiness, needs an immediate check. The aim is safety, not punishment; patients who expect judgment are less likely to tell the nurse what they took.

Responding to Opioid Toxicity

Opioid toxicity is an airway and breathing emergency. In hospital, the nurse follows the code blue or rapid response policy (Chapter 6) and the naloxone order or medical directive. The sequence is:

1. **Check responsiveness:** shout the patient's name and shake the shoulders; check breathing and pulse.

2. **Call for help:** activate the code blue or rapid response team, as policy directs, and ask for the emergency cart and naloxone.

3. **Support breathing:** open the airway and ventilate with a bag-valve-mask and oxygen. In the community, rescue breaths with a barrier are used. If there is no pulse, start cardiopulmonary resuscitation (CPR) (Figure 11.1).

4. **Give naloxone:** by the intramuscular or intranasal route, or intravenously in hospital when the order or medical directive allows. Naloxone can begin to work within about 2 minutes. If there is no response after 2 to 3 minutes, a further dose is given, and doses are repeated as directed while ventilation continues (Health Canada, 2024a; Ontario Ministry of Health, 2026).

5. **Monitor closely:** the duration of action of most opioids is longer than that of naloxone, so sedation and slow breathing can return after the patient wakes (Emergent BioSolutions Canada, 2026). This return is called **recurrent toxicity**. Ontario's naloxone program warns that this is a particular risk with fentanyl and carfentanil (Ontario Ministry of Health, 2026). The nurse watches sedation, breathing and oxygen saturation at the frequency the order or policy sets, and escalates any return of drowsiness at once.

Naloxone can cause sudden **precipitated withdrawal** in a person who is physically dependent on opioids: body aches, vomiting, diarrhea, sweating, fever, a racing heart, high blood pressure, and agitation or aggression (Emergent BioSolutions Canada, 2026). The nurse turns a vomiting patient onto the side, stays calm and explains what happened.

After the event, the patient needs a trauma-informed response (Chapter 2). Many people wake frightened, ashamed or in withdrawal. The nurse speaks without blame, treats withdrawal and pain promptly through the team, and offers an addiction medicine consultation. The nurse documents the time found, the findings, every naloxone dose and route, ventilation, the response and the people notified (Chapter 1).

Figure 11.1 Ventilating with a bag-valve-mask during resuscitation training. In opioid toxicity, supporting breathing comes first while naloxone takes effect.

CLINICAL SAFETY

Responding to Opioid Toxicity on the Unit

- Treat an unresponsive patient with slow or absent breathing as opioid toxicity until proven otherwise, whatever the patient's history.
- Call for help first: activate the code blue or rapid response team by policy.
- Airway and ventilation come first. Bag-valve-mask ventilation with oxygen keeps the patient alive while naloxone takes effect, and it also treats breathing problems that naloxone cannot reverse, such as sedation from benzodiazepines or veterinary sedatives.
- Know where naloxone and the bag-valve-mask are kept on your unit before you need them.
- Give naloxone by the route and dose in the order, medical directive or policy. Repeat as directed if breathing does not improve within 2 to 3 minutes.
- Expect that sedation may return as naloxone wears off. Continue monitoring for as long as the order or policy requires, and never leave a recently reversed patient unobserved.
- After reversal, use a calm, trauma-informed approach. Explain what happened, manage withdrawal symptoms through the team, and avoid blame or threats of discharge.

Table 11.3 Opioid toxicity or opioid withdrawal? Comparing the cues (Emergent BioSolutions Canada, 2026; Government of Ontario, 2026; Health Canada, 2024a; Wesson & Ling, 2003)

Feature	Opioid toxicity	Opioid withdrawal
Level of consciousness	Very drowsy to unrousable; may not respond to voice or a firm shake	Awake and alert; often restless, anxious or irritable
Breathing	Slow, shallow or absent; snoring or gurgling	Normal or fast; yawning is common
Pupils	Very small (pinpoint)	Enlarged
Skin	Pale, cold or clammy; blue, grey or purple lips and nail beds	Sweating, gooseflesh; runny nose and watery eyes
Heart rate and blood pressure	Pulse may be slow or absent; blood pressure may fall	Heart rate often fast; blood pressure may rise
Gastrointestinal	Vomiting with a risk of aspiration	Nausea, cramps, vomiting and diarrhea
Immediate nursing priority	Call for help, support ventilation and give naloxone	Assess with a validated scale, report and treat symptoms as ordered

Opioid Withdrawal

Opioid withdrawal is the set of symptoms that follows stopping or sharply reducing opioids in a person who is physically dependent on them. With short-acting opioids, symptoms begin within hours of the last dose. Early cues include yawning, a runny nose, watery eyes, sweating, anxiety and cravings. As withdrawal progresses, the pupils enlarge, gooseflesh appears, and muscle and joint aches, tremor, cramps, nausea, vomiting and diarrhea follow (Table 11.3).

The **Clinical Opiate Withdrawal Scale (COWS)** is an 11-item scale that a clinician completes to give a consistent rating of withdrawal and to follow it over time (Wesson & Ling, 2003). It combines observed signs, such as resting pulse, pupil size, tremor and restlessness, with what the patient reports, such as aches and stomach upset. The nurse scores only findings caused by withdrawal, not those explained by recent activity, a cold or pre-existing pain. The total places withdrawal in a severity band from mild to severe, which guides medication timing and shows whether treatment is working. Hospitals set how often COWS is repeated.

Opioid withdrawal is intensely uncomfortable. Its main dangers come from what it leads to. Persistent vomiting and diarrhea that go untreated can cause dehydration and a high blood sodium level, and deaths from these complications have been reported (Darke et al., 2017; Chapter 3). Untreated withdrawal is one reason patients leave hospital before treatment is complete (Chapter 5, section 5.5). A person who returns to use after days without opioids has lower tolerance, which raises the risk of overdose (Khan et al., 2024). Withdrawal from medetomidine is a newer concern: an Ontario public health alert describes rapid heart rate, severe hypertension and vomiting that can be life-threatening and need medical treatment (Simcoe Muskoka District Health Unit, 2026). The nurse reports severe or worsening withdrawal promptly.

Starting or Continuing OAT in Hospital

A hospital stay is a chance to start **opioid agonist treatment (OAT)**, a long-acting opioid that prevents withdrawal and reduces cravings (Chapter 5, section 5.5). Canada's 2024 national guideline recommends buprenorphine and methadone as standard first-line options, with slow-release oral morphine as a second-line option. It recommends against offering withdrawal management alone, without ongoing treatment, and states that psychosocial treatment should never be a condition of receiving OAT (Yakovenko et al., 2024).

For a patient already on OAT, the team confirms the current dose and the time of the last dose with the community pharmacy before giving the first hospital dose (Chapter 5, section 5.5).

Buprenorphine is started differently from other opioids. In a **standard induction**, the patient stops other opioids and waits until withdrawal is clearly present, often measured with COWS, before the first dose. Starting too early can cause precipitated withdrawal. With fentanyl in the supply, precipitated withdrawal has been reported even in patients already in moderate to severe withdrawal (Randhawa et al., 2020). **Low-dose buprenorphine initiation**, sometimes called microdosing, is an alternative: very small, gradually increasing doses are started while the patient continues their usual opioid, which is stopped once an effective dose is reached. Early Canadian reports found it well tolerated but called for more research (Randhawa et al., 2020), and British Columbia's provincial guideline includes low-dose initiation as a way to avoid a period of withdrawal before treatment starts (British Columbia Centre on Substance Use [BCCSU], 2023). The Going Deeper box explains why it works.

Buprenorphine is also available as an extended-release injection given under the skin once a month by a health care professional (Indivior UK, 2025). Methadone no longer requires a special federal exemption to prescribe; Health Canada removed this requirement in 2018. Prescribers must still meet provincial or territorial rules and those of their regulatory college (Health Canada, 2018d).

GOING DEEPER

Buprenorphine, Precipitated Withdrawal and Low-Dose Starts

Required for RN students; optional for PN students.

Buprenorphine is a **partial agonist** at the mu-opioid receptor (Indivior UK, 2025). It switches the receptor on, but only part of the way, so its effect levels off as the dose rises. This ceiling is one reason it is safer than full agonists. Buprenorphine also has very high affinity for the mu receptor: it binds more tightly than full agonists such as fentanyl, heroin or hydromorphone (Randhawa et al., 2020).

These two properties explain precipitated withdrawal. If buprenorphine is given while a full agonist still occupies the receptors, it pushes the full agonist off and replaces a strong effect with a weaker one. To the brain, the sudden drop feels like abrupt withdrawal, often more severe than withdrawal that develops gradually. Standard induction avoids this by waiting until enough full agonist has left the receptors that the patient is already in withdrawal. At that point buprenorphine relieves symptoms instead of causing them.

Fentanyl complicates this timing. It is highly fat-soluble and moves into body tissues. With repeated use, it is stored there and released slowly, so it leaves the body more gradually than its short effect would suggest (Randhawa et al., 2020). Fentanyl may still be occupying receptors even when the patient feels withdrawal, and the first buprenorphine dose can then precipitate it.

Low-dose initiation takes another approach. Very small doses of buprenorphine are given while the patient keeps taking the full agonist. Each small dose occupies only a few receptors, too few to displace the full agonist enough to trigger withdrawal. Over several days the buprenorphine doses increase and overlap, gradually taking over the receptors. Once buprenorphine reaches an effective level, the full agonist is stopped (Randhawa et al., 2020). Protocols vary between hospitals; the nurse follows the prescribed schedule exactly, watches for withdrawal and oversedation, and reports both.

MEDICATIONS

Naloxone and Opioid Agonist Treatment in Canada

- **Naloxone nasal spray (NARCAN):** a single-use device delivering 4 mg in 0.1 mL into one nostril. Ontario take-home kits contain two devices (Emergent BioSolutions Canada, 2026; Ontario Ministry of Health, 2026).
- **Injectable naloxone:** Ontario take-home kits hold two 1 mL doses of naloxone 0.4 mg/mL, supplied in ampoules, vials or prefilled syringes, for intramuscular injection (Ontario Ministry of Health, 2026).
- Since Health Canada changed its prescription status in March 2016, naloxone for emergency use in an opioid overdose has been available without a prescription. Participating Ontario pharmacies supply kits free, without a health card (Health Canada, 2024a; Ontario Ministry of Health, 2026; Chapter 5, section 5.4).
- **Buprenorphine-naloxone sublingual tablets:** first-line OAT (Yakovenko et al., 2024), dissolved under the tongue. The naloxone has no effect when taken as directed; it is included to deter injection (Indivior UK, 2021).
- **Buprenorphine extended-release injection (Sublocade):** given under the skin by a health care professional only, never intravenously (Indivior UK, 2025).
- **Methadone oral solution:** first-line OAT, taken by mouth as a liquid (Yakovenko et al., 2024).
- **Slow-release oral morphine (Kadian):** second-line OAT; a once-daily capsule whose pellets are swallowed whole (Alberta Health Services, 2026; Yakovenko et al., 2024).

OAT doses are set by the prescriber and are not given in this book.

11.5 Stimulants, Cannabis and Other Substances

Stimulants and cannabis bring people to hospital in different ways. Stimulant toxicity can be a medical emergency, whereas cannabis more often contributes quietly to other problems, such as persistent vomiting or interactions with anesthesia.

Stimulants

Cocaine and methamphetamine are the stimulants most often seen in Canadian acute care. Stimulants are involved in many toxic drug deaths, often together with opioids, and in 2025 stimulant-related deaths outnumbered opioid-related deaths in several provinces and territories, including Ontario (section 11.1).

Stimulant toxicity is an exaggerated sympathetic ("fight or flight") response to a stimulant. Its cues include agitation, a fast or irregular heartbeat, high blood pressure, rapid breathing, high body temperature, enlarged pupils and psychosis. Seizures, coma, and liver or kidney failure can follow (Health Canada, 2023a). Chest pain needs urgent assessment, because stimulants strain the heart; heart attack, stroke and sudden cardiac death are among their serious harms (Health Canada, 2023a). Hyperthermia is especially dangerous: it can progress quickly to failure of several organs and to cardiac arrest (NSW Health, 2024). Psychosis is also common with methamphetamine; Palis and MacDonald (2023), citing an earlier review, report that up to 40% of people who use it may experience psychosis. A patient with paranoia or hallucinations is frightened, not simply difficult. The nurse keeps a safe distance, speaks simply and watches for delirium (Chapter 8).

Nursing care focuses on safety and early escalation:

- Provide a quiet, low-stimulation space. Speak calmly, explain each step and keep the patient's dignity.
- Check temperature often and start cooling measures as ordered.
- Apply cardiac monitoring and continuous pulse oximetry as ordered, and repeat vital signs often.
- Give benzodiazepines for agitation as ordered; early sedation reduces the heat the body produces (NSW Health, 2024).
- Report chest pain, a temperature that keeps rising, seizures, confusion or a falling level of consciousness at once, using rapid response criteria (Chapter 6).
- Avoid physical restraint wherever possible. Struggling against restraint in severe agitation can precipitate cardiac arrest (NSW Health, 2024). De-escalation and restraint alternatives are covered in Chapter 8.

No medication has been approved in Canada to treat stimulant use disorder (Palis & MacDonald, 2023). Non-drug approaches, such as **contingency management**, which gives small tangible rewards for meeting treatment goals, may be offered, and some clinicians prescribe stimulants as a harm reduction measure (Palis & MacDonald, 2023). Because the stimulant supply may also contain opioids, the nurse teaches patients who use stimulants about naloxone as well.

Cannabis

Non-medical cannabis has been legal in Canada since October 17, 2018, when the **Cannabis Act** took effect (Health Canada, n.d.). Its main psychoactive compound, tetrahydrocannabinol (THC), impairs the skills needed to drive and raises the heart rate. High doses can cause anxiety and short-lived psychotic symptoms (Health Canada, 2018b).

The Lower-Risk Cannabis Use Guidelines, developed in Canada and updated in 2022, give people practical ways to reduce harm (Fischer et al., 2022). In summary, not using is the only sure way to avoid risk. People who choose to use can delay starting until after late adolescence, choose lower-THC products from the legal market, avoid smoking and deep inhalation, avoid daily or near-daily use, and never drive while impaired. People who are planning a pregnancy, pregnant or breastfeeding are advised not to use. The guidelines also advise caution when combining cannabis with alcohol or other psychoactive drugs, and they identify groups at higher risk of harm, including people with a personal or close family history of psychosis, people with a mood or substance use disorder, people with existing heart and blood vessel risks, and older adults (Fischer et al., 2022). This matters in acute care, where many older patients already take sedating medications.

Cannabinoid hyperemesis syndrome (CHS) is repeated episodes of severe nausea, vomiting and abdominal pain in people who have used cannabis heavily, usually daily, for a long time (King & Holmes, 2015). A telling cue is that patients take repeated hot showers or baths because the heat eases their symptoms. Standard antiemetics often fail. The team first rules out dangerous causes such as bowel obstruction, perforation or pancreatitis. The nurse monitors fluid balance, because vomiting can cause dehydration and acute kidney injury (Chapter 3). Lasting remission requires stopping cannabis (King & Holmes, 2015), so the nurse explains the link in a respectful, non-judgmental way.

Health Canada (2018c) estimates that about 1 in 10 people who use cannabis develop an addiction to it (cannabis use disorder), and up to 1 in 2 of those who use it daily or near-daily. People who use cannabis regularly may develop withdrawal once admitted to hospital; it usually starts within 1 or 2 days and can last a few weeks. Its cues include irritability, anxiety, poor sleep, low appetite, restlessness, cravings and low mood (Health Canada, 2018c). The nurse recognizes these as withdrawal, not as a personality problem, and reports them. Asking about cannabis use before surgery is part of the preoperative assessment (Chapter 7).

Other Substances

Benzodiazepine-related drugs and veterinary sedatives found in the unregulated supply (section 11.4) can cause deep, prolonged sedation that naloxone does not reverse (Health Canada, 2024a; Simcoe Muskoka District Health Unit, 2026). A patient may need airway support and close monitoring for hours. The nurse asks every patient who uses drugs what they take, how often and when they last used, because unexpected sedation or withdrawal can follow.

11.6 Harm Reduction and Transitions

Principles of Harm Reduction

Harm reduction is a set of practical, evidence-based approaches that reduce the health and social harms of substance use without requiring a person to stop using. It begins where the person is. The nurse respects the patient's goals, offers choices and keeps the door open to treatment without making care depend on it. Canada's 2024 opioid use disorder guideline makes a strong recommendation that harm reduction be offered across the whole continuum of care, including sterile drug use supplies, overdose prevention education and take-home naloxone (Yakovenko et al., 2024).

Several services make up this continuum:

- **Supervised consumption sites:** places where people use drugs they bring with them, in the presence of trained staff who respond to overdoses. According to Health Canada (2026d), Canadian and international evidence shows that these services save lives and link people to social services and treatment. Because people do not have to hurry or use alone, accidental overdose is also less likely.
- **Naloxone distribution:** free take-home kits and training for people at risk and their families and friends (Ontario Ministry of Health, 2026).
- **Sterile supplies and safe disposal:** sterile needles and other equipment, which help reduce the spread of infections such as HIV (Health Canada, 2026d).
- **Drug checking:** services that test a sample to show what it contains, so a person can decide whether and how to use it (Health Canada, 2026d; Figures 11.3 and 11.4; Figure 11.2).

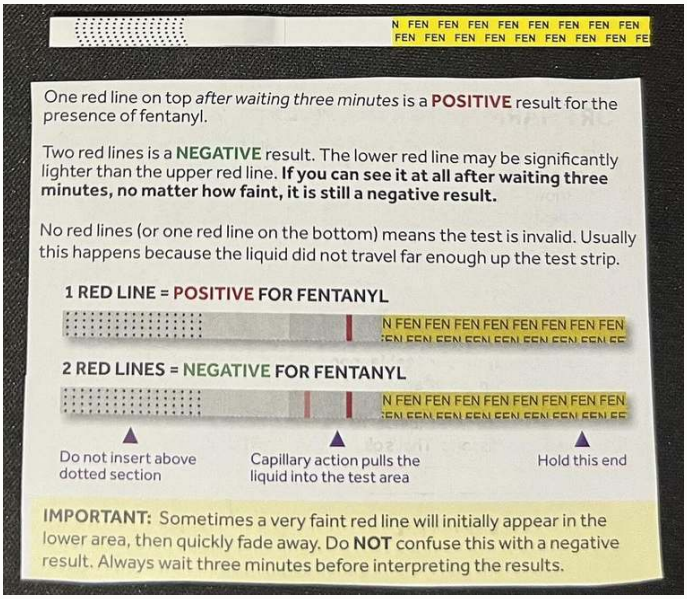

Figure 11.2 A rapid fentanyl test strip and interpretation guide used in community and hospital harm-reduction drug checking (one red line = positive for fentanyl; two red lines = negative). (credit: "Fentanyl-test-strip" by WikiLinuz/Wikimedia Commons, CC BY-SA 4.0)

Figure 11.3 A harm reduction table at a community event in Portland, Oregon, offering free naloxone and fentanyl test strips. (credit: "Harm Reduction Drug Testing Table" by Sarahmirk/Wikimedia Commons, CC BY-SA 4.0)

Harm reduction services also connect people with health care. Supervised consumption sites may offer wound care, testing for HIV, hepatitis C and sexually transmitted infections, and referral to treatment (Health Canada, 2026d). For a patient admitted with an injection-related infection, these services may be where wound care and testing continue after discharge.

Harm reduction also belongs in hospital. Patients who use drugs in hospital often do so to cope with untreated withdrawal or pain, and staff responses vary widely when policy is unclear (Strike et al., 2020). The nurse treats withdrawal and pain promptly, asks about use without judgment, requests an addiction medicine consultation, and offers naloxone and harm reduction supplies according to hospital policy. Honest conversation keeps patients safer than hidden use, because the nurse can then check on them and act quickly. Chapter 5, section 5.5, covers how to respond when a patient wants to leave early.

Policy in Canada (2026)

Drug policy in Canada changes often and differs between provinces and territories. This book describes it as of October 2026.

Figure 11.4 A public needle disposal box in a parking lot in Denver, Colorado. Safe disposal sites for used needles are part of harm reduction services. (credit: "Needle disposal box" by Jeffrey Beall/Wikimedia Commons, CC BY 4.0)

Federal law: The *Controlled Drugs and Substances Act* prohibits possessing a controlled substance. An organization that wants to operate a supervised consumption site needs an exemption from Health Canada under section 56.1 of this Act. Applications include broad community consultation, and exemptions are generally granted for 1 year (Health Canada, 2018a). Under a separate class exemption, provinces and territories may set up overdose prevention sites to meet urgent public health needs (Health Canada, 2026d).

Ontario: The *Community Care and Recovery Act, 2024*, passed on December 4, 2024, as part of a larger bill, bars anyone from establishing or operating a supervised consumption site less than 200 metres from a school, a licensed child care centre or an EarlyON Child and Family Centre. The prohibition took effect on April 1, 2025, and the Act also requires provincial approval before a municipality or local board applies for a federal supervised consumption exemption (*Community Care and Recovery Act, 2024*). In Toronto, at least five sites had to stop operating at their locations by March 31, 2025 (Toronto Public Health, 2025). Ontario is funding Homelessness and Addiction Recovery Treatment (HART) Hubs. These bring together primary care, addiction services such as RAAM, withdrawal management, supportive housing and social services; several replaced former consumption sites (Ontario Ministry of Health, 2025). Toronto Public Health (2025) notes that the HART Hub model does not include supervised consumption, needle exchange or safer supply services.

British Columbia: From January 31, 2023, a federal exemption allowed adults in British Columbia to possess a small total amount (up to 2.5 g) of certain illegal drugs for personal use without being arrested or charged. In May 2024, possession in public spaces was removed from the exemption (Health Canada, 2024b). The exemption expired on January 31, 2026, and was not renewed (Government of British Columbia, 2026).

Because services open, close and change, the nurse checks which local services exist before teaching a patient about them.

Leaving Hospital Safely

The days after discharge are a period of high risk. During a hospital stay, a person may use less or not at all, or their OAT may be interrupted, so tolerance falls. If they return to their usual amount, an overdose becomes more likely (Khan et al., 2024). A hospital stay can also disconnect people from their usual supply and routines, which may lead to using alone. In a British Columbia study of hospital stays from 2015 to 2019, patients who left before medically advised had a higher rate of overdose in the following 30 days than those discharged on their physician's advice, even after adjustment for other differences (Khan et al., 2024).

The nurse starts discharge planning on admission rather than on the last day, because patients who use drugs sometimes leave suddenly (Chapter 5, section 5.5). Teaching works best when it is hands-on: the nurse opens a kit with the patient, names each item and asks the patient to show the steps back. Discharge planning includes:

- **Take-home naloxone:** a kit and hands-on teaching for the patient and the people they live or use with (Ontario Ministry of Health, 2026).
- **Never using alone:** if the patient does use alone, the **National Overdose Response Service (NORS)** offers a confidential, non-judgmental phone and text line (1-888-688-6677), available 24 hours a day from anywhere in Canada, that supports people while they use and provides overdose response (Health Canada, 2026b; National Overdose Response Service, n.d.).

- **Drug checking**, where it is available locally (Health Canada, 2026d).
- **OAT continuity:** a prescription that bridges to the next appointment, a call or written communication to the community pharmacy and prescriber about the last dose given, and a plan for the first dose after discharge (Chapter 5, section 5.5).
- **Follow-up:** a RAAM clinic, primary care provider or addiction service. In Ontario, many RAAM clinics accept people without an appointment or referral (section 11.2).
- **Housing and income supports:** a social work referral, because housing and income affect recovery and safety.
- **Indigenous and culturally specific supports:** an Indigenous patient navigator or liaison, or community programs, if the patient wishes (Chapter 2). The Hope for Wellness Help Line (1-855-242-3310) offers counselling and crisis support to Indigenous people across Canada, 24 hours a day, in several languages including Cree, Ojibway and Inuktitut (Health Canada, 2026b).

The federal *Good Samaritan Drug Overdose Act* has been law since May 4, 2017. When someone calls 9-1-1 or the local emergency number about an overdose, the Act offers some legal protection to the caller, the person who overdosed and others present when help arrives; the caller is protected whether they stay or leave. It shields them from charges of simple possession of a controlled substance, and from charges for breaking conditions linked to simple possession, such as those of probation, parole or pre-trial release. It does not cover outstanding warrants, drug production or trafficking, or other crimes (Health Canada, 2026a).

SCOPE IN PRACTICE

Naloxone, Withdrawal Monitoring and OAT

CNO's Scope of Practice standard explains nursing roles through authority, competence and context (College of Nurses of Ontario, 2025; Chapter 1, section 1.3).

- **Authority:** In hospital, RNs and RPNs give naloxone under an order or a medical directive, according to policy. Naloxone is also available without a prescription, and the NARCAN product monograph and Health Canada state that a bystander may give the nasal spray in an emergency (Emergent BioSolutions Canada, 2026; Health Canada, 2024a). Nurses give OAT and withdrawal medications as ordered. Physicians and, where provincial or territorial rules allow, nurse practitioners (NPs) prescribe OAT; prescribers must meet provincial or territorial and regulatory college requirements (Health Canada, 2018d).
- **Competence:** The nurse needs the knowledge and skill to recognize opioid toxicity, ventilate with a bag-valve-mask, give naloxone, and monitor withdrawal with a validated tool such as COWS.
- **Context:** Employer policy sets who manages buprenorphine starts and how often scores are repeated. When a patient's condition or needs change, the RPN consults the RN.
- **Every nurse acts:** Any nurse who finds a patient with slow or absent breathing calls for help, ventilates and gives naloxone by policy, whoever is assigned to the patient.

Employer policy and the province or territory matter. CNO's revised Scope of Practice and Medication standards take effect March 1, 2027 (College of Nurses of Ontario, 2026).

PATIENT EDUCATION

Going Home Safer

The nurse teaches the patient, and anyone they live or use with, to:

- Carry a naloxone kit. Participating pharmacies in Ontario give kits free, with no health card or prescription needed.
- Recognize an overdose: cannot be woken, slow or no breathing, snoring or gurgling, tiny pupils, and blue or grey lips or nail beds.
- Respond: shout and shake, call 9-1-1, give naloxone, give rescue breaths or chest compressions, and repeat naloxone after 2 to 3 minutes if there is no change. Stay until help arrives, because the overdose can return.
- Know that the *Good Samaritan Drug Overdose Act* protects people who call for help from charges of simple possession.
- Avoid using alone. If alone, call or text NORS at 1-888-688-6677.
- Remember that tolerance is lower after a hospital stay. Start with a much smaller amount, go slowly, and use drug checking where available.
- Know the OAT plan: the pharmacy, the time of the next dose and the follow-up appointment.
- Keep the numbers for the clinic, the pharmacy and a crisis line.

PRACTICE STORY

"He Came Back"

Names and details are fictional; this is a composite story.

Nurse: Ananya Nadarajah, RPN. Years in practice: 4. Setting: medical unit, community hospital, Ontario.

Mr. Dale Whitford was 36 and on his third day of intravenous (IV) antibiotics for cellulitis of his forearm, at a site where he had injected. He had told the admitting team he used fentanyl, and he had declined to start OAT. That afternoon I noticed his bathroom door had been closed for a long time. I knocked twice and got no answer.

I found him slumped against the wall, grey around the lips, with a few snoring breaths a minute. I shouted his name and shook his shoulders. Nothing. I pulled the bathroom call bell and yelled for help. My RN, Marc, called the rapid response team and brought the emergency cart while I tilted Dale's head back and started ventilating with a bag-valve-mask on oxygen.

Our hospital has a naloxone medical directive. Marc gave the first dose into Dale's thigh while I kept ventilating. After about 3 minutes there was still no change, so Marc gave a second dose. A minute later Dale coughed, pushed the mask away and swore at us. He was sweating and shaking, and he vomited. I rolled him onto his side.

The rapid response team took over. Once Dale was back in bed, he wouldn't look at me. "Go ahead," he said. "Kick me out." I told him nobody was kicking him out, that I was glad he was alive, and that we would stay close for the next few hours because the fentanyl could outlast the naloxone. He was drowsy again 50 minutes later, and the team gave another dose.

The next morning, he asked me what the addiction medicine team could actually do. I paged them. By the end of my shift, he had started a low-dose buprenorphine plan, and he had a naloxone kit in his bag.

Reflect: Which of Priya's actions were within her authority as an RPN, and when did the situation call for the RN and the rapid response team? How did Priya's words after the event affect Dale's choice the next morning?

Chapter 11 Summary

Introduction

- About 540 people are hospitalized in Canada every day for harm from alcohol or other drugs, and alcohol accounts for more than half of these stays (CIHI, 2026).
- Nurses on every unit care for people who use substances; this chapter is the book's home for substance use in hospital.

11.1 Substance Use, Stigma and Health

- Substance use runs along a continuum; a substance use disorder is diagnosed by at least 2 of 11 criteria over 12 months, graded mild, moderate or severe.
- Tolerance and withdrawal alone, from medicines taken as prescribed, do not mean a disorder.
- Canada recorded 7,146 opioid-related deaths in 2024 and 5,608 in 2025 (15 per day); the toxic drug supply keeps changing.
- Trauma, poverty, housing, pain and, for some Indigenous communities, colonization and residential schools drive harm; culture and community are sources of healing.
- Stigma leads to delayed care, poorer care and leaving hospital early; person-first, clinical language is one remedy.

11.2 Screening and Brief Intervention in Hospital

- Every patient is asked about alcohol and other drugs at admission, privately and in the same neutral way.
- Canada's 2026 guideline update screens with weekly and per-occasion drinks compared with *Canada's Guidance on Alcohol and Health*; earlier tools such as the AUDIT-C and single-question screens may still appear on admission forms.
- A positive screen leads to a brief, motivational conversation and referral, such as an addiction medicine consult or a RAAM clinic.

11.3 Alcohol Withdrawal

- Withdrawal reflects an overexcited nervous system after the brain adapts to heavy drinking; repeated withdrawals worsen through kindling.

- Minor symptoms start within 6 to 12 hours; hallucinosis, seizures and delirium tremens follow in typical windows.
- PAWSS predicts risk at admission; the CIWA-Ar measures current severity but needs a patient who can communicate and is not delirious.
- Benzodiazepines, usually symptom-triggered, are first-line, with supportive care, electrolyte replacement and prompt escalation.
- Thiamine is given before glucose to prevent Wernicke encephalopathy, which rarely shows its full triad.
- Naltrexone or acamprosate, psychosocial care and follow-up treat the underlying alcohol use disorder.

11.4 Opioid Toxicity and Withdrawal

- The unregulated drug supply is dominated by fentanyl and fentanyl analogues and increasingly contains non-opioid sedatives, such as benzodiazepine-related drugs and veterinary sedatives, that naloxone does not reverse.
- Opioid toxicity presents as unresponsiveness, slow or absent breathing, pinpoint pupils and cyanosis; cyanosis can be harder to see on darker skin, so the nurse checks the lips, gums, nail beds and inner eyelids.
- The response is to call for help, ventilate, give naloxone per order or medical directive, repeat as directed, and monitor closely, because most opioids outlast naloxone.
- Opioid withdrawal causes yawning, enlarged pupils, gooseflesh, aches and gastrointestinal upset; COWS rates its severity, and untreated withdrawal raises the risk of leaving hospital and of overdose.
- Buprenorphine and methadone are first-line OAT. Buprenorphine starts either with standard induction, after withdrawal begins, or with low-dose initiation.

11.5 Stimulants, Cannabis and Other Substances

- Stimulant toxicity causes agitation, tachycardia, hypertension, hyperthermia, chest pain, seizures and psychosis; the nurse escalates early, cools, gives sedation as ordered and avoids physical restraint.
- No medication is approved in Canada for stimulant use disorder.
- Cannabis has been legal since October 17, 2018; the Lower-Risk Cannabis Use Guidelines describe ways to reduce harm.
- Cannabinoid hyperemesis syndrome causes repeated vomiting with heavy long-term use, is eased by hot showers and resolves only when cannabis stops.
- Cannabis withdrawal usually starts within 1 or 2 days and causes irritability, anxiety, poor sleep and low appetite.

11.6 Harm Reduction and Transitions

- Harm reduction meets people where they are and is recommended across the continuum of care, including in hospital.
- Supervised consumption sites operate under a federal section 56.1 exemption. Ontario's 2024 law bars sites within 200 metres of schools and child care centres, and the province is funding HART Hubs. British Columbia's decriminalization exemption ended on January 31, 2026.
- Overdose risk rises after discharge because tolerance falls during a hospital stay.
- Discharge planning includes take-home naloxone, never using alone or calling NORS, drug checking, OAT continuity, RAAM follow-up, and social and culturally specific supports.
- The Good Samaritan Drug Overdose Act protects people who call for help from charges of simple possession.

Key Terms (35)

alcohol withdrawal: the signs and symptoms of an overexcited nervous system that follow stopping or sharply reducing heavy, prolonged alcohol use.

alcoholic hallucinosis: hallucinations during alcohol withdrawal in a person who otherwise remains oriented.

AUDIT-C: a short alcohol screening tool built from the consumption questions of the Alcohol Use Disorders Identification Test.

brief intervention: a short, structured conversation, based on motivational interviewing, that helps a person consider their substance use and choose a change.

cannabinoid hyperemesis syndrome (CHS): repeated episodes of severe nausea, vomiting and abdominal pain in people with heavy long-term cannabis use, often eased by hot showers and resolved by stopping cannabis.

Cannabis Act: the federal law under which non-medical cannabis has been legal and regulated in Canada since October 17, 2018.

CIWA-Ar: the Clinical Institute Withdrawal Assessment for Alcohol, revised; a 10-area scale that measures the current severity of alcohol withdrawal.

Clinical Opiate Withdrawal Scale (COWS): an 11-item clinician-rated scale that rates the severity of opioid withdrawal and tracks it over time.

contingency management: a non-drug treatment that gives small tangible rewards for meeting treatment goals.

delirium tremens: the most severe form of alcohol withdrawal, with delirium, hallucinations, agitation and autonomic overactivity, usually beginning 48 to 72 hours after the last drink; also called alcohol withdrawal delirium.

drug checking: a service that tests a drug sample to show what it contains.

Good Samaritan Drug Overdose Act: a 2017 federal law that, when someone calls for emergency help with an overdose, protects the caller and others at the scene from charges of simple possession and related breaches of conditions.

harm reduction: practical, evidence-based approaches that reduce the harms of substance use without requiring a person to stop using.

kindling: the tendency for each episode of alcohol withdrawal to be more severe than the last after repeated cycles of heavy drinking and withdrawal.

Korsakoff syndrome: a lasting memory disorder, often following untreated Wernicke encephalopathy, in which the person cannot form new memories.

low-dose buprenorphine initiation: starting buprenorphine with very small, gradually increasing doses while the usual opioid continues until an effective dose is reached; also called microdosing.

naloxone: an opioid antagonist that temporarily reverses opioid toxicity; it does not reverse non-opioid sedatives.

National Overdose Response Service (NORS): a confidential national phone and text line that provides overdose response for people who use drugs alone.

opioid agonist treatment (OAT): treatment of opioid use disorder with a long-acting opioid, such as buprenorphine or methadone, that prevents withdrawal and reduces cravings.

opioid toxicity: a life-threatening depression of breathing and consciousness caused by opioids; often called an opioid overdose or poisoning.

opioid withdrawal: the symptoms that follow stopping or sharply reducing opioids in a person who is physically dependent on them.

partial agonist: a drug that activates a receptor only part of the way, so its effect levels off as the dose rises.

PAWSS: the Prediction of Alcohol Withdrawal Severity Scale; a 10-item tool that estimates a hospitalized patient's risk of complicated alcohol withdrawal.

person-first language: wording that names the person before a condition, such as "person who uses drugs."

precipitated withdrawal: sudden, often severe withdrawal triggered when naloxone or buprenorphine displaces a full opioid agonist from its receptors.

recurrent toxicity: the return of sedation and slow breathing after naloxone wears off, because most opioids act longer than naloxone.

standard induction: starting buprenorphine after other opioids have been stopped and withdrawal is clearly present.

stigma: negative attitudes, beliefs and behaviours directed at a group because of their situation, expressed as stereotypes, prejudice and discrimination at self, social and structural levels.

stimulant toxicity: an exaggerated sympathetic response to a stimulant, with agitation, fast heart rate, high blood pressure, high body temperature and possible seizures or psychosis.

substance use disorder: a health condition in which a person keeps using a substance despite significant problems linked to that use, diagnosed when at least 2 of 11 criteria occur within 12 months and graded mild, moderate or severe.

supervised consumption site: a service where people use drugs they bring with them in the presence of trained staff who can respond to an overdose; it operates under a federal exemption.

symptom-triggered treatment: giving withdrawal medication when a patient's withdrawal score reaches a set threshold, rather than on a fixed schedule.

unregulated drug supply: drugs made and sold outside legal and quality controls, often containing fentanyl and other toxic substances of unknown strength.

Wernicke encephalopathy: an acute, potentially fatal brain disorder caused by thiamine deficiency, classically with confusion, ataxia and abnormal eye movements.

withdrawal seizure: a generalized tonic-clonic seizure caused by alcohol withdrawal, usually within the first two days after the last drink.

Licensure Review & Clinical Judgment Questions (30)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Denise Arsenault (Questions 1–4): Denise Arsenault, 47, is admitted to a medical unit in Belleville, Ontario, with community-acquired pneumonia. At admission she tells the nurse she drinks about a bottle of wine every evening; her last drink was 14 hours ago. Her PAWSS score is 5. A registered practical nurse (RPN) is caring for her, with an RN on the team.

1. [CORE] Six hours later, Ms. Arsenault is restless and sweating, her hands tremble, her heart rate is 112 beats/min and she says she cannot sleep. She is oriented and denies seeing or hearing anything unusual. Which interpretation is most likely?

a. Anxiety about being admitted to hospital

b. Early alcohol withdrawal

c. An allergic reaction to her antibiotic

d. Delirium tremens

Answer: b — About 20 hours after her last drink, tremor, sweating, tachycardia, restlessness and insomnia match minor alcohol withdrawal, and her PAWSS score shows high risk (b) (section 11.3). Anxiety (a) may be present but does not explain the full pattern in a person who drinks daily; labelling it anxiety could delay treatment. An allergic reaction (c) would bring rash, hives, swelling or breathing changes, not tremor. Delirium tremens (d) usually starts 48 to 72 hours after the last drink and involves disorientation and hallucinations, which she does not have.

2. [CORE] The protocol directs the nurse to monitor Ms. Arsenault with the CIWA-Ar. Which statement about this tool is accurate?

a. It predicts, at admission, whether she is likely to go on to develop seizures or delirium tremens.

b. It can be completed from her vital signs alone.

c. A high score confirms that her symptoms are caused by alcohol withdrawal rather than by another illness.

d. It relies on her ability to describe her symptoms, so it becomes unreliable if she is delirious.

Answer: d — Much of the CIWA-Ar depends on what the patient reports, so it is not recommended once a patient is delirious or cannot communicate (d) (section 11.3). Predicting severe withdrawal is the job of PAWSS, not the CIWA-Ar (a). The scale combines observation with the patient's own report, so it cannot be completed from vital signs alone (b). It is not a diagnostic tool: pain, fever, anxiety and infection can also raise the score (c).

3. [CORE] The prescriber orders intravenous thiamine and an infusion of dextrose 5% in water for Ms. Arsenault, who has been eating poorly. Which action by the nurse is best?

a. Give the thiamine before starting the dextrose infusion.

b. Start the dextrose infusion first, then give the thiamine when it is finished.

c. Hold the thiamine until her nutrition laboratory results are back.

d. Give the thiamine only if she develops confusion or an unsteady gait.

Answer: a — Glucose metabolism uses up thiamine, so giving glucose first to a person who is deficient can deepen the deficiency and put her at risk of Wernicke encephalopathy; thiamine goes first (a) (section 11.3). Reversing the order (b) creates that risk. Thiamine is given to everyone at risk without waiting for results (c). Waiting for signs (d) is unsafe, because most patients never show the full triad and the damage may become permanent.

4. [CORE] On her third day, Ms. Arsenault is picking at the air and does not know where she is. Her heart rate is 128 beats/min, her temperature is 38.1 °C and she is sweating heavily. Which action should the RPN take first?

a. Complete a CIWA-Ar right away and give the as-needed benzodiazepine dose that her total score indicates under the protocol.

b. Apply wrist restraints so she cannot pull out her intravenous line.

c. Stay with her, keep her safe, and immediately notify the RN and call for help per the unit's rapid response criteria.

d. Document the findings and reassess her in one hour.

Answer: c — Disorientation, hallucinations, fever and tachycardia on day 3 suggest delirium tremens or another serious cause of delirium, such as worsening infection; this is deterioration that needs immediate escalation while the patient is kept safe (c) (section 11.3; Chapter 1, section 1.3; Chapter 6). The CIWA-Ar is unreliable in delirium, and medicating without escalation delays the team response (a). Restraints increase agitation and injury risk and are not a first action (b; Chapter 8). Waiting an hour (d) could allow life-threatening deterioration.

5. [CORE] Which phrases reflect the non-stigmatizing language recommended in Canadian federal guidance? Select all that apply.

a. "A person who uses drugs"

b. "His urine drug screen was clean."

c. "A recurrence of substance use"

d. "She is an alcoholic."

e. "A person with an alcohol use disorder"

f. "He is drug-seeking again."

Answer: a, c, e — Person-first, clinical terms (a, c, e) describe a person and a health condition without blame (section 11.1, Table 11.1). "Clean" (b) should be replaced by "negative test result." "Alcoholic" (d) defines the person by a condition. "Drug-seeking" (f) is a label that can lead to needed medicine being withheld; the nurse describes what the patient said and did and the need behind it.

6. [CORE] A nurse is completing the admission history for a 39-year-old patient having elective knee surgery. Which approach to alcohol screening best reflects current Canadian guidance?

a. Ask only patients who smell of alcohol, appear intoxicated or have a known history of heavy drinking.

b. Ask about alcohol only if the patient's liver enzymes are abnormal.

c. Ask every patient, privately and neutrally, how many standard drinks they have in an average week.

d. Replace questions about alcohol with a urine drug screen, which gives a more objective measure of recent use.

Answer: c — Canada's guideline recommends routine screening of all adults, now using questions about weekly and per-occasion drinking (c) (section 11.2). Selective screening (a) misses many people who drink heavily and reinforces stereotypes. Liver tests (b) are not a screening tool and can be normal in people who drink heavily. A urine drug screen (d) does not measure drinking patterns, is not a substitute for asking and needs the patient's consent.

7. [CORE] Which statement about Wernicke encephalopathy is accurate?

a. Most patients do not show all three classic signs.

b. It occurs only in people who have an alcohol use disorder.

c. Intravenous glucose should be given before thiamine to provide energy to the brain.

d. The memory loss of Korsakoff syndrome usually resolves fully within a few weeks once thiamine is given.

Answer: a — Only about 10% to 16% of patients show the full triad of confusion, ataxia and abnormal eye movements, so the nurse reports even one sign in a patient at risk (a) (section 11.3). Malnutrition, bariatric surgery, prolonged vomiting and cancer are other causes (b). Thiamine is given before glucose, not after (c). Korsakoff syndrome is a lasting memory disorder; it usually does not resolve (d).

8. [CORE] A patient admitted for cellulitis drank heavily every day until admission. The nurse knows that the risk of delirium tremens is greatest during which period after the last drink?

a. Within the first 6 hours

b. 12 to 24 hours

c. 24 to 48 hours

d. 48 to 72 hours

Answer: d — Delirium tremens typically begins 48 to 72 hours after the last drink and can last up to 5 days (d) (section 11.3, Table 11.2). Minor withdrawal begins in the first hours (a). Hallucinosis usually begins at 12 to 24 hours (b). Withdrawal seizures usually occur at 24 to 48 hours (c). Timing varies, so the nurse keeps monitoring throughout.

9. [CORE] An RPN on an Ontario medical unit is caring for a patient on an alcohol withdrawal protocol. Over three assessments, the patient's scores have risen despite as-needed doses, and the patient now reports seeing insects on the wall. Which action best fits the RPN's scope of practice?

a. Continue giving as-needed doses exactly as the protocol directs and reassess the patient at the next scheduled assessment time.

b. Consult the RN promptly, share the assessment findings, and keep caring for the patient while the plan is reviewed.

c. Hand the patient's care to the RN and stop assessing the patient.

d. Ask the patient's family to stay overnight so that someone is with the patient to watch for any changes.

Answer: b — Under CNO's Scope of Practice standard, the RPN considers authority, competence and context; as a patient's needs change, the RPN consults the RN and continues to provide care within their competence, following employer policy (b) (section 11.3; Chapter 1, section 1.3). Continuing the protocol unchanged (a) ignores signs that treatment is not working and that withdrawal may be progressing. Consultation does not mean abandoning assessment (c). Family presence can comfort but does not replace professional assessment and escalation (d).

Case: Mr. Kevin Lachance (Questions 10–15): Mr. Kevin Lachance, 42, was admitted 3 days ago with an abscess of the right thigh, which was drained in the operating room. He receives IV antibiotics. On admission he said he smokes fentanyl most days, and he declined to start opioid agonist treatment. The unit has a medical directive for naloxone. At 1510, after a visitor leaves, the nurse finds him slumped in his chair. He moans but does not open his eyes to a firm shake of his shoulders. His respiratory rate is 6 and shallow, with gurgling sounds. oxygen saturation (SpO2) is 82% on room air, heart rate 56 and blood pressure 102/60 mm Hg. His pupils are pinpoint and his lips and nail beds look grey. His temperature is 37.2 °C and his capillary blood glucose is 6.1 mmol/L. A piece of foil and a straw lie on his tray table.

10. [CORE] Which of Mr. Lachance's findings require immediate action? Select all that apply.

a. Respiratory rate of 6 and shallow, with gurgling

b. Capillary blood glucose of 6.1 mmol/L

c. No eye opening to a firm shake of the shoulders

d. SpO2 82% on room air

e. Temperature 37.2 °C

f. Grey lips and nail beds

Answer: a, c, d, f — Slow, shallow breathing with gurgling (a), unresponsiveness to a firm shake (c), low oxygen saturation (d) and grey lips and nail beds (f) show that breathing is failing and need immediate action (section 11.4). A glucose of 6.1 mmol/L (b) is within the usual range and makes hypoglycemia an unlikely cause. A temperature of 37.2 °C (e) is normal.

11. [CORE] The nurse analyzes the cues. Which interpretation of Mr. Lachance's findings is most accurate?

a. The grey colour points to a primary heart problem, and the pinpoint pupils are probably a drug side effect.

b. The cluster of cues fits opioid toxicity, though another sedative in the drug supply may also contribute.

c. The cues fit opioid withdrawal, because he has had no prescribed opioids since admission.

d. The cues fit sepsis from the thigh abscess, because sepsis can reduce the level of consciousness.

Answer: b — Unresponsiveness, slow breathing, pinpoint pupils and cyanosis are the cluster of opioid toxicity, and the unregulated supply often contains non-opioid sedatives such as benzodiazepine-related drugs (b) (section 11.4). Grey colour reflects poor oxygenation from slow breathing, not a primary heart problem (a). Withdrawal causes alertness, enlarged pupils and normal or fast breathing (c) (Table 11.3). He has no fever, and pinpoint pupils with a respiratory rate of 6 are not typical of sepsis (d).

12. [CORE] Which problem is the priority for Mr. Lachance?

a. Risk of infection at the drained abscess site

b. Risk of opioid withdrawal after naloxone is given

c. Acute pain from the thigh wound

d. Inadequate breathing caused by opioid toxicity

Answer: d — Inadequate breathing threatens his life within minutes, so it comes first (d) (section 11.4). Wound infection (a) and pain (c) are real but not immediately life-threatening. Precipitated withdrawal (b) may follow naloxone, but it is uncomfortable rather than immediately dangerous and does not outrank restoring breathing.

13. [CORE] Which actions should the nurse plan for Mr. Lachance now? Select all that apply.

a. Call for help through the code blue or rapid response system, as policy directs

b. Leave the room to find his physician and obtain a written order for naloxone

c. Open the airway and ventilate with a bag-valve-mask and oxygen

d. Give naloxone by the route and dose set in the medical directive

e. Search his belongings for drugs before starting treatment

f. Prepare to repeat naloxone if breathing has not improved after 2 to 3 minutes

Answer: a, c, d, f — Calling for help (a), supporting ventilation (c), giving naloxone under the medical directive (d) and preparing to repeat it if there is no response (f) are the core steps of the response (section 11.4). The medical directive already provides authority, and leaving an unresponsive patient to seek an order (b) delays care. Searching belongings (e) delays treatment and is not part of the emergency response.

14. [CORE] Mr. Lachance woke 2 minutes after a second dose of naloxone. At 1600 he was alert, with a respiratory rate of 16. At 1625 the nurse finds him hard to rouse, with a respiratory rate of 8 and SpO2 89% on 2 L/min of oxygen. What should the nurse do first?

a. Stimulate him, support his breathing and call the rapid response team.

b. Increase the oxygen to 6 L/min and recheck him in 15 minutes.

c. Let him sleep, because he did not sleep the night before.

d. Document the findings and report them at the next handover.

Answer: a — Returning sedation and slow breathing signal recurrent toxicity as naloxone wears off, so the nurse acts at once: stimulates him, supports breathing, calls for help and gives naloxone as directed (a) (section 11.4). Raising oxygen and waiting (b) can mask worsening hypoventilation. Assuming he is only tired (c) misses a life-threatening cue. Delaying the report (d) delays rescue.

15. [CORE] By 1900, after a further dose of naloxone and close monitoring, the team reviews Mr. Lachance's care. Which findings show that the plan is working? Select all that apply.

a. He is awake and talking, with a respiratory rate of 16 and SpO2 96% on room air.

b. He has had no further episodes of sedation since the last dose.

c. He says he will leave tonight because he expects to be judged.

d. He agrees to see the addiction medicine team in the morning.

e. He accepts a naloxone kit and can describe how to use it.

f. He has refused all withdrawal assessments since 1700.

Answer: a, b, d, e — Normal breathing and oxygenation (a) and no further sedation (b) show that the immediate danger has passed. Agreeing to an addiction medicine consultation (d) and accepting naloxone with correct teach-back (e) show progress toward safer care (sections 11.4 and 11.6). A plan to leave because he expects judgment (c) and refusing withdrawal assessments (f) show the relationship and the withdrawal plan still need attention.

16. [CORE] A nurse assesses four patients who use opioids. Which finding is most consistent with opioid withdrawal rather than opioid toxicity?

a. Pinpoint pupils and a respiratory rate of 8

b. Snoring respirations and no response to voice

c. Enlarged pupils, yawning and gooseflesh

d. Grey lips and slow, shallow breathing

Answer: c — Enlarged pupils, yawning and gooseflesh are cues of withdrawal (c) (section 11.4, Table 11.3). Pinpoint pupils with slow breathing (a), snoring respirations with unresponsiveness (b) and grey lips with shallow breathing (d) are cues of opioid toxicity.

17. [CORE] The nurse is caring for a patient whose withdrawal is being monitored with the Clinical Opiate Withdrawal Scale (COWS). Which statement about COWS is accurate?

a. It rates observed signs and reported symptoms to track the severity of withdrawal over time.

b. It is a screening questionnaire that the patient completes to identify opioid use disorder.

c. It is used to score how deeply sedated a patient is after receiving an opioid.

d. It counts every elevated pulse, including a pulse raised by walking to the bathroom.

Answer: a — COWS is a clinician-rated scale that combines observed signs and reported symptoms to rate withdrawal and track it over time (a) (section 11.4). It does not diagnose opioid use disorder (b). Sedation is rated with a sedation scale, not COWS (c) (Chapter 5). Only findings caused by withdrawal are scored, so a pulse raised by activity is not counted (d).

18. [CORE] Two minutes after receiving naloxone for opioid toxicity, a patient is awake, sweating, vomiting and shouting. A family member asks whether the naloxone was harmful. Which response by the nurse is best?

a. "This is an allergic reaction to naloxone, so it cannot be given again."

b. "These are signs that the opioid is still working and he needs more naloxone."

c. "These symptoms mean he took a stimulant, not an opioid."

d. "Naloxone blocked the opioid suddenly, which caused withdrawal symptoms."

Answer: d — Naloxone can precipitate sudden withdrawal in a person who is physically dependent on opioids, with vomiting, sweating and agitation (d) (section 11.4). An allergic reaction would cause hives, wheezing or swelling, not this pattern (a). An awake patient is no longer showing opioid toxicity, so more naloxone is not indicated (b). The response to naloxone points to an opioid, not a stimulant (c).

19. [CORE] A patient admitted after using methamphetamine is agitated and pacing. Temperature is 39.4 °C, heart rate 138 and blood pressure 172/98 mm Hg. Which action is the priority?

a. Apply four-point restraints to prevent the patient from leaving.

b. Report the findings at once and begin cooling and sedation as ordered.

c. Encourage the patient to walk in the hallway to calm down.

d. Recheck the temperature in 4 hours to see whether it falls.

Answer: b — A high temperature with severe agitation is dangerous in stimulant toxicity, so the nurse escalates at once and begins cooling and ordered sedation (b) (section 11.5). Physical restraint can precipitate cardiac arrest in severe agitation (a). Activity increases heat production (c). Waiting 4 hours (d) allows hyperthermia to progress.

20. [CORE] A patient has had three admissions this year for severe vomiting. The patient uses cannabis several times a day and says hot showers are the only thing that helps. After serious causes are ruled out, which teaching is most appropriate?

a. "Switching to edible cannabis products should stop the vomiting."

b. "Taking a scheduled antiemetic every day should prevent future episodes."

c. "Stopping cannabis is what makes these episodes go away for good."

d. "Long hot showers are the most effective way to treat the cause."

Answer: c — The pattern suggests cannabinoid hyperemesis syndrome, and lasting remission requires stopping cannabis (c) (section 11.5). The syndrome is linked to heavy long-term use, not only to smoking, so edibles are not a solution (a). Standard antiemetics often fail (b). Hot showers ease symptoms but do not treat the cause (d).

21. [CORE] Which nursing action best reflects the principle of harm reduction?

a. Offering a naloxone kit and teaching to a patient who plans to keep using

b. Telling a patient that treatment is available only after they stop using

c. Removing a patient's access to visitors after drug use is suspected

d. Making a referral to addiction services a condition of pain management

Answer: a — Harm reduction reduces risk without requiring a person to stop using, and take-home naloxone is a core example (a) (section 11.6). Requiring abstinence first (b), punishing suspected use (c) and making pain care conditional (d) work against harm reduction and trust.

22. [CORE] A patient who uses fentanyl is being discharged after 9 days in hospital. Which statement shows that the patient understands overdose risk after discharge?

a. "I can go right back to my usual amount, since I haven't used for a while."

b. "I'm safest if I use alone so that no one gets in trouble."

c. "Overdose only happens to people who inject, and I smoke."

d. "My tolerance is lower now, so the amount I used to take could kill me."

Answer: d — After a hospital stay with little or no use, tolerance falls, so returning to the previous amount can cause an overdose (d) (section 11.6). The usual amount is now riskier, not safer (a). Using alone removes the chance of rescue (b). Overdose can occur with any route, including smoking (c).

23. [CORE] The nurse teaches a patient and a family member how to respond to an opioid overdose with the take-home naloxone kit. Which instructions are accurate? Select all that apply.

a. Call 9-1-1 if the person does not respond to shouting and shaking.

b. Give a second dose if there is no improvement after 2 to 3 minutes.

c. Wait for paramedics before giving naloxone, because it is a prescription drug.

d. Give rescue breaths or chest compressions as part of the response.

e. Stay with the person until help arrives, even after they wake up.

f. Avoid giving naloxone if you are not sure the person took an opioid.

Answer: a, b, d, e — The steps are to shout and shake, call 9-1-1 (a), give naloxone, give rescue breaths or compressions (d), repeat naloxone after 2 to 3 minutes if there is no change (b), and stay because the overdose can return (e) (sections 11.4 and 11.6). Naloxone is available without a prescription and bystanders may give it (c). It is unlikely to cause harm when the cause is not an opioid, so uncertainty is not a reason to withhold it (f).

24. [CORE] A patient being discharged says, "If my friend overdoses, I won't call 9-1-1, because the police will charge me." Which response by the nurse is most accurate?

a. "Calling 9-1-1 protects you from every criminal charge."

b. "A federal law protects you from a charge of simple possession if you call for help."

c. "That law protects only the person who overdosed, not the caller."

d. "That protection applies only if you stay until the ambulance arrives."

Answer: b — When someone calls for help with an overdose, the Good Samaritan Drug Overdose Act protects the people at the scene from charges of simple possession (b) (section 11.6). It does not cover all charges, such as trafficking or outstanding warrants (a). It covers the caller and others at the scene as well as the person who overdosed (c). It applies whether or not the caller stays (d).

25. [CORE] An RPN on a medical unit hears a call bell from a patient assigned to another nurse and finds the patient unresponsive, with a respiratory rate of 4. What should the RPN do first?

a. Find the assigned RN, because the patient is not on the RPN's assignment.

b. Check the patient's medication record for recent opioid doses.

c. Wait at the bedside until the assigned nurse returns from break.

d. Call for help and begin to support the patient's breathing.

Answer: d — Every nurse who finds a patient deteriorating acts at once and escalates, whoever is assigned (d) (section 11.6, Scope in Practice box). Looking for the assigned nurse (a), reviewing records (b) and waiting (c) all delay rescue breathing and naloxone.

26. [CORE] An RPN cares for a patient who started buprenorphine-naloxone yesterday. Today the patient's withdrawal score is rising, and the patient reports new chest tightness. Which action by the RPN is most appropriate?

a. Give an extra buprenorphine-naloxone dose from the patient's own supply.

b. Continue the plan and reassess the withdrawal score at the end of the shift.

c. Consult the RN and report the findings to the prescriber promptly.

d. Change the buprenorphine-naloxone schedule to manage the rising score.

Answer: c — The patient's condition is changing, so the RPN consults the RN and the findings are reported promptly (c) (section 11.6, Scope in Practice box). Nurses give OAT only as ordered and never from a patient's own supply without an order (a). Waiting until the end of the shift (b) delays assessment of chest tightness. Changing the schedule (d) is a prescriber's decision.

27. [RN] A student nurse asks why buprenorphine can cause withdrawal in a patient who has recently used fentanyl. Which explanation by the RN is most accurate?

a. Buprenorphine contains enough naloxone when swallowed to block all opioid receptors.

b. Buprenorphine binds tightly to mu receptors but activates them only partly, displacing fentanyl.

c. Buprenorphine speeds up the liver's breakdown of fentanyl.

d. Buprenorphine is an opioid antagonist with no effect at the mu receptor.

Answer: b — As a high-affinity partial agonist, buprenorphine displaces full agonists such as fentanyl and replaces a strong effect with a weaker one, which feels like abrupt withdrawal (b) (section 11.4, Going Deeper box). The naloxone in sublingual tablets is poorly absorbed when taken as directed and is there to discourage injection (a). Buprenorphine does not speed fentanyl breakdown (c). It is a partial agonist, not an antagonist (d).

28. [RN] A patient who smoked fentanyl 6 hours ago asks for buprenorphine now, under a standard induction plan. The patient has a mild withdrawal score. What is the RN's best response?

a. Explain that the first dose waits until withdrawal is clearer, and notify the prescriber.

b. Give the first dose now, because any withdrawal means the receptors are free.

c. Give naloxone first to clear fentanyl from the receptors before buprenorphine.

d. Tell the patient that buprenorphine cannot be used after fentanyl.

Answer: a — Standard induction waits until withdrawal is clearly present, so that buprenorphine relieves withdrawal instead of precipitating it; the RN explains this and informs the prescriber (a) (section 11.4). Mild withdrawal soon after fentanyl does not mean the receptors are free (b). Naloxone would cause severe withdrawal (c). Buprenorphine can be started after fentanyl, by standard or low-dose induction (d).

29. [RN] Which statement best describes the principle of low-dose buprenorphine initiation?

a. Buprenorphine is started only after all opioids have been stopped for several days.

b. A single large dose of buprenorphine is given to block fentanyl quickly.

c. Methadone is given first, and buprenorphine is added once withdrawal begins.

d. Small, increasing buprenorphine doses overlap with the usual opioid, which stops later.

Answer: d — In low-dose initiation, small doses of buprenorphine gradually occupy receptors while the full agonist continues, and the full agonist stops once buprenorphine reaches an effective level (d) (section 11.4, Going Deeper box). Waiting for several days without opioids (a) is the barrier the approach avoids. A large first dose (b) risks precipitated withdrawal. Starting with methadone (c) is not part of the method.

30. [RN] Why can standard buprenorphine induction be harder for people who use fentanyl?

a. Fentanyl is a partial agonist that competes with buprenorphine at the receptor.

b. Fentanyl is cleared by the kidneys more slowly than other opioids.

c. Fentanyl is stored in fatty tissue and released slowly, so it may still occupy receptors.

d. Fentanyl causes withdrawal that cannot be measured with standard scales.

Answer: c — Fentanyl is highly fat-soluble, accumulates in tissues with repeated use and is released slowly, so it may still occupy receptors when withdrawal is felt (c) (section 11.4, Going Deeper box). Fentanyl is a full agonist, not a partial agonist (a). The issue is tissue storage, not kidney clearance (b). Withdrawal from fentanyl can still be measured with COWS (d).

III Respiratory Nursing Care

UNIT CLINICAL SCOPE & INTEGRATION

Covers comprehensive bedside respiratory assessment, oxygen delivery devices, tracheostomy and chest tube management, lower respiratory tract infections, tuberculosis, lung cancer, chronic obstructive pulmonary disease (COPD), asthma, acute respiratory distress syndrome (ARDS), mechanical ventilation principles, and pulmonary embolism.

Contents of UNIT III

Chapter	Chapter Title	Visual Assets	Page
Chapter 12	Respiratory Assessment and Oxygen Therapy	10 Figs • 4 Tbls	p. 318
Chapter 13	Lower Respiratory Infections and Lung Cancer	7 Figs • 4 Tbls	p. 349
Chapter 14	Obstructive and Restrictive Lung Disease	7 Figs • 4 Tbls	p. 380
Chapter 15	Acute Respiratory Failure and Pulmonary Embolism	6 Figs • 4 Tbls	p. 409

12 Respiratory Assessment and Oxygen Therapy

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Relate ventilation, diffusion, perfusion and oxygen transport to assessment findings.
2. Perform a focused respiratory assessment, describing findings accurately on a range of skin tones.
3. Interpret pulse oximetry and its limits, including reduced accuracy with darker skin pigmentation.
4. Give and monitor oxygen safely to an ordered target range with the right delivery device.
5. Promote airway clearance and prevent pulmonary complications.
6. Care for patients with artificial airways and tracheostomies, including recognizing and responding to airway emergencies.
7. Teach patients and families about home oxygen and tracheostomy care.
8. Distinguish RN and RPN roles in airway care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4, 5, 6	Clinician; Scholar	Foundations of Practice
3, 7	Advocate; Educator	Foundations of Practice; Ethical Practice
6, 8	Professional; Collaborator	Legal Practice; Collaborative Practice

Introduction

Every cell needs a steady supply of oxygen and a way to get rid of carbon dioxide. When breathing fails, a patient can deteriorate quickly, so nurses check the airway and breathing first in any emergency and reassess them often. A rising respiratory rate or new effort to breathe is often one of the first clues that a patient is getting worse, which is why breathing is part of the early warning scores in Chapter 6. Yet breathing is easy to under-assess: short counts underestimate the respiratory rate (Hill et al., 2018), and a reassuring oximeter reading can distract from a patient who looks unwell.

This chapter is the book's home for respiratory assessment and oxygen therapy. Section 12.1 reviews how the lungs move air and exchange gases, section 12.2 covers the focused respiratory assessment, including colour on a range of skin tones, and section 12.3 explains pulse oximetry, its limits and the oxygen values on an arterial blood gas. Sections 12.4 to 12.6 cover oxygen therapy, airway clearance, and artificial airways and tracheostomy care. Related topics live elsewhere: acid–base balance (Chapter 3, section 3.7), aerosol-generating procedures (Chapter 4), opioid-induced respiratory depression (Chapter 5), recognizing deterioration (Chapter 6), postoperative pulmonary complications (Chapter 7), and respiratory disorders (Chapters 13 to 15).

12.1 Breathing and Gas Exchange: A Brief Review

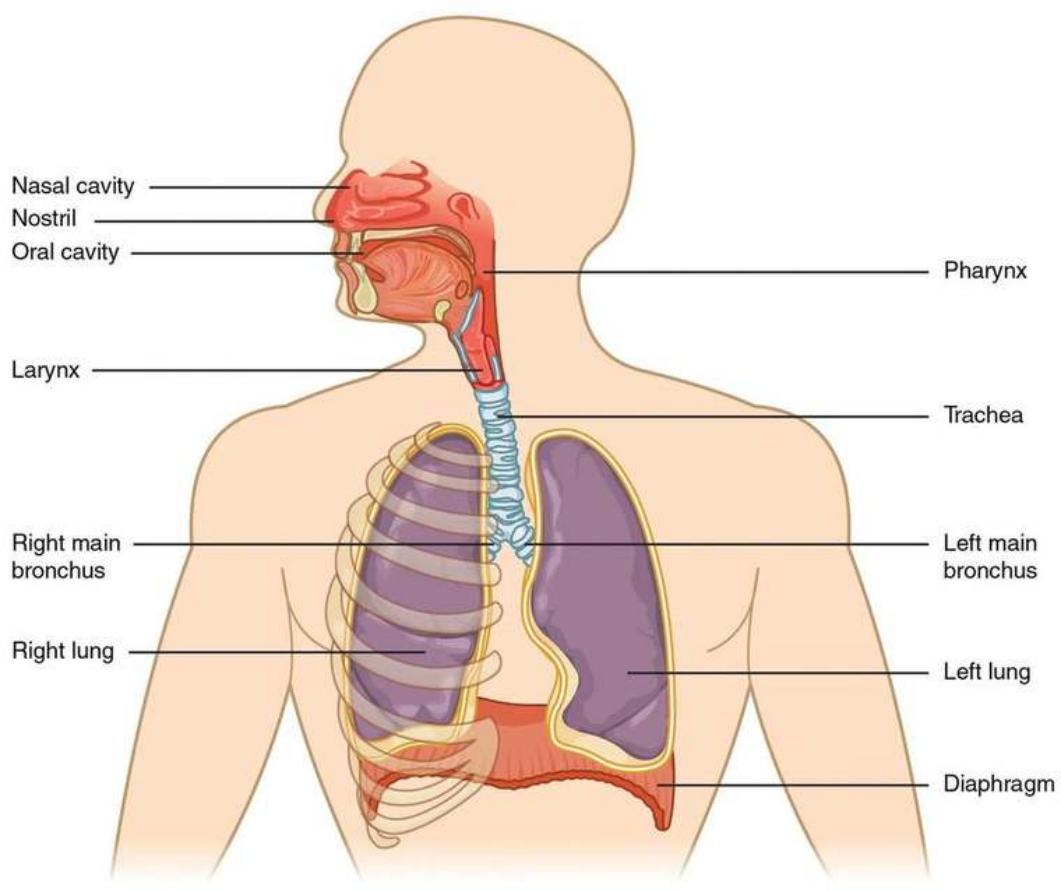

Figure 12.1 The main structures of the respiratory system, from the nose and mouth to the lungs and diaphragm. (credit: Figure 22.2, "Major Respiratory Structures," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

Moving Air

The respiratory system brings oxygen into the blood and removes carbon dioxide (CO_2). Air passes through the upper airway and trachea into bronchi that branch again and again and end in tiny air sacs called **alveoli**, where gas exchange takes place (Figures 12.1 and 12.2). A thin membrane, the **pleura**, covers each lung and lines the chest wall.

Ventilation is the movement of air into and out of the lungs. Breathing in is active: the diaphragm contracts and moves down, and the muscles between the ribs lift the rib cage, drawing air in. Quiet breathing out is mostly passive, as the lungs and chest wall spring back. When more air is needed, accessory muscles in the neck and shoulders help lift the chest.

Two properties decide how hard the breathing muscles must work. **Compliance** is how easily the lungs and chest wall stretch; stiff, scarred or fluid-filled lungs need more effort for each breath. **Airway resistance** is how much the airways oppose airflow; spasm, swelling or secretions raise it. The effort spent on breathing is the **work of breathing** (Sharma & Goodwin, 2006). When it rises, the patient breathes faster and uses accessory muscles; if the effort can't be kept up, breathing can fail (Chapter 15).

Gas Exchange

Oxygen and CO_2 cross the **alveolar–capillary membrane**, the thin barrier between alveolar air and capillary blood, by **diffusion**: each gas moves from higher to lower pressure. Diffusion slows when the area for exchange shrinks, when the membrane thickens with inflammation or scarring, or when blood moves past too quickly. Carbon dioxide dissolves far more readily than oxygen, so a diffusion problem lowers blood oxygen but rarely raises CO_2 (Sarkar et al., 2017).

Perfusion is blood flow through the lung capillaries. When the air reaching part of the lung does not match the blood flowing past it, the result is a **ventilation–perfusion (V/Q) mismatch**. This mismatch causes low blood oxygen more often than any other mechanism (Sarkar et al., 2017). Two extremes help explain it:

- **Shunt:** Blood flows past alveoli that get no air, such as collapsed or fluid-filled alveoli, and returns to the heart without picking up oxygen. Extra oxygen helps little, because it never reaches that blood (Sarkar et al., 2017).
- **Dead space:** Air reaches alveoli with little or no blood flow, so it takes no part in gas exchange (Sarkar et al., 2017). A clot blocking a pulmonary artery is one cause (Chapter 15).

The lung partly protects itself through **hypoxic pulmonary vasoconstriction**: small arteries in poorly ventilated areas narrow and steer blood toward alveoli that are getting air (Sarkar et al., 2017).

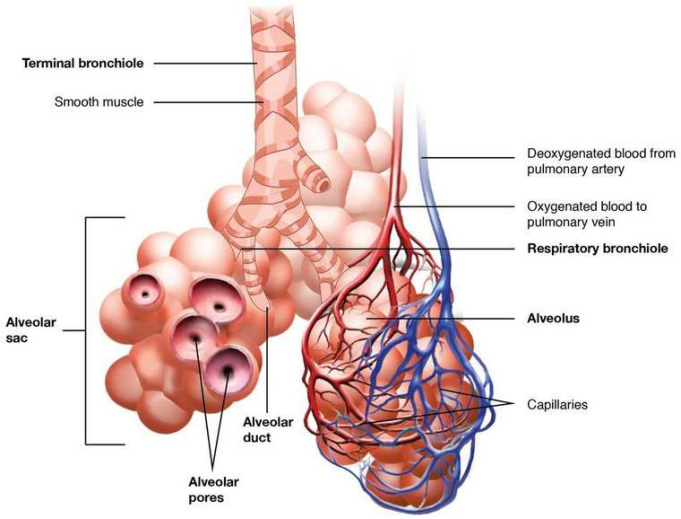

Figure 12.2 The respiratory zone: bronchioles end in alveolar ducts and clusters of alveoli, each wrapped in capillaries where gas exchange takes place. (credit: Figure 22.10, “Respiratory Zone,” in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

Hypoxemia is low oxygen in the arterial blood; **hypoxia** is too little oxygen in the tissues. Hemoglobin and cardiac output can protect the tissues of a patient with hypoxemia, and tissue hypoxia can occur with normal blood oxygen when delivery is poor or cells cannot use oxygen, as in cyanide poisoning (Sarkar et al., 2017).

Control of Breathing and Oxygen Transport

Brainstem centres set the rate and depth of breathing in response to chemical sensors. Sensors in the brainstem and in the **carotid bodies**, small clusters of cells beside the carotid arteries in the neck, respond to CO2 mainly through its effect on acidity (pH). This fast feedback is a major way the body keeps arterial CO2 and pH steady from moment to moment. The carotid bodies also sense low arterial oxygen, and acidosis strengthens their response to it (Guyenet & Bayliss, 2015).

Many clinicians were taught that oxygen given to a person with chronic obstructive pulmonary disease (COPD) removes a "hypoxic drive" and stops them breathing. Research has not supported this idea. In people at risk, high oxygen levels raise CO2 mainly by relaxing hypoxic pulmonary vasoconstriction, which worsens V/Q mismatch; a brief fall in breathing effort plays only a small part. Withholding oxygen from patients with hypoxemia because of this myth is unsafe (Abdo & Heunks, 2012); the nurse gives oxygen to the target range the prescriber orders (section 12.4).

Oxygen saturation is the percentage of hemoglobin carrying oxygen: SaO2 when measured on an arterial sample, SpO2 when estimated by a pulse oximeter (section 12.3). The **oxygen–hemoglobin dissociation curve** relates saturation to the partial pressure of oxygen in arterial blood (PaO2). The curve is S-shaped. Above about 90% saturation it is flat, so large changes in PaO2 change saturation very little. Below a PaO2 of about 60 mm Hg it is steep, so a small drop in PaO2 causes a large drop in saturation (Collins et al., 2015). A patient whose saturation is drifting toward 90% therefore has little reserve, so a falling trend needs prompt action.

12.2 Focused Respiratory Assessment

If a patient is in distress, the nurse checks airway, breathing and circulation first, acts and calls for help (Chapter 6); the detailed assessment follows once the patient is safe. A focused respiratory assessment combines history, inspection, palpation, percussion and auscultation with pulse oximetry (section 12.3). Each finding is compared with the patient's baseline and the last assessment.

History

Dyspnea is the patient's own experience of uncomfortable or difficult breathing, so only the patient can report it. The nurse asks:

- **Onset:** Sudden, or over days or weeks?
- **Triggers and relief:** What brings it on (activity, lying flat, allergens) and what eases it?
- **Effect on activity:** What can the patient no longer do? Does it occur at rest or at night?

A rating scale gives a baseline for later comparison. The modified Medical Research Council (mMRC) dyspnea scale grades breathlessness from 0, breathless only with hard exercise, to 4, too breathless to leave the house or breathless while dressing (Canadian Lung Association, n.d.).

The nurse asks how long any cough has lasted and about sputum colour, amount and thickness. Coughing up blood (**hemoptysis**) is always reported. Sharp chest pain that worsens with a deep breath or cough suggests irritation of the pleura. Other questions cover:

- **Smoking and vaping:** Current and past tobacco use, e-cigarettes and cannabis smoking.
- **Exposures:** Dusts and fumes at work, wildfire smoke, and radon at home. Radon is the leading cause of lung cancer in people who don't smoke and the second leading cause overall, and radon and smoking together greatly increase the risk (Health Canada, 2019). The nurse can ask whether the home has been tested.
- **Devices:** Inhalers, home oxygen or a continuous positive airway pressure (CPAP) machine, and the patient's usual oxygen saturation.

Inspection

Inspection begins at the door with the **level of consciousness**: new restlessness, anxiety or confusion can signal low oxygen. New drowsiness in a patient at risk of CO_2 retention is also a warning sign (O'Driscoll et al., 2017b).

Next comes the **respiratory rate**. The nurse counts for a full 60 seconds, ideally while the patient is unaware of it. Shorter counts give systematically lower rates, and awareness of being watched lowers the rate (Hill et al., 2018). The nurse notes rhythm, depth and patterns:

- **Tachypnea:** A rate faster than the normal adult range; a nonspecific early sign of many problems (Chapter 6).
- **Bradypnea:** A rate slower than the normal adult range, as with opioids (Chapter 5).
- **Kussmaul breathing:** Deep, rapid breaths in metabolic acidosis, such as diabetic ketoacidosis, as the body blows off CO_2 (Chapter 3, section 3.7).
- **Cheyne–Stokes breathing:** A repeating cycle in which breathing deepens, fades, then stops for a time; common in heart failure, mostly during sleep (Lorenzi-Filho et al., 2005).

Signs of increased **work of breathing** include use of the neck and shoulder muscles, nostril flaring, pulling in of the skin between the ribs or above the collarbones (retractions), pursed-lip breathing, sitting forward with hands braced on the knees (the tripod position), and speaking only a few words between breaths. A patient working hard to breathe needs help now, even if the oxygen saturation looks acceptable.

Both sides of the chest should rise equally. A curved upper spine can stiffen the chest wall in older adults (Sharma & Goodwin, 2006).

Colour. Cyanosis is a bluish or greyish colour caused by too much hemoglobin that is not carrying oxygen. **Central cyanosis** appears in the tongue, lips and lining of the mouth and signals low arterial oxygen, an emergency. **Peripheral cyanosis** affects only the fingers, toes or nail beds, with a normal tongue, and usually reflects slow blood flow to cold extremities. Judging oxygen by colour is unreliable for everyone and harder still on darker skin. Studies, mostly in newborns, show that visual checks miss low oxygen in darker skin and that the tongue and lips are the most useful places to look (Fair et al., 2025). On darker skin, cyanosis may look grey or whitish around the mouth and in the conjunctivae rather than blue (Pusey-Reid et al., 2023). The nurse therefore:

- looks at the tongue, lips, inside of the mouth and conjunctivae in natural or bright, indirect light, rather than fluorescent light (Pusey-Reid et al., 2023);
- compares with the patient's baseline and asks the patient or family what is normal for them;
- never waits for cyanosis, a late sign, but acts on the respiratory rate, work of breathing, level of consciousness and pulse oximetry.

Pallor can signal anemia or poor blood flow. On brown skin, pallor may look yellow-brown, and on very dark skin, ash-grey; the conjunctivae and the lining of the mouth are easier to judge than the limbs (Pusey-Reid et al., 2023). In a study of adolescents and adults in India, the tongue was the most useful site for detecting severe anemia, ahead of the conjunctivae, palms and nail beds. Observers often disagreed, and the absence of pallor did not rule out milder anemia, so a hemoglobin level is needed when anemia is suspected (Kalantri et al., 2010).

Clubbing is a painless enlargement of the fingertips, with loss of the normal angle where the nail meets the skin. When the backs of matching fingers are placed together, a small diamond-shaped gap normally shows between the nail beds; in clubbing, it disappears. Clubbing is linked to lung cancer and to chronic infective, diffuse lung and heart diseases. COPD itself rarely causes it, so new clubbing in a person with COPD raises concern about lung cancer (Matsuura, 2019; Figure 12.3).

Figure 12.3 Clubbing of the fingers with cyanosis of the nail beds. On darker skin, cyanosis may look grey rather than blue. (credit: modification of "Showing bilateral grade III clubbing with cyanosis of the extremities" by Twayana et al./BMC Research Notes, CC BY 4.0)

Palpation and Percussion

To check **chest expansion**, the nurse places both hands on the lower back of the chest, thumbs near the spine, and asks for a deep breath. The thumbs should move apart equally; a lagging side may hold fluid or collapsed lung. **Tactile fremitus** is the vibration felt through the chest wall when the patient speaks; fluid or air between lung and chest wall dampens it, and an effusion is less likely when fremitus is not reduced (Wong et al., 2009).

The nurse also feels for tenderness and for **subcutaneous emphysema**, air trapped under the skin that crackles under the fingertips. It can appear around a chest injury, chest tube or tracheostomy (section 12.6; Chapter 15); the nurse marks its edges and reports new or spreading crepitus.

Percussion is tapping on the chest to judge what lies beneath. Normal air-filled lung sounds **resonant**; a **dull** note suggests fluid or solid tissue, such as an effusion or consolidation; a **hyperresonant** note suggests extra air, as with a pneumothorax. Dullness is the most accurate bedside sign of pleural effusion, though a chest X-ray is still needed (Wong et al., 2009).

Auscultation

For reliable findings (Figure 12.4), the nurse:

- chooses a quiet setting and has the patient sit up, or turns a patient who can't sit from side to side;
- warms the stethoscope and places the diaphragm on bare skin, never over clothing;
- has the patient take slow, deep breaths with the mouth open;
- starts at the top of the lungs and moves down, comparing the same spot on each side, listening to at least one full breath at each site (Sarkar et al., 2015).

Normal breath sounds vary by location. **Vesicular** sounds over most of the lungs are soft and low-pitched, with breathing in longer than breathing out. **Bronchial** sounds over the upper sternum are loud and high-pitched, with breathing out longer. **Tracheal** sounds are harsh and loud (Sarkar et al., 2015). Quiet or absent sounds over one area suggest less airflow or fluid or air between the lung and the stethoscope.

Adventitious sounds are extra sounds not normally heard. A European Respiratory Society (ERS) task force has worked to standardize their names (Pasterkamp et al., 2016), and its members found that clinicians agree more often when they use simple, broad terms such as crackles and wheezes (Melbye et al., 2016). Table 12.1 summarizes the main sounds.

Figure 12.4 Listening to the lungs from the back, on bare skin, comparing side to side.

- **Crackles:** brief, non-musical pops, usually on breathing in, described as fine or coarse (Sarkar et al., 2015). Crackles predict pneumonia on X-ray better than any single symptom (Melbye et al., 2016).
- **Wheezes:** continuous, musical sounds from narrowed airways, usually on breathing out. A wheeze in one spot suggests a local blockage. In severe asthma, airflow may be too low to make any sound, a "silent chest" (Sarkar et al., 2015).
- **Rhonchi:** low-pitched, continuous, snoring sounds; the term is used interchangeably with "low-pitched wheeze" (Melbye et al., 2016).
- **Stridor:** a loud, high-pitched, musical sound, mostly on breathing in and loudest over the neck, caused by a narrowed upper airway (Sarkar et al., 2015). Stridor is an emergency: the nurse stays with the patient, keeps them upright and calls for immediate help.
- **Pleural friction rub:** a grating sound in both phases of breathing, from inflamed pleural layers rubbing together (Sarkar et al., 2015).

Table 12.1 Normal and adventitious breath sounds (based on Sarkar et al., 2015, and Melbye et al., 2016; original wording)

Sound	What it sounds like	Where and when	What it may suggest	Nursing action
Vesicular (normal)	Soft, low-pitched rustling	Over most of the lungs; breathing in is longer than breathing out	Normal airflow	Record as baseline and compare at each assessment
Bronchial (normal in its usual place)	Loud, hollow, high-pitched	Over the upper sternum; breathing out is longer	Normal over large airways; heard elsewhere may mean consolidation	Compare sides; report bronchial sounds over the outer lung
Fine crackles	Soft, high-pitched, many brief pops	Usually late in breathing in; often at the bases	Interstitial lung disease, early heart failure, resolving pneumonia	Check for other changes; report new crackles
Coarse crackles	Louder, lower-pitched, fewer pops	Breathing in, sometimes breathing out	Secretions or fluid in larger airways	Encourage coughing and deep breathing; report if new or with distress
Wheeze	Continuous, musical, often high-pitched	Usually breathing out; widespread or in one spot	Narrowed airways; a local wheeze may mean a blockage	Assess work of breathing and SpO2; give ordered inhaled medication; report
Rhonchi (low-pitched wheeze)	Continuous, low-pitched, snoring	Breathing in or out	Secretions or narrowing in larger airways	Note any change after coughing; support airway clearance
Stridor	Loud, high-pitched, musical	Mainly breathing in; loudest over the neck	Narrowed upper airway	Emergency: stay with the patient, call for immediate help, keep upright

Sound	What it sounds like	Where and when	What it may suggest	Nursing action
Pleural friction rub	Grating, creaking, leathery	Breathing in and out, often where it hurts	Inflamed pleura	Assess pain; report a new rub

LIFESPAN CONSIDERATIONS

Breathing and Older Adults

Aging changes the lungs and chest in ways that matter for assessment. Changes in the spine and chest wall make the respiratory system less compliant, which raises the work of breathing. The lung tissue loses some of its supporting structure, and the breathing muscles become weaker, which can make coughing less effective at clearing the airways (Sharma & Goodwin, 2006).

Older adults also respond less strongly to low oxygen and high CO2, and they feel breathlessness less. As a result, an older patient may report little dyspnea even when the problem is serious. Reserve is smaller, so illnesses that raise the demand for breathing, such as pneumonia or heart failure, can lead to breathing failure more quickly (Sharma & Goodwin, 2006).

The nurse therefore counts respirations carefully and treats a new rise in rate, new confusion or a change in function as possible signs of respiratory illness. A weak cough and swallowing problems raise the risk of aspiration. Chapter 8 covers delirium, atypical presentations and other priorities for older adults in hospital.

12.3 Pulse Oximetry and Other Measures

How Pulse Oximetry Works

Pulse oximetry estimates arterial oxygen saturation without a needle. A probe on a finger, toe or earlobe (see Figure 6.1) shines red light (about 660 nm) and infrared light (about 940 nm) through the tissue. Hemoglobin carrying oxygen absorbs more infrared light, and hemoglobin without oxygen absorbs more red light. The device looks only at the part of the signal that pulses with each heartbeat, which comes from arterial blood, and filters out skin, bone and venous blood (Miyake et al., 2003). The result is the SpO2. It is usually within about 2% of the SaO2 measured on an arterial blood sample, and it is generally reliable above a saturation of about 88% but less so below it (Collins et al., 2015).

Good technique makes the reading trustworthy:

- Choose a warm site with good blood flow, and keep the patient's hand still and supported.
- Wait for a steady reading, and check the signal-strength indicator or waveform that most devices display (Collins et al., 2015).
- Compare the pulse rate on the oximeter with the patient's heart rate; a mismatch suggests a poor signal.
- Record the SpO2 with the oxygen device and flow, for example "SpO2 93% on nasal cannula at 2 L/min."

A single reading means less than the trend. An independent review in the United Kingdom recommended that people using oximeters at home watch for changes in readings rather than rely on one reading, and that clinicians be taught to follow trends and not to give or withhold treatment on fixed thresholds alone (Department of Health and Social Care [DHSC], 2024).

Pulse oximetry measures oxygen saturation only. It gives no direct information about CO2, pH or ventilation, and a normal SpO2 does not remove the need for a blood gas, especially in a patient receiving oxygen (O'Driscoll et al., 2017b). A patient on oxygen can keep a normal SpO2 while CO2 builds up from slow, shallow breathing; Chapter 5 (section 5.4) explains how capnography detects this.

Accuracy and Skin Pigmentation

Pulse oximeters can overestimate saturation in people with darker skin pigmentation, causing **occult hypoxemia**: a dangerously low arterial saturation hidden behind a reassuring SpO2.

In a widely cited study, Sjoding and colleagues (2020) compared pulse oximetry with arterial blood gases in Black and White patients in the United States. They defined occult hypoxemia as an SaO2 below 88% when the SpO2 read 92% to 96%. Among adult inpatients receiving supplemental oxygen at the University of Michigan, this occurred in 11.7% of such paired readings from Black

patients and 3.6% from White patients. In a cohort from intensive care units at 178 US hospitals, the figures were 17.0% and 6.2%. Race is a poor stand-in for skin pigmentation, and later studies have measured skin colour directly:

- A 2022 systematic review of 32 studies (6,505 participants) found that pulse oximetry probably overestimates saturation in people with high skin pigmentation, by an average of 1.11 percentage points. The average error was small, but individual readings varied around it, and the review could not say how large the problem is outside hospitals (Shi et al., 2022).
- An English study of 903 critically ill adults, in which skin tone was measured with a spectrophotometer, tested five fingertip oximeters used in a home monitoring program. On average, all five read 0.6 to 1.5 percentage points higher when skin tone was darker than when it was lighter. Readings above 94% when the SaO2 was 92% or lower, which falsely looked reassuring, were 2.3 to 7.1 times more common with darker skin, depending on the device (Martin et al., 2026).

Regulators have responded. The UK review, published March 11, 2024, found that oximeters read oxygen levels too high in people with darker skin tones, more so when saturation is low, and that testing on participants with light skin had made their readings the norm. It called for better guidance, labelling and testing (DHSC, 2024). On January 7, 2025, the US Food and Drug Administration (FDA) released draft guidance for manufacturers. It recommends larger clinical studies across skin tones that rate skin tone with both a subjective 10-point scale and an objective measurement, and labelling that states how a device performs across skin tones (FDA, 2025). Canadian action is described in the Canadian Context box.

What the nurse does:

- Looks at the whole patient: respiratory rate, work of breathing, level of consciousness, colour and heart rate.
- Follows trends and is not reassured by a "normal" SpO2 when the patient looks unwell.
- Asks for an arterial blood gas (ABG) when the SpO2 and the patient don't match, and escalates (Chapter 6).
- Reports device concerns according to employer policy.

The nurse never adds or subtracts points from a reading based on a patient's race or skin colour. No validated correction exists, and estimating one invites error and bias (Chapter 2).

Other Limits

Several other factors can make SpO2 readings wrong or impossible to obtain (Table 12.2). Carbon monoxide deserves special attention. Standard oximeters cannot tell hemoglobin carrying carbon monoxide from hemoglobin carrying oxygen, so a person with carbon monoxide poisoning can show a normal SpO2 while their blood carries dangerously little oxygen (Collins et al., 2015; O'Driscoll et al., 2017b). Severe anemia is a similar trap: saturation can read normal although the blood holds little oxygen, because there is little hemoglobin to carry it (O'Driscoll et al., 2017b).

Table 12.2 Factors that affect pulse oximetry readings (Collins et al., 2015; Health Canada, 2022; Miyake et al., 2003; O'Driscoll et al., 2017b; FDA, 2021; original wording)

Factor	Effect on the reading	What the nurse does
Poor perfusion (cold hands, shock, vasoconstriction)	Weak signal; reading may be wrong or absent	Warm the site or try another; check the signal indicator; assess circulation and escalate if shock is suspected
Movement or shivering	False readings and false alarms	Support and steady the limb; wait for a steady waveform before recording
Nail polish or artificial nails	Reading may be inaccurate; some studies found dark colours lowered it	Remove the polish or use another site, per policy
Darker skin pigmentation	Reading may be falsely high, hiding hypoxemia	Assess the whole patient; follow trends; request an ABG when in doubt
Carbon monoxide poisoning	Reading may be falsely normal	Don't trust the SpO2; give high-concentration oxygen as ordered and request an arterial co-oximetry measurement
Severe anemia	SpO2 may be normal even though total oxygen in the blood is low	Check hemoglobin; assess for signs of poor oxygen delivery

Factor	Effect on the reading	What the nurse does
Bright ambient light (for example, fluorescent or procedure lights)	Interference with the light sensor	Shield the probe
Some intravenous dyes (for example, methylene blue)	Temporary false readings	Note the timing of the dye; confirm with an ABG if needed

Other Measures

Capnography measures the CO2 in each exhaled breath. It shows how well a patient is ventilating, which pulse oximetry cannot. Its use with opioids is covered in Chapter 5 (section 5.4) and its use in critical care in Chapter 15.

An **arterial blood gas** is a blood sample taken from an artery, usually the radial artery. It measures pH, PaCO2 and bicarbonate (Chapter 3, section 3.7) along with two oxygen values:

- **PaO2:** the partial pressure of oxygen dissolved in arterial blood. Canadian laboratories report it in millimetres of mercury (mm Hg). Reference ranges vary by laboratory. For example, Alberta Precision Laboratories (2021) lists 70 to 90 mm Hg for adults, while the Medical Council of Canada's list of reference values for its exams gives 83 to 116 mm Hg (Medical Council of Canada, n.d.). British and European guidelines often use kilopascals (kPa); 1 kPa is about 7.5 mm Hg (O'Driscoll et al., 2017b).
- **SaO2:** the percentage of hemoglobin carrying oxygen, measured directly by the blood gas analyzer's co-oximeter. It is the standard against which the SpO2 is judged (Collins et al., 2015).

An ABG is usually requested when a patient is critically ill, when SpO2 falls unexpectedly or more oxygen is needed to reach the target, or when a patient at risk of CO2 retention becomes drowsy or more breathless (O'Driscoll et al., 2017b). A venous blood gas is sometimes used to check pH and CO2, but venous oxygen values do not reliably estimate arterial oxygen, so a venous sample cannot replace an ABG for judging oxygenation (Collins et al., 2015).

CANADIAN CONTEXT

Pulse Oximetry and Equity

Health Canada regulates pulse oximeters as medical devices. Since December 16, 2019, Canadian hospitals have had to report documented medical device incidents to Health Canada within 30 calendar days of first documenting them. A medical device incident is a failure of a device, a decline in how well it works, or a problem with what its label or instructions say, when the problem has led to death or a serious decline in a person's health, or could do so (Health Canada, 2020). The rule covers all hospitals that a province or territory licenses or designates, as well as federal facilities that provide in-patient care. A nurse who suspects that an oximeter gave a falsely reassuring reading reports it through the hospital's safety reporting system. The hospital then decides whether the event meets this standard.

Health Canada's (2022) guidance for health care providers notes reports that oximeter readings can be less accurate in people with dark skin, with a bias toward occult hypoxemia, and that accuracy may also fall as true saturation drops. It advises following trends or taking readings at different sites, considering a blood gas to confirm oxygenation when signs conflict or a reading is in doubt, and, when a blood gas is not possible, assuming the reading is inaccurate and taking a precautionary approach. It also asks providers to check that a device is licensed in Canada and to report device problems (Health Canada, 2022). The main studies described in this section come from the United States and England. Canadian nurses use the same devices and the same safeguards: whole-patient assessment, trends, and an ABG when in doubt.

GOING DEEPER

Oxygenation on the Arterial Blood Gas

Required for RN students; optional for PN students.

Three numbers describe oxygen in arterial blood, and they measure different things:

- **PaO2** is the pressure of oxygen dissolved in the plasma. It reflects how well oxygen moves from the alveoli into the blood.
- **SaO2** is the percentage of hemoglobin carrying oxygen, measured directly by co-oximetry.
- **SpO2** is the pulse oximeter's estimate of SaO2.

The oxygen–hemoglobin dissociation curve links PaO2 to SaO2. Because the top of the curve is flat, PaO2 can fall a long way from a high value before saturation changes much. Below a PaO2 of about 60 mm Hg, the curve is steep, so small changes in

PaO2 bring large changes in saturation. Small increases in oxygen can then produce worthwhile gains in saturation (Collins et al., 2015).

The curve can shift. A **right shift** means hemoglobin holds oxygen less tightly, so it releases oxygen more easily to the tissues. Causes include a higher temperature, more CO2, a lower pH (acidosis) and more 2,3-diphosphoglycerate (2,3-DPG), a red cell compound that rises in chronic hypoxia. A **left shift**, from the opposite changes, means hemoglobin holds oxygen more tightly. This helps it pick up oxygen in the lungs but means it releases less to the tissues. One way to describe the curve's position is the P50, the PaO2 at which hemoglobin is 50% saturated, which is about 26 mm Hg in normal adult blood (Collins et al., 2015).

In practice, a patient who has a fever and acidosis has a curve shifted to the right. At any given PaO2, that patient's saturation is lower, although the tissues can draw oxygen more easily. The registered nurse (RN) reads PaO2, SaO2 and SpO2 together, alongside pH and PaCO2 (Chapter 3, section 3.7). Ratios that combine PaO2 with the inspired oxygen are taught with acute respiratory failure in Chapter 15.

12.4 Oxygen Therapy

Oxygen is one of the most common treatments on medical and surgical units. Too little leaves tissues short of oxygen; too much brings its own harms. This section covers ordering, target ranges, devices used on general units, monitoring and weaning, and safety at home. Measuring oxygenation was covered in section 12.3; respiratory failure and ventilation are covered in Chapter 15.

Oxygen Is a Drug

Medical oxygen is a drug; in Canada its containers carry a Drug Identification Number (DIN) (College of Respiratory Therapists of Ontario [CRTO], 2022). Like any medication, it needs an order or a **medical directive**, an order written in advance for any patient who meets set conditions (College of Nurses of Ontario [CNO], 2025; Chapter 1, section 1.3). Respiratory therapists (RTs) hold their own legal authority for oxygen (CRTO, 2024), and in many hospitals nurses and RTs manage it together.

The order states an **oxygen target range** for SpO2 (section 12.3), and often a starting device and flow. The British Thoracic Society (BTS) guideline advises that every patient admitted to hospital have a target range ordered (O'Driscoll et al., 2017a).

In sudden critical illness, the BTS guideline states that oxygen is started at once and documented afterward; a missing prescription must never stop a patient from receiving oxygen they need (O'Driscoll et al., 2017a). Ontario law allows anyone to give first aid or temporary assistance in an emergency (College of Nurses of Ontario [CNO], 2025), and hospitals may have directives that let nurses start oxygen. The nurse follows policy, calls for help (Chapter 6), documents and obtains an order.

Target Ranges

Hypoxemia starves tissues of oxygen (section 12.1), but **hyperoxia**, more oxygen in the blood than the body needs, also harms. A systematic review known as IOTA pooled 25 randomized trials of more than 16,000 acutely ill adults. Liberal oxygen was associated with more deaths, whether measured in hospital, at 30 days or at the longest follow-up, with no gain in other outcomes that matter to patients; the authors suggested that supplemental oxygen may become unfavourable above an SpO2 of about 94% to 96% (Chu et al., 2018). A high saturation on supplemental oxygen also hides a later fall in SpO2, so deterioration is noticed late (Barnett et al., 2022).

Current guidelines agree on the principle; their ranges differ slightly:

- **Most acutely ill adults:** the BTS guideline recommends 94% to 98% (O'Driscoll et al., 2017a). The Thoracic Society of Australia and New Zealand (TSANZ) recommends 92% to 96% (Barnett et al., 2022). A BMJ Rapid Recommendation panel strongly recommended keeping SpO2 no higher than 96% in acutely ill adult medical patients on oxygen, and judged about 90% to 94% reasonable for most patients (Siemieniuk et al., 2018).
- **Patients at risk of hypercapnic respiratory failure:** all three suggest 88% to 92%. This group includes people with COPD, obesity hypoventilation syndrome or severe obesity, neuromuscular disease, chest wall deformities such as severe kyphoscoliosis, cystic fibrosis and bronchiectasis (Barnett et al., 2022; O'Driscoll et al., 2017a). The BTS guideline suggests this range pending blood gas results (O'Driscoll et al., 2017a).

The nurse works to the range the prescriber orders and asks for one when it is missing. The BMJ panel also recommended not starting oxygen in acute stroke or myocardial infarction when SpO2 on room air is above 92% (Siemieniuk et al., 2018).

Hypercapnia is a raised level of carbon dioxide in arterial blood (partial pressure of carbon dioxide [PaCO2] above 45 mm Hg). In susceptible patients, high oxygen concentrations can raise PaCO2 (Barnett et al., 2022; section 12.3). The answer is careful titration, never withholding oxygen: the BTS guideline warns never to delay or stop oxygen for a seriously ill patient, and that stopping it suddenly can cause life-threatening rebound hypoxemia (O'Driscoll et al., 2017a). An at-risk patient who is breathless, has a falling saturation or becomes drowsy needs a blood gas (O'Driscoll et al., 2017b; Chapter 3, section 3.7).

Figure 12.5 A nasal cannula, the most common low-flow oxygen device. (credit: "Nasal cannula" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Delivery Devices

Oxygen devices fall into two groups. A **low-flow device** delivers a variable concentration of oxygen that depends on how fast and deeply the patient breathes; nasal cannulas, simple face masks and non-rebreather masks are in this group. A **high-flow device** delivers a fixed fraction of inspired oxygen (FiO2) whatever the patient's breathing pattern; Venturi masks and high-flow nasal cannulas are in this group (CRTO, 2022). Room air has an FiO2 of 0.21 (21%). Table 12.3 compares the devices used on general units.

The **nasal cannula** is the most common device (CRTO, 2022; Figure 12.5), and the BTS guideline prefers it for most patients who need oxygen (O'Driscoll et al., 2017a). The patient can talk and eat while wearing it. A simple face mask (Figure 12.6, a) must run at 5 L/min or more, because lower flows let the patient rebreathe carbon dioxide (Barnett et al., 2022). A **non-rebreather mask** has a reservoir bag and runs at 15 L/min for a seriously ill patient (O'Driscoll et al., 2017a; Figure 6.4).

A **Venturi mask** (air-entrainment mask) mixes oxygen with room air through a colour-coded valve to give a set concentration, often 24% or 28% for patients at risk of hypercapnia. Turning up the flow does not raise the concentration delivered (O'Driscoll et al., 2017a; Figure 12.6, b).

Figure 12.6 (a) A simple face mask. (b) A Venturi mask; the colour-coded valve sets the oxygen concentration. (credit: (a) “Simple face mask” and (b) “Venturi mask” by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Figure 12.7 A high-flow nasal cannula system on a pole stand, with an oxygen–air blender, a heated humidifier and heated tubing. Hospital policy decides where it is used. (credit: "High Flow Nasal Cannula Classic" by BreathDriver/Wikimedia Commons, CC BY-SA 4.0)

A **high-flow nasal cannula (HFNC)** delivers heated, humidified, blended air and oxygen through wide-bore nasal prongs at flows of up to 60 L/min (Barnett et al., 2022; CRTO, 2022; Figure 12.7). TSANZ advises considering it in selected patients with severe hypoxemic respiratory failure (Barnett et al., 2022). Hospital policy decides whether it is used on general units, and RTs often set it up.

Humidification adds water vapour to inspired gas. It is not needed for low-flow oxygen by mask or cannula, and it is reasonable for high-flow systems used for more than 24 hours. Bubble bottles, which bubble oxygen through a container of water, should not be used (O'Driscoll et al., 2017a). A tracheostomy bypasses the nose, so these patients need humidification (section 12.6).

Tubing and masks press on the skin. The nurse checks the ears, nares and bridge of the nose at each assessment and pads or repositions devices as policy allows (Chapter 35).

Table 12.3 Oxygen delivery devices on general units (Barnett et al., 2022; CRTO, 2022; O'Driscoll et al., 2017a; original wording)

Device	Flow range	Approximate oxygen delivered	Best used for	Nursing points
Nasal cannula (low flow)	About 1–4 L/min (BTS lists 2–6 L/min for most patients)	FiO2 about 0.24–0.35 at 1–4 L/min	Most patients who need modest oxygen	Comfortable; patient can eat and talk; check ears and nares for pressure; no humidifier needed for low flow
Simple face mask (low flow)	5–10 L/min	FiO2 about 0.35–0.60	Patients who need more oxygen than a cannula gives	Never run below 5 L/min (carbon dioxide rebreathing); remove for eating; watch for rising need

Device	Flow range	Approximate oxygen delivered	Best used for	Nursing points
Non-rebreather (reservoir) mask (low flow)	15 L/min	FiO2 above 0.60	Serious illness while the team assesses and escalates	Bag must stay inflated; a patient who needs it needs urgent medical review
Venturi (air-entrainment) mask (high flow)	Set by the colour-coded valve (for example, 24% at 2–3 L/min; 28% at 4 L/min)	FiO2 about 0.24–0.60, fixed by the valve	Patients at risk of hypercapnia who need a precise concentration	Raising the flow does not raise the concentration; change the valve to change FiO2, per order
High-flow nasal cannula	Up to 60 L/min, depending on the system	FiO2 about 0.21–1.0, set on a blender	Severe hypoxemic respiratory failure, per policy	Heated and humidified; RT usually sets up; rising FiO2 need calls for urgent review

Monitoring and Weaning

After every change of device, flow or FiO2, the nurse reassesses the whole patient: SpO2, respiratory rate, work of breathing, heart rate and level of consciousness. The BTS guideline asks that SpO2 be recorded after 5 minutes on a new oxygen setting, and that blood gases be rechecked after 30 to 60 minutes in a patient with COPD or another risk factor for hypercapnic respiratory failure (O'Driscoll et al., 2017a). The device, flow or FiO2 and SpO2 are documented together (O'Driscoll et al., 2017a). Oxygen treats hypoxemia, not breathlessness (CRTO, 2022); a breathless patient whose SpO2 is in range needs the cause found.

Weaning follows the order or directive. When the patient is stable and SpO2 is above range, oxygen is stepped down, usually to a low flow by cannula, and stopped once SpO2 is in range on two consecutive observations. The nurse watches SpO2 on room air for about 5 minutes and rechecks it an hour later. The target range stays on the order in case of deterioration (O'Driscoll et al., 2017a).

A rising oxygen need is a warning sign. TSANZ advises senior clinician review at an FiO2 of 0.40 or more (or 6 L/min or more by simple face mask) and intensive care review at an FiO2 of 0.50 or more (or 8 L/min or more by simple face mask) (Barnett et al., 2022). The nurse uses the early warning score, the rapid response team and SBAR (Situation, Background, Assessment, Recommendation) communication (Chapter 6).

MEDICATIONS

Oxygen

- **Indication:** hypoxemia, and emergencies in which hypoxemia is likely. Oxygen does not treat breathlessness when SpO2 is in the target range (CRTO, 2022).
- **How it is ordered:** as a target SpO2 range, often with a starting device and flow. The nurse adjusts the flow or device within the order or a medical directive to keep SpO2 in range (O'Driscoll et al., 2017a).
- **Adverse effects:** hyperoxia, which is linked to higher mortality in acutely ill adults (Chu et al., 2018); a rise in PaCO2 in patients at risk of hypercapnia (Barnett et al., 2022); dryness of the nose and mouth; pressure injuries from tubing and masks; and fire, because oxygen makes materials burn faster and hotter.
- **Monitoring:** SpO2, respiratory rate, work of breathing, heart rate and level of consciousness after each change; blood gases as ordered for patients at risk of hypercapnia.
- **Never:** stop oxygen abruptly in a patient at risk of hypercapnia, or delay oxygen in a seriously ill patient (O'Driscoll et al., 2017a).

Oxygen Safety and Home Oxygen

Oxygen does not burn, but it feeds a fire: clothing, bedding, hair and furniture ignite more easily and burn faster and hotter (City of Calgary, n.d.; Office of the Fire Marshal and Emergency Management [OFMEM], n.d.). Ontario's Fire Marshal reports that smoking materials are the most common source of ignition in fires, injuries and deaths involving medical oxygen in the province, and that smoking, including electronic cigarettes, is never safe in the home while oxygen is in use (OFMEM, n.d.). After several burn incidents involving people who used e-cigarettes while on home oxygen, Health Canada warned of the fire risk (Lacasse et al., 2015). Nurses offer smoking cessation support without judgment (Chapter 14). Fire services also advise keeping oxygen away from

flames and stoves, avoiding oily products such as petroleum jelly, and securing cylinders upright, with liquid oxygen at least 10 feet (about 3 m) from heat (City of Calgary, n.d.; OFMEM, n.d.).

In Ontario, home oxygen is funded through the Assistive Devices Program (ADP). A person qualifies by living in Ontario, holding a valid health card and meeting medical criteria, for example, low blood oxygen at rest; income is not considered. ADP pays 75% of the cost and the person pays 25%, but ADP pays the full cost for people aged 65 or older, people in long-term care, people on certain social assistance programs and people receiving services through Ontario Health atHome. A physician or nurse practitioner does the needed tests and completes the application form; an ADP-registered supplier submits it, sets up the system and teaches its use. Home oxygen must be renewed every year (Government of Ontario, 2025). Each other province and territory has its own program and rules.

Before discharge, the nurse helps the patient plan for travel, since carriers have their own rules for medical oxygen, and for power outages, since concentrators need electricity (Figure 12.8).

CLINICAL SAFETY

Oxygen and Fire

Oxygen-enriched air turns a small spark into a fast, hot fire, and the face and airway are closest to the source. In hospital and at home, the nurse:

- confirms that no one smokes or vapes near oxygen, including in a bathroom or at a doorway; smoking is never safe while oxygen is in use (OFMEM, n.d.);
- keeps oxygen away from open flames, heaters and stoves, and from sparking devices such as hair dryers and electric razors (City of Calgary, n.d.; OFMEM, n.d.);
- avoids petroleum jelly and oil-based creams on the face while oxygen is in use (OFMEM, n.d.);

- secures cylinders upright (City of Calgary, n.d.) and turns oxygen off at the source when it is not in use;
- knows the hospital fire plan: where the oxygen shut-off valves are and who may close them.

If a patient's tubing or mask catches fire, the nurse removes the device, turns off the oxygen and follows the fire response plan.

PATIENT EDUCATION

Living With Home Oxygen

The nurse teaches the patient and family, using teach-back:

- **Use oxygen as prescribed.** Use the flow rate and the hours of use the prescriber set. Do not change the flow without asking.
- **Never smoke or vape near oxygen.** Ask visitors not to smoke in the home. Put up "No Smoking" and "No Open Flames" signs both inside the home and outside it (City of Calgary, n.d.).
- **Keep it away from heat.** Stay well away from stoves, candles, fireplaces and gas or kerosene heaters. Never cook with the oxygen on (City of Calgary, n.d.).
- **Choose skin products carefully.** Avoid petroleum jelly and oily lotions while oxygen is in use (OFMEM, n.d.).
- **Store cylinders safely.** Keep cylinders secured and upright, and follow the supplier's instructions (City of Calgary, n.d.).
- **Protect the skin.** Check behind the ears and inside the nose for soreness every day.
- **Plan ahead.** Ask the supplier about backup oxygen for a power outage, and check rules with the airline or carrier before travelling.
- **Know when to call.** Increased breathlessness, new confusion or drowsiness, or chest pain needs prompt care; call 9-1-1 for severe breathlessness or chest pain.

12.5 Airway Clearance

Pain, weakness, sedation, immobility and thick secretions all make it harder to clear mucus. Retained secretions block small airways and can cause atelectasis (collapse of alveoli) and infection. This section covers everyday measures and suctioning. Postoperative pulmonary complications are covered in Chapter 7, section 7.6, and pneumonia in Chapter 13.

Helping Patients Clear Secretions

The first steps are simple. The nurse helps the patient sit upright, take slow deep breaths and cough effectively. A **huff cough** (the forced expiratory technique) is a forced breath out through an open mouth and throat, rather than a cough against a closed glottis (Strickland et al., 2013). Some patients find huffing easier than coughing. An American Association for Respiratory Care (AARC) guideline for hospitalized patients advises that teaching effective cough technique may help, and that extra airway clearance treatments are not needed when a patient can clear secretions by coughing (Strickland et al., 2013).

Moving is one of the best airway clearance treatments. The same guideline recommends early mobility and walking after surgery, both to reduce complications and to help clear the airways (Strickland et al., 2013). Pain control matters too. A patient who splints the chest or abdomen because of pain takes shallow breaths and avoids coughing, while too much sedation blunts breathing and cough (Chapter 5). A pillow held firmly over an incision makes coughing easier.

An **incentive spirometer** (Figure 7.1) is a hand-held device that gives visual feedback as the patient breathes in slowly and deeply. The steps below follow the technique in the AARC guideline (Restrepo et al., 2011):

1. The patient sits up and holds the device upright.

2. The patient breathes out normally, then seals the lips tightly around the mouthpiece.

3. The patient breathes in slowly, raising the indicator toward the target set for them, and keeps the lungs inflated for at least 5 seconds.

4. At full inspiration, the patient removes the mouthpiece, holds the breath, then breathes out normally.

5. After a rest, the patient repeats the breaths, then coughs or huffs.

No specific frequency is supported by evidence; studies have used, for example, 10 breaths every 1 to 2 hours while awake. After a return demonstration, the patient is encouraged to use the device independently. The guideline does not recommend incentive spirometry alone as routine care before or after surgery; it recommends using it together with deep breathing, directed coughing, early mobility and good pain control, and suggests that deep breathing exercises give the same benefit. It is not suitable for patients who cannot understand or be supervised in its use, such as those who are delirious or heavily sedated, or for patients who cannot breathe deeply because of pain (Restrepo et al., 2011). Its role after surgery is discussed in Chapter 7, section 7.6.

A **positive expiratory pressure (PEP) device** makes the patient breathe out against resistance, which helps hold airways open; oscillating PEP devices add vibration to loosen mucus. Evidence for routine PEP is limited outside cystic fibrosis, and AARC suggests that airway clearance treatments may be considered for patients with COPD whose secretions are hard to clear, guided by the patient's preference (Strickland et al., 2013). **Chest physiotherapy**, which uses percussion, vibration and postural drainage, is not recommended for routine treatment of uncomplicated pneumonia (Strickland et al., 2013). Physiotherapists and RTs assess for and provide these treatments. Patients with neuromuscular disease and a weak cough may need cough-assist techniques from the RT (Strickland et al., 2013).

Oral and Nasopharyngeal Suctioning

Suctioning is used when a patient cannot clear secretions despite their best cough. The nurse looks for cues: visible secretions, gurgling sounds or coarse crackles, reduced breath sounds, more effort to breathe, a falling SpO2 and restlessness (American Association for Respiratory Care [AARC], 2004). Suctioning is uncomfortable and has risks, so it is done when assessment shows a need, not on a fixed schedule.

Figure 12.9 Oral suctioning with a rigid Yankauer suction tip on a manikin. (credit: “Suctioning with a yankauer” by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Oral suctioning clears the mouth and the back of the throat with a rigid suction tip, often called a Yankauer (Figure 12.9). It helps a patient who has a weak cough, cannot swallow secretions or is vomiting. The nurse sweeps the tip along the cheeks and gums and avoids touching the back of the throat, which can trigger gagging.

Nasopharyngeal and nasotracheal suctioning pass a flexible catheter through the nose into the pharynx or the trachea of a patient who has no artificial airway. Suction is applied only while the catheter is withdrawn. When suctioning is needed often, a nasopharyngeal airway protects the nose from repeated trauma (AARC, 2004). The AARC guideline lists epiglottitis and croup as absolute contraindications. Relative contraindications include blocked nasal passages, a nosebleed, an acute injury to the head, face or neck, a bleeding disorder, laryngospasm, an irritable airway and recent tracheal surgery. For adults, it advises suction pressures of about 100 to 150 mm Hg, never more than 150 mm Hg, and suction applied for no more than 15 seconds (AARC, 2004). Complications include hypoxemia, bronchospasm, laryngospasm, nosebleed, slow or irregular heart rhythms and vomiting. The nurse monitors SpO2, heart rate and rhythm, breathing and the patient's response before, during and after the procedure, and documents the amount, colour and thickness of the secretions (AARC, 2004). Passing a catheter beyond where the nasal passages narrow is a controlled act in Ontario (Scope in Practice box, section 12.6).

Suctioning can spread respiratory droplets. The nurse uses Routine Practices and any additional precautions the patient's condition calls for (Chapter 4).

Patients with reduced consciousness, a weak cough or a swallowing problem are at risk of aspiration. The nurse keeps the head of the bed raised unless contraindicated, keeps suction at the bedside, and asks for a speech-language pathologist (SLP) swallowing assessment when the patient coughs or chokes on food or drink.

CLINICAL JUDGMENT

Falling Saturation After Surgery

Names and details are fictional; this is a composite story.

Ms. Gloria Mendes, 58, is on day 1 after an open bowel resection. She has an opioid by patient-controlled analgesia and oxygen at 2 L/min by nasal cannula, ordered to keep SpO2 at 92% to 96%.

- **Recognize cues:** At 0800, SpO2 is 93%. By 1100 it is 89%, then 88%. Her respiratory rate is 24 with shallow breaths. She holds her abdomen and will not cough: "It hurts too much." Breath sounds are diminished at both bases. She answers questions but drifts off between them. Her temperature is 37.9 °C.
- **Analyze cues:** Shallow breathing and a weak cough suggest atelectasis and retained secretions, with pain as a cause. Her drowsiness raises a second concern: opioid-induced respiratory depression (Chapter 5, section 5.4).
- **Prioritize hypotheses:** Her low SpO2 is the most urgent problem; it may be worsened by both splinting and sedation.
- **Generate solutions:** Restore SpO2 within the ordered range, assess sedation with a validated scale, improve pain control without deeper sedation, and clear secretions.
- **Take action:** The nurse sits Ms. Mendes upright and increases the oxygen within the order to reach the target range. She assesses sedation and respiratory rate, and calculates the early warning score (Chapter 6). She calls the surgical resident using SBAR, reporting falling SpO2, rising oxygen need, drowsiness and fever, and asks for a pain review. With a pillow over the incision, she coaches huff coughing and incentive spirometry (Chapter 7, section 7.6).
- **Evaluate outcomes:** An hour later, SpO2 is 94% on 3 L/min, Ms. Mendes is alert, and she coughs up thick sputum. The nurse plans to walk with her that afternoon and to wean the oxygen as SpO2 allows.

12.6 Artificial Airways and Tracheostomy Care

Some patients need help keeping their airway open. This section covers simple airway adjuncts, the endotracheal tube in brief, and care of the patient with a tracheostomy, including the emergencies every nurse must be able to recognize and act on.

Artificial Airways

An **oropharyngeal airway** is a curved plastic device placed in the mouth to hold the tongue away from the back of the throat. It is used for a patient with a markedly reduced level of consciousness; a more alert patient may gag on it. A **nasopharyngeal airway** is a soft tube passed through a nostril into the pharynx. The AARC nasotracheal suctioning guideline recommends one when suctioning is needed often (AARC, 2004). Both devices are sized to the patient, are inserted by trained staff as policy allows, and need regular checks of placement and skin.

An **endotracheal tube** passes through the mouth or nose and the larynx into the trachea. It is placed by a trained provider, usually for mechanical ventilation in critical care (Chapter 15).

Tracheostomy Basics

A **tracheostomy** is a surgical opening into the front of the trachea, held open by a tube. Unless the upper airway itself is blocked, air may still pass between the mouth and nose and the lungs, so in an emergency oxygen is given to both the face and the tracheostomy (National Tracheostomy Safety Project [NTSP], n.d.-b). A **laryngectomy** is different: the larynx is removed and the trachea is brought out to the skin of the neck as an end stoma. A patient after laryngectomy is a **neck breather**, with no connection between the mouth and nose and the lungs, and cannot be given oxygen or ventilated by the mouth or nose (NTSP, n.d.-b). Usually no tube sits in a laryngectomy stoma (NTSP, n.d.-b). Bedside signs that state which airway the patient has are essential.

Tracheostomy tubes vary, but they share common parts (Figure 12.10):

- **Outer cannula:** the main tube that sits in the trachea.
- **Flange:** the flat plate that rests on the neck and holds the ties.
- **Inner cannula:** a removable tube inside the outer cannula. It can be taken out to be cleaned or replaced, or removed at once if secretions block it (Hess & Altobelli, 2014; NTSP, n.d.-a).

- **Cuff:** a balloon near the tip of some tubes. When inflated, it seals the trachea, so air passes through the tube rather than around it. Tubes may be cuffed or uncuffed (Hess & Altobelli, 2014).
- **Fenestration:** an opening in the back wall of some tubes, above the cuff. With the cuff deflated, it lets air pass up through the larynx for speech; a solid inner cannula closes it (Hess & Altobelli, 2014).
- **Obturator:** a smooth, rounded guide placed inside the tube during insertion and taken out as soon as the tube is in position (Hess & Altobelli, 2014). It is kept at the bedside.

The cuff pressure is checked routinely and adjusted as needed (Mitchell et al., 2013). Higher pressures raise the risk of injury to the trachea, and a pressure that is too low makes silent aspiration more likely; one review gives 20 to 30 cm H2O as the range to maintain (Hess & Altobelli, 2014). Who measures it, and the range used, are set by hospital policy; RTs often do this.

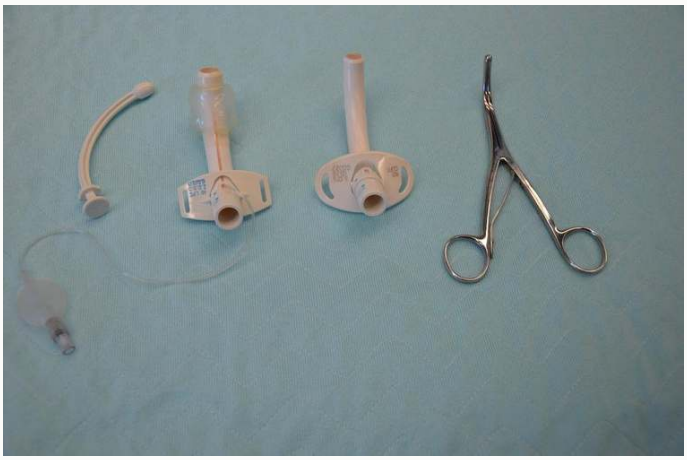

Figure 12.10 Tracheostomy equipment, from left: obturator, cuffed tube, uncuffed tube and tracheal dilators. (credit: "Obturator, cuffed tracheostomy tube, non-cuffed tracheostomy tube, tracheal dilators" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

Tracheostomy Care

Tracheostomy care keeps the airway open, the skin healthy and the patient safe. The nurse assesses the stoma at least every shift for redness, swelling, discharge, odour, bleeding and skin breakdown, and cleans the stoma and under the flange as policy directs. The inner cannula is cleaned or replaced regularly in hospital and at home (Mitchell et al., 2013). Ties hold the tube securely; the nurse checks their fit and changes them as policy directs, with a second person holding the tube when policy requires it. An American consensus statement advises using ties unless the patient has had a recent flap reconstruction (Mitchell et al., 2013).

A tracheostomy bypasses the nose, which normally warms and moistens air. Humidification is used after surgery and as needed afterward, for example with thick secretions (Mitchell et al., 2013). A heat and moisture exchanger or a humidified tracheostomy mask is used, as ordered.

The supplies needed to replace the tube must be kept within reach at the bedside (Mitchell et al., 2013). The nurse checks the bedside emergency equipment at the start of every shift. Policy sets the list, which usually includes:

- a spare tube of the same size and one a size smaller, and the obturator;
- working suction with catheters of the right size;
- oxygen, with a tracheostomy mask and a face mask;
- a bag-valve mask;
- spare ties, scissors, gloves and water-based lubricant.

Losing one's voice is frightening. A communication plan starts before a planned tracheostomy, and may include an SLP referral and a speaking valve (Mitchell et al., 2013). Writing boards, picture boards, a call bell within reach, and yes-or-no questions help. A **speaking valve** is a one-way valve that lets air in through the tube and sends exhaled air up through the larynx so the patient can speak. A patient must never use a speaking or swallowing valve while the cuff is inflated (Mitchell et al., 2013); the cuff must be completely deflated first (Hess & Altobelli, 2014), because with the cuff up and the valve on, the patient cannot breathe out. The cuff is deflated and the valve is placed only after the team, often the SLP and RT, has assessed the patient. An SLP often assesses swallowing before the patient eats or drinks. Tracheostomy care follows infection prevention and control (IPAC) practices (Chapter 4).

Suctioning a Tracheostomy

The tube is suctioned when assessment shows a need, such as secretions that can be seen or heard in the airway or changed breath sounds, not on a routine schedule (Blakeman et al., 2022; Mitchell et al., 2013). The AARC artificial airway suctioning guideline recommends the following (Blakeman et al., 2022):

- Give extra oxygen before suctioning (preoxygenation).
- Use shallow suctioning routinely, passing the catheter only to a premeasured depth at about the end of the tube; use deep suctioning only when shallow suctioning does not work.
- Choose a catheter that blocks less than half of the airway's lumen in adults, so air can flow around it.
- Keep suction below 200 mm Hg of negative pressure in adults, and as low as will work.
- Keep suctioning as brief as possible, applying suction for no more than 15 seconds.
- Generally avoid putting normal saline down the tube.
- Use sterile technique for open suctioning when possible, and perform hand hygiene immediately before.

The nurse lets the patient recover between passes, watches SpO2, heart rate and rhythm, and documents the secretions and the patient's tolerance. Closed (in-line) and open systems can both be used safely in adults (Blakeman et al., 2022). The technique taught for home may differ; the team decides it.

Tracheostomy Emergencies

Tracheostomy emergencies include **decannulation** (the tube coming out of the trachea), a blocked tube and bleeding. Bedside staff are the first to recognize and respond to them (NTSP, n.d.-a). Cues include noisy or high-pitched breathing (stridor), no air moving at the tube, a suction catheter that will not pass, a tube that looks longer or sits at an odd angle, air or voice leaking around the tube, distress, agitation and a falling SpO2. Published guidance teaches first responders to call for help, assess the airway, apply oxygen, remove speaking valves and inner tubes, and try to pass a suction catheter: the problems that are easiest to fix come first (McGrath et al., 2012; NTSP, n.d.-a). Table 12.4 summarizes these first actions.

Table 12.4 Tracheostomy emergencies: cues and first actions (based on Mitchell et al., 2013; NTSP, n.d.-a, n.d.-b; original wording)

Emergency	Cues	First nursing actions	Who to call
Blocked tube	Noisy or no airflow at the tube; suction catheter will not pass; distress; falling SpO2	Call for help; give oxygen to the face and the tube; remove the speaking valve, cap or heat and moisture exchanger; remove the inner cannula; try to pass a suction catheter; if it still will not pass, deflate the cuff if trained to do so	Rapid response or code team and the airway team, per policy
Displaced tube or decannulation	Tube partly or fully out, or longer than usual; air or voice escaping around it; distress; falling SpO2	Call for help; give oxygen to the face and the stoma; do not force the tube back; bring the spare tubes and obturator for the responding team, which reinserts the same size or one size smaller	Rapid response or code team, and the team that placed the tube if it is new
Bleeding	Fresh blood from the stoma or in suctioned secretions; coughing blood	Call for help at once; give oxygen to the face and the tracheostomy; suction to keep the tube clear; record the amount	Rapid response or code team and the surgical team
Laryngectomy stoma blocked	Neck breather with noisy or no airflow at the stoma; distress	Call for help; give high-flow oxygen at the stoma, and if unsure whether the patient is a neck breather, give it over the face too; remove any stoma cover and any tube in the stoma; suction through the stoma; do not remove a voice prosthesis (tracheoesophageal puncture prosthesis)	Rapid response or code team and the airway team

If the tube cannot be cleared, an expert removes and replaces it, using a tube of the same size or one size smaller (Mitchell et al., 2013). If the patient stops breathing, the resuscitation team takes over the airway; for a neck breather, ventilation must go through the stoma (NTSP, n.d.-b). After any emergency, the nurse documents the event and the team reviews it.

Going Home With a Tracheostomy

Teaching starts early and involves the patient and family caregivers. Before discharge, caregivers learn to use all the home equipment, to clean the stoma and the tube, and to recognize breathing distress and signs of infection or skin breakdown. They should receive a written home care manual (Mitchell et al., 2013). Each caregiver practises suctioning, inner cannula care, tie changes and the emergency plan with return demonstration. The plan names who to call, where the spare tubes are, and that 9-1-1 is called for an airway emergency. When the patient or family cannot manage care, home nursing should be considered (Mitchell et al., 2013). In Ontario, home and community care is arranged through Ontario Health atHome, and home equipment is arranged by the team and suppliers. The nurse also confirms that the patient has a way to call for help without speaking.

SCOPE IN PRACTICE

Suctioning and Tracheostomy Care

- **Authority:** In Ontario, putting an instrument beyond the point where the nasal passages narrow, beyond the larynx or into an artificial opening into the body is a controlled act, as is administering a substance by inhalation. RNs and RPNs are authorized to perform these acts with an order or directive, or by initiation where the regulation allows it. Nurses cannot initiate controlled acts in public hospitals (CNO, 2025). Tracheostomy suctioning and nasotracheal suctioning therefore need an order or medical directive in a public hospital. The law also allows people to assist a person with routine activities of living that involve some of these acts (CNO, 2025), which matters when family caregivers learn tracheostomy care. RTs hold their own authority to suction beyond the larynx (an order is needed in a public hospital) and, with an order, to change tracheostomy tubes (CRTO, 2024).
- **Competence:** The nurse performs only the care they have the knowledge, skill and judgment to do safely, and seeks education first.
- **Context:** Employer policy decides who changes tracheostomy tubes, who manages cuffs and HFNC, and whether these patients are assigned to RNs, RPNs or both. In an airway emergency, every nurse acts at once and calls for help. The RPN consults the RN as the patient's needs change.
- Other provinces and territories differ. CNO's revised Scope of Practice standard takes effect March 1, 2027.

PRACTICE STORY

The Quiet Alarm

Names and details are fictional; this is a composite story.

Nurse: Sonia Subramanian, RN. Years in practice: 6. Setting: medical unit, community hospital, Ontario.

It was 0320, and Mr. Harold Fitzgerald's oximeter was beeping softly. He was 72 and had come to us from the intensive care unit four days earlier with a cuffed tracheostomy after a long stay with pneumonia. At bedtime his secretions had been thick, and I had suctioned him once.

When I walked in, he was sitting bolt upright, eyes wide, pulling at his gown. His SpO2 read 85%. I held my hand over the tube and felt almost nothing. I pressed the call bell for help, asked my RPN colleague to call the rapid response team, and put the oxygen on his face and over the tube.

Then I went through the steps we had practised in our skills day. I took off the heat and moisture exchanger and pulled out the inner cannula. It was packed with dried mucus. I could hear air rush through the outer tube. I passed a suction catheter, and it slid in easily; I cleared thick, tan secretions. His SpO2 climbed to 90%, then 94%, and he let go of his gown.

The rapid response team arrived to a patient who was breathing comfortably. The RT put in a new inner cannula, checked the cuff and increased the humidification. We reviewed his chart together: his humidifier had been switched to a smaller device during transfer, and nobody had changed it back.

What stays with me is how quiet it was. He could not call out. If I had waited to finish my charting, the outcome could have been very different. Now I check the bedside equipment and humidification at the start of every shift, and I teach new staff where the spare inner cannula is kept.

Reflect: Which cues told Priya the tube was blocked, and why did she start with the inner cannula? Under CNO's Scope of Practice standard, what authority, competence and context would an RPN need to suction this tracheostomy, and when should the RPN involve the RN?

Chapter 12 Summary

Introduction

- A change in breathing is often one of the first signs that a patient is deteriorating; nurses check airway and breathing first and reassess them often.
- This chapter covers the brief respiratory review, focused assessment, pulse oximetry, oxygen therapy, airway clearance and artificial airways.

12.1 Breathing and Gas Exchange: A Brief Review

- Ventilation moves air; compliance and airway resistance determine the work of breathing.
- Oxygen and CO2 cross the alveolar–capillary membrane by diffusion; V/Q mismatch is the most common cause of hypoxemia, and shunt responds poorly to extra oxygen.
- Hypoxemia is low arterial oxygen; hypoxia is too little oxygen in the tissues.
- The "hypoxic drive" explanation is a myth; oxygen is never withheld from a hypoxemic patient, but is given to the ordered target range.
- The oxygen–hemoglobin curve is flat above about 90% saturation and steep below a PaO2 of about 60 mm Hg, so a falling trend needs prompt action.

12.2 Focused Respiratory Assessment

- The history covers dyspnea (with a scale such as the mMRC), cough and sputum, pleuritic pain, smoking and vaping, exposures including radon, and home devices.
- Respirations are counted for a full 60 seconds without the patient's awareness; shorter counts underestimate the rate.
- Increased work of breathing (accessory muscles, retractions, tripod position, short phrases) needs action even when SpO2 looks acceptable.
- Cyanosis and pallor are late, unreliable signs, especially on darker skin; the nurse looks at the tongue, lips and mouth, compares with baseline and asks the patient or family.
- Auscultation is done on bare skin, top to bottom, side to side; crackles, wheezes, rhonchi, stridor and friction rubs each suggest different problems, and stridor is an emergency.

12.3 Pulse Oximetry and Other Measures

- Pulse oximeters estimate SaO2 from red and infrared light; trends and the whole patient matter more than one reading.
- Pulse oximeters can overestimate saturation in darker skin pigmentation, causing occult hypoxemia; race-based correction is never used.
- Poor perfusion, motion, nail polish, ambient light, carbon monoxide and severe anemia also affect readings; carbon monoxide gives falsely normal values.
- SpO2 does not measure CO2 or ventilation; capnography and the ABG fill that gap.
- Canadian laboratories report PaO2 in mm Hg, with reference ranges that vary by laboratory; venous blood gases cannot assess oxygenation.

12.4 Oxygen Therapy

- Oxygen is a drug: it needs an order or medical directive, except that it is started at once in an emergency and documented afterward.
- The order states a target SpO2 range. Guidelines suggest about 92% to 96% (TSANZ) or 94% to 98% (BTS) for most acutely ill adults, no higher than 96% (BMJ), and 88% to 92% for patients at risk of hypercapnia.
- Liberal oxygen is linked to higher mortality and hides deterioration, but oxygen is never delayed or stopped for a seriously ill patient, and it is never stopped suddenly in a patient at risk of hypercapnia.

- Low-flow devices (nasal cannula, simple face mask, non-rebreather) give a variable FiO2; high-flow devices (Venturi mask, HFNC) give a fixed FiO2.
- The nurse reassesses after each change, weans when the patient is stable and above range, and escalates a rising oxygen need.
- Oxygen feeds fire: no smoking or vaping, no flames or oily products, cylinders secured upright. Ontario's ADP funds home oxygen; other provinces and territories have their own programs.

12.5 Airway Clearance

- Upright positioning, deep breathing, huff coughing, early mobility and good pain control are the foundation of airway clearance.
- Incentive spirometry needs a slow, deep breath held for at least 5 seconds; AARC recommends it only alongside deep breathing, coughing, mobility and analgesia, not alone.
- Chest physiotherapy and PEP devices are not routine; physiotherapists and RTs assess for them.
- Suctioning is done when assessment shows a need. Nasotracheal suctioning is avoided with facial, head or neck injury and in other listed conditions, and is limited to 15 seconds per pass.

12.6 Artificial Airways and Tracheostomy Care

- Oropharyngeal airways are for patients with a markedly reduced level of consciousness; a nasopharyngeal airway helps when nasotracheal suctioning is needed often.
- A patient with a tracheostomy may still move air through the upper airway, so oxygen goes to the face and the tracheostomy in an emergency; a neck breather after laryngectomy cannot, so oxygen goes to the stoma.
- Daily care covers the stoma, inner cannula, ties, humidification, communication and bedside emergency equipment, including spare tubes of the same size and one size smaller.
- Tracheostomy suctioning follows AARC guidance: preoxygenate, shallow passes, catheter under half the lumen, adult pressure below 200 mm Hg, no more than 15 seconds, no routine saline.
- In a blocked or displaced tube, the nurse calls for help, gives oxygen to the face and stoma, removes the speaking valve and inner cannula, and tries a suction catheter.

Key Terms (60)

airway resistance: how much the airways oppose airflow; narrowing from spasm, swelling or secretions raises it.

alveolar–capillary membrane: the thin barrier between alveolar air and capillary blood across which oxygen and carbon dioxide diffuse.

alveoli: the tiny air sacs at the ends of the smallest airways, where gas exchange takes place.

arterial blood gas (ABG): analysis of an arterial blood sample for pH, PaCO2, bicarbonate, PaO2 and SaO2.

capnography: continuous measurement of carbon dioxide in each exhaled breath, used to monitor ventilation.

carotid bodies: small clusters of sensing cells beside the carotid arteries that respond to low arterial oxygen and to acidity.

central cyanosis: a bluish or greyish colour of the tongue, lips and oral lining that signals low arterial oxygen.

chest physiotherapy: External chest wall techniques (percussion, vibration and postural drainage) used to help move secretions.

Cheyne–Stokes breathing: a repeating cycle of breaths that deepen, then fade, followed by a pause in breathing.

clubbing: painless enlargement of the fingertips with loss of the normal angle at the nail bed, linked to lung cancer and chronic lung and heart disease.

compliance: how easily the lungs and chest wall stretch; low compliance makes each breath take more effort.

crackles: brief, non-musical, discontinuous popping sounds, usually heard when breathing in; described as fine or coarse.

cuff: A balloon near the tip of some tracheostomy and endotracheal tubes that seals the trachea when inflated.

dead space: air that reaches alveoli with little or no blood flow and so takes no part in gas exchange.

decannulation: Removal of a tracheostomy tube from the trachea, planned or accidental.

diffusion: the movement of a gas from an area of higher partial pressure to one of lower partial pressure, as across the alveolar–capillary membrane.

dyspnea: the patient's own experience of uncomfortable or difficult breathing.

endotracheal tube: A tube passed through the mouth or nose and the larynx into the trachea, usually for mechanical ventilation.

hemoptysis: coughing up blood.

high-flow device: An oxygen device that delivers a fixed FiO2 whatever the patient's breathing pattern, such as a Venturi mask or high-flow nasal cannula.

high-flow nasal cannula (HFNC): A system that delivers heated, humidified, blended air and oxygen through wide-bore nasal prongs at high flows and a set FiO2.

huff cough: A forced breath out through an open mouth and throat (the forced expiratory technique), used to move secretions.

humidification: Adding water vapour to inspired gas to prevent drying of the airway.

hypercapnia: A raised level of carbon dioxide in arterial blood (PaCO2 above 45 mm Hg).

hyperoxia: More oxygen in the blood than the body needs; in acutely ill adults, liberal oxygen use is linked to higher mortality.

hypoxemia: a low level of oxygen in the arterial blood.

hypoxia: too little oxygen in the body's tissues.

hypoxic pulmonary vasoconstriction: narrowing of small pulmonary arteries in poorly ventilated lung, which steers blood toward better-ventilated alveoli.

incentive spirometer: A hand-held device that gives visual feedback to encourage slow, deep breaths held at full inspiration.

inner cannula: A removable tube inside a tracheostomy tube that can be cleaned or replaced, or removed at once if secretions block it.

Kussmaul breathing: deep, rapid breathing seen in metabolic acidosis.

laryngectomy: Surgical removal of the larynx, after which the trachea opens to the neck as an end stoma.

low-flow device: An oxygen device whose delivered concentration varies with the patient's breathing pattern, such as a nasal cannula, simple face mask or non-rebreather mask.

medical directive: An order written in advance by an authorized prescriber that applies to any patient who meets set conditions.

nasal cannula: Two short prongs in the nostrils that deliver low-flow oxygen; the most common oxygen device.

nasopharyngeal airway: A soft tube passed through a nostril into the pharynx to keep the upper airway open.

neck breather: A person who breathes only through a neck stoma after laryngectomy and cannot be oxygenated or ventilated through the mouth or nose.

non-rebreather mask: A face mask with a reservoir bag, run at 15 L/min, that delivers a high oxygen concentration to a seriously ill patient.

obturator: A rounded guide placed inside a tracheostomy tube during insertion; kept at the bedside.

occult hypoxemia: low arterial oxygen saturation hidden by a pulse oximetry reading that looks acceptable.

oropharyngeal airway: A curved device placed in the mouth to hold the tongue off the back of the throat in a patient with a markedly reduced level of consciousness.

oxygen target range: The SpO2 range the prescriber orders, within which the nurse adjusts oxygen.

oxygen–hemoglobin dissociation curve: the S-shaped curve relating PaO2 to hemoglobin saturation; flat above about 90% saturation and steep below a PaO2 of about 60 mm Hg.

perfusion: blood flow through the capillaries of the lungs.

peripheral cyanosis: a bluish colour limited to the fingers, toes or nail beds, usually from slow peripheral blood flow.

pleural friction rub: a grating or creaking sound in both phases of breathing, caused by inflamed pleural layers rubbing together.

positive expiratory pressure (PEP) device: A device that makes the patient breathe out against resistance to help hold airways open; oscillating versions add vibration.

pulse oximetry: a non-invasive method that estimates arterial oxygen saturation (SpO2) from the absorption of red and infrared light by pulsing arterial blood.

rhonchi: low-pitched, continuous, snoring sounds; used interchangeably with "low-pitched wheeze."

shunt: blood flow past alveoli that receive no air, so the blood returns to the heart without gaining oxygen.

speaking valve: A one-way valve on a tracheostomy tube that lets air in and directs exhaled air up through the larynx for speech; used only with the cuff deflated.

stridor: a loud, high-pitched, musical sound, mainly on breathing in, that signals a narrowed upper airway and is an emergency.

subcutaneous emphysema: air trapped under the skin, felt as crackling under the fingertips.

tactile fremitus: the vibration felt through the chest wall when a patient speaks.

tracheostomy: A surgical opening into the front of the trachea, held open by a tube.

ventilation: the movement of air into and out of the lungs.

ventilation–perfusion (V/Q) mismatch: an imbalance between the air reaching parts of the lung and the blood flowing past them; it causes hypoxemia more often than any other mechanism.

Venturi mask: An air-entrainment mask that mixes oxygen with room air through a valve to give a fixed oxygen concentration.

wheeze: a continuous, musical sound produced by narrowed airways, usually heard when breathing out.

work of breathing: the effort the breathing muscles spend to move air; signs of increased work include accessory muscle use, retractions and speaking in short phrases.

Licensure Review & Clinical Judgment Questions (35)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Florence Mensah (Questions 1–4): Florence Mensah, 81, was admitted to a medical unit in Kingston, Ontario, two days ago with cellulitis of the left leg. Tonight she says she "can't catch her breath." A registered practical nurse (RPN) is caring for her, with an RN on the team. Mrs. Mensah has dark skin.

1. [CORE] Which finding best shows that Mrs. Mensah's work of breathing has increased?

a. She sits forward, hands on her knees, speaking a few words per breath.

b. Her respiratory rate, counted over one full minute, is 18 breaths/min.

c. Her chest rises equally on both sides each time she breathes in.

d. She says she slept poorly last night because of noise on the unit.

Answer: a — The tripod position and speaking only a few words between breaths are signs of increased work of breathing (a) (section 12.2). A rate of 18 breaths/min counted over a full minute (b) and equal chest rise (c) are reassuring findings. Poor sleep from noise (d) does not reflect her breathing effort.

2. [CORE] The RPN wants to check Mrs. Mensah for central cyanosis. Which approach is best?

a. Press on a fingernail and time how long the colour takes to return to normal.

b. Compare the skin on her forearms with the skin on her chest under the room light.

c. Inspect her tongue, lips and mouth in good light; ask family about her usual colour.

d. Rely on the pulse oximeter alone, because cyanosis cannot be seen on dark skin.

Answer: c — Central cyanosis appears in the tongue, lips and lining of the mouth. Good light and a comparison with the patient's usual colour, which the patient or family can describe, improve assessment on every skin tone (c) (section 12.2). Nail bed refill (a) tests peripheral circulation, not central oxygenation. Skin on the arms and chest (b) is a poor place to judge oxygen, especially on darker skin. Pulse oximetry is useful, but it may overestimate saturation in darker skin pigmentation, and the nurse still looks at the patient (d) (section 12.3).

3. [CORE] On auscultation, the RPN hears soft, high-pitched popping sounds at both lung bases late in each breath in. These sounds do not clear when Mrs. Mensah coughs. How should the RPN interpret this finding?

a. Stridor, which suggests narrowing of the upper airway

b. A pleural friction rub, which suggests inflamed pleura

c. Wheezes, which suggest narrowing of the small airways

d. Fine crackles, which may suggest fluid in the small airways

Answer: d — Brief, soft, high-pitched popping sounds late in inspiration are fine crackles. They can occur in early heart failure and interstitial lung disease, among other causes (d) (section 12.2, Table 12.1). Stridor (a) is a loud, musical sound heard mainly over the neck. A friction rub (b) is a grating sound heard in both phases. Wheezes (c) are continuous and musical, not popping.

4. [CORE] Mrs. Mensah's SpO2 reads 95% on room air. Her respiratory rate is 28 breaths/min, she is newly restless, and she looks unwell to the RPN. What should the RPN do next?

a. Record the SpO2 as normal and reassess her at the next scheduled set of vital signs.

b. Promptly report all of her findings, not just the SpO2, to the RN and escalate per policy.

c. Move the probe from finger to finger until the reading rises to above 97%.

d. Subtract 3% from the reading to correct for her skin colour, and act on that value.

Answer: b — A rising respiratory rate and new restlessness are warning signs. Pulse oximeters can overestimate saturation in people with darker skin pigmentation, so the nurse acts on the whole patient and escalates; the team may request an ABG (b) (section 12.3; Chapter 6). Reassuring herself with the SpO2 (a) delays care. Moving the probe in search of a higher number (c) is a misuse of the device. No validated correction exists, and race- or colour-based adjustments are never used (d).

5. [CORE] A nurse is assessing a patient's respiratory rate. Which technique gives the most accurate count?

a. Count the breaths for 15 seconds, then multiply the result by 4.

b. Ask the patient to breathe normally, then count for 30 seconds and double it.

c. Use the rate recorded at the last vital signs if the patient looks comfortable.

d. Count for a full 60 seconds while the patient is unaware of the count.

Answer: d — Counting for a full minute, without the patient knowing, avoids the underestimation seen with shorter counts and the slowing that happens when people know they are being watched (d) (section 12.2). A 15-second count (a) and a 30-second count (b) both give systematically lower rates, and telling the patient (b) can change their breathing. Copying an old value (c) misses change, which is the point of reassessment.

6. [CORE] A patient who had surgery on the neck the previous day develops a loud, high-pitched, musical sound heard mainly when breathing in, louder over the neck than the chest. What is the nurse's priority?

a. Encourage the patient to cough and use the incentive spirometer.

b. Document the finding as a wheeze and reassess in an hour.

c. Stay with the patient, keep them upright and call for immediate help.

d. Give the as-needed inhaled bronchodilator that is ordered and recheck in 20 minutes.

Answer: c — The sound is stridor, which means the upper airway is narrowed and can close; it is an emergency (c) (section 12.2). Coughing and deep breathing (a) do not treat upper airway narrowing. Calling it a wheeze and waiting (b) delays urgent care. A bronchodilator (d) acts on the lower airways and would delay calling for help.

7. [CORE] A nurse auscultates a patient's chest. Which finding is normal?

a. Soft, low-pitched rustling sounds over most of the lung fields, with breathing in longer than breathing out

b. Loud, high-pitched sounds over the outer lung fields, with breathing out longer than breathing in

c. Continuous musical sounds heard on breathing out over both lungs

d. Grating, creaking sounds heard on breathing in and out over the lower right chest

Answer: a — Vesicular sounds are soft and low-pitched over most of the lungs, with inspiration longer than expiration (a) (section 12.2). Bronchial sounds are normal over the upper sternum, but heard over the outer lung (b) they may signal consolidation. Continuous musical sounds (c) are wheezes from narrowed airways. Grating sounds in both phases (d) suggest a pleural friction rub.

8. [CORE] Which findings suggest central cyanosis rather than peripheral cyanosis?

a. Bluish fingertips on cold hands, with a pink tongue

b. Bluish or greyish colour of the tongue and the inside of the lips

c. Bluish toes in a patient with known poor circulation in the legs

d. Pale nail beds that turn pink when the hands are warmed

Answer: b — Central cyanosis appears in the tongue, lips and oral lining and signals low arterial oxygen (b) (section 12.2). Blue fingertips with a pink tongue (a) and blue toes with poor circulation (c) are peripheral cyanosis from slow blood flow. Nail beds that pink up with warming (d) reflect peripheral circulation and cold, not central oxygenation.

9. [CORE] A nurse is assessing for pallor in patients with a range of skin tones. Which statement reflects the evidence?

a. The palms are the most reliable site for detecting anemia in people with darker skin.

b. Pallor is easy to see on all skin tones, so laboratory testing is rarely needed.

c. If no pallor is seen at any site, the patient's anemia can be safely ruled out.

d. The tongue is a useful site, but a hemoglobin level is still needed if anemia is suspected.

Answer: d — In a hospital study of adolescents and adults in India, the tongue was the most useful site for detecting severe anemia, but observers often disagreed and a hemoglobin level is still needed (d) (section 12.2). The palms (a) were less accurate than the tongue. Pallor is not easy to judge (b). The absence of pallor does not rule out milder anemia (c).

10. [CORE] A patient is brought to the emergency department after running a gas generator inside a closed garage. The patient has a headache and is confused. The SpO2 reads 99%. Which interpretation is correct?

a. Oxygenation is normal, so the confusion must have another cause, such as a stroke.

b. A reading this high happens with carbon monoxide only in people with darker skin.

c. The SpO2 may be falsely normal, because the oximeter reads carbon monoxide as oxygen.

d. The patient is breathing fast, and the hyperventilation has raised the SpO2 to 99%.

Answer: c — In carbon monoxide poisoning, standard two-wavelength oximeters count carbon monoxide-bound hemoglobin as oxygen-bound hemoglobin, so SpO2 can look normal while oxygen delivery is dangerously low (c) (section 12.3, Table 12.2). Assuming normal oxygenation (a) is the trap this question tests. Carbon monoxide affects readings on all skin tones (b). Hyperventilation (d) cannot raise saturation far on the flat top of the curve, and it does not explain the history.

11. [CORE] Which factors can make a pulse oximetry reading inaccurate? Select all that apply.

a. Dark nail polish on the finger under the probe

b. Cold hands with poor circulation

c. The patient's age

d. Shivering or other movement of the hand

e. Darker skin pigmentation

f. Bright procedure lights shining on the probe

Answer: a, b, d, e, f — Dark nail polish (a), poor perfusion (b), movement (d), darker skin pigmentation (e) and bright ambient light (f) can all make readings wrong or unreliable (section 12.3, Table 12.2). Age itself (c) is not a factor that affects how the device reads, although older adults may have cold hands or poor circulation.

12. [CORE] A patient on 4 L/min oxygen by nasal cannula after receiving an opioid has an SpO2 of 97%. The patient is hard to rouse, with slow, shallow breathing. Which statement explains why the nurse must not be reassured by the SpO2?

a. Pulse oximetry does not measure CO2, so CO2 can rise while SpO2 stays normal.

b. Pulse oximeters become inaccurate whenever a patient is receiving extra oxygen.

c. An SpO2 of 97% shows hyperoxia, which is what is causing the patient's drowsiness.

d. Nasal cannulas interfere with the light signal sent and received by a finger probe.

Answer: a — Pulse oximetry gives no information about CO2 or ventilation; extra oxygen can keep SpO2 normal while CO2 builds up from hypoventilation (a) (section 12.3; Chapter 5, section 5.4). Oximeters remain accurate on oxygen (b); the problem is what they don't measure. An SpO2 of 97% is not evidence of harmful hyperoxia (c), and the drowsiness fits opioid-related hypoventilation. Nasal cannulas do not affect finger probes (d).

13. [CORE] A student nurse asks why oxygen should not be withheld from a patient with COPD who has low oxygen levels. Which response by the nurse is accurate?

a. "People with COPD breathe only because of low oxygen, so we give oxygen only if they stop breathing."

b. "Oxygen is safe for them in any amount, so we always start with the highest flow the device allows."

c. "Withholding it is unsafe; we give oxygen to the ordered target range and watch for rising CO2."

d. "Oxygen has no effect on CO2 in people with COPD, so they need no extra monitoring once it starts."

Answer: c — Research has not supported the hypoxic drive theory, and withholding oxygen from a hypoxemic patient is unsafe. Oxygen is titrated to the ordered target, with monitoring for CO2 retention (c) (section 12.1). The idea that these patients breathe only because of low oxygen (a) is the myth itself. Too much oxygen can raise CO2 in people at risk, so maximal flow (b) is not appropriate. Oxygen can affect CO2, mainly through worsening V/Q mismatch, so monitoring is needed (d).

14. [RN] A patient with sepsis has a temperature of 39.4 °C and an arterial pH of 7.28. How will these conditions affect oxygen transport?

a. The curve shifts left, so hemoglobin releases oxygen more easily to the tissues.

b. The curve shifts right, so hemoglobin releases oxygen more easily to the tissues.

c. The curve does not shift, because only the level of 2,3-DPG can move the curve.

d. The curve shifts right, so hemoglobin picks up oxygen more easily in the lungs.

Answer: b — A higher temperature and a lower pH shift the oxygen–hemoglobin dissociation curve to the right. Hemoglobin's hold on oxygen loosens, so it releases oxygen more readily to the tissues, and saturation is lower at any given PaO2 (b) (section 12.3, Going Deeper box). A left shift (a) has the opposite effect and is not caused by fever or acidosis. Temperature, CO2 and pH all shift the curve, as does 2,3-DPG (c). A right shift makes it harder, not easier, for hemoglobin to pick up oxygen in the lungs (d).

15. [RN] An RN reviews an ABG for a patient with pneumonia: PaO2 58 mm Hg; SaO2 89%. The pulse oximeter read 94% when the sample was drawn. Which interpretation is most accurate?

a. The patient is on the steep part of the curve, and the SpO2–SaO2 gap should be reported.

b. The pulse oximeter is more accurate than the ABG, so the ABG result should be repeated.

c. A PaO2 of 58 mm Hg is within normal limits for an adult, so no further action is needed.

d. SaO2 and SpO2 cannot be compared, because the two values measure different things.

Answer: a — Below a PaO2 of about 60 mm Hg, the curve is steep, so this patient has little reserve. The SaO2 is the standard against which the SpO2 is judged, so a 5-point gap is significant and should be reported (a) (section 12.3, Going Deeper box). The co-oximetry SaO2, not the oximeter, is the reference measure, so repeating the ABG to match the oximeter is not the answer (b). A PaO2 of 58 mm Hg is below the reference ranges reported by Canadian laboratories (c). SpO2 is an estimate of SaO2, so the two are directly compared (d).

Case: Mr. Alan Kowalczyk (Questions 16–21): Mr. Alan Kowalczyk, 66, is on a surgical unit 9 days after a surgical tracheostomy for airway swelling after surgery to drain a deep neck abscess. His secretions have been thick. He has a cuffed tracheostomy tube with an inner cannula, and he breathes humidified oxygen at an FiO2 of 0.35 by tracheostomy mask, ordered to keep SpO2 at 92% to 96%. The cuff is deflated during the day per the care plan and inflated at night. At 0215, the nurse answers his call bell. He is sitting up, agitated and pointing at his neck. His respiratory rate is 32, heart rate 118 and SpO2 84%. Breath sounds are faint on both sides. The nurse cannot feel air moving at the tube, and there is no misting in the mask.

16. [CORE] Which finding is most important for the nurse to recognize as a cue that Mr. Kowalczyk's airway is in danger?

a. Heart rate of 118

b. No air felt moving at the tracheostomy tube

c. Agitation and pointing at his neck

d. FiO2 of 0.35 by tracheostomy mask

Answer: b — Absent airflow at the tube is a direct sign that the tracheostomy is not working and is the cue that defines the emergency (section 12.6). A fast heart rate is a non-specific stress response that can have many causes. Agitation matters, but it does not point to the airway by itself. The FiO2 is the treatment he was already on, not a finding of deterioration.

17. [CORE] The nurse analyzes the cues. Which explanation fits them best?

a. Secretions are blocking the tracheostomy tube.

b. He is having a panic attack after waking.

c. His oxygen tubing has come off the wall outlet.

d. He has developed pneumonia overnight.

Answer: a — No airflow at the tube, no misting, faint breath sounds and a falling SpO2 in a patient with thick secretions point to a blocked tube (section 12.6, Table 12.4). A panic attack does not stop airflow through the tube. A disconnected oxygen supply would lower SpO2 more slowly and would not stop air moving at the tube. Pneumonia develops over hours to days and would not abolish airflow.

18. [CORE] What should the nurse do first?

a. Remove the tracheostomy ties so the tube can be changed.
b. Instill normal saline into the tube to loosen secretions.
c. Call for help and give oxygen to his face and the tracheostomy.
d. Leave the room to get the spare tracheostomy tubes.

Answer: c — First responders call for help, assess the airway and apply oxygen to both the face and the tracheostomy, because a tracheostomy patient may still move air through the upper airway (section 12.6; NTSP, n.d.-a). Cutting ties risks displacing the tube before expert help arrives. Saline instillation is not recommended. The spare tubes should already be at the bedside, and leaving the patient alone in an airway emergency is unsafe.

19. [CORE] Help is on the way and oxygen is applied. Which action should the nurse take next?

a. Inflate the cuff with more air to improve the seal.
b. Place a speaking valve so he can describe his symptoms.
c. Raise the oxygen flow to the tracheostomy mask.
d. Remove the inner cannula and check for airflow.

Answer: d — Removing the inner cannula is a quick, low-risk step that often clears a blockage, because secretions collect inside it (section 12.6; Table 12.4). Adding air to the cuff does nothing for a blocked lumen and makes it harder to breathe around the tube. A speaking valve with the cuff inflated would stop him breathing out and must never be used. More oxygen cannot pass a blocked tube.

20. [CORE] The nurse removes the inner cannula, which is clear. A suction catheter will not pass beyond a few centimetres, and his SpO2 is now 80%. The rapid response team is arriving. Which action is most appropriate while the team takes over?

a. Push the suction catheter harder to break up the plug.
b. Deflate the cuff, if trained to do so, and bring the spare tubes and obturator.
c. Reinsert the inner cannula and wait for the SpO2 to improve before doing more.
d. Give the ordered oxygen by nasal cannula instead of the mask.

Answer: b — When a catheter will not pass, the tube itself is blocked or misplaced. Deflating the cuff may let air move around the tube through the upper airway, and the responding team will need the spare tubes to replace it (section 12.6; Table 12.4). Forcing the catheter can injure the trachea. Reinserting the inner cannula and waiting wastes critical time. Switching to a nasal cannula alone does not deal with the blocked tube.

21. [CORE] The team replaces the tracheostomy tube. Which finding best shows that the intervention has worked?

a. His chest rises equally, a suction catheter passes easily and SpO2 is 94%.
b. He is calmer and has stopped calling for the nurse.
c. His heart rate has dropped from 118 to 100.
d. The cuff holds its pressure after inflation.

Answer: a — Equal chest rise, easy catheter passage and an SpO2 back in the ordered range together show a patent, working airway (section 12.6). Being calmer and quieter could also mean exhaustion or falling consciousness. A lower heart rate is encouraging but is not specific to the airway. A cuff holding pressure does not show that the tube is in the trachea or open.

22. [CORE] A nurse is teaching a patient going home with oxygen and his family about fire safety. Which statements by the family show understanding? Select all that apply.

a. "He can vape inside if he turns the oxygen down first."
b. "We'll put 'No Smoking' signs inside and outside the house."
c. "He should stay well away from the gas stove and not cook while using oxygen."
d. "Petroleum jelly is the best thing for his dry lips while he wears the cannula."
e. "We'll keep the cylinders secured and standing upright."
f. "Oxygen itself is explosive, so we'll keep it in the garage."

Answer: b, c, e — Posting signs, keeping away from stoves and not cooking, and securing cylinders upright are all recommended by fire services (section 12.4). Smoking or vaping is never safe while oxygen is in use, whatever the flow. Petroleum jelly and oily products should be avoided while oxygen is in use. Oxygen itself does not burn, but it feeds a fire, and cylinders are kept secured and upright where the supplier directs.

23. [CORE] A patient with COPD is admitted with an acute exacerbation. The prescriber has not yet written an oxygen target. Which target range would the nurse expect for this patient, based on current guidelines?

a. 94% to 98%
b. 92% to 96%
c. 88% to 92%
d. 85% to 88%

Answer: c — For patients at risk of hypercapnic respiratory failure, such as those with COPD, the BTS, TSANZ and BMJ guidance all suggest 88% to 92% (section 12.4). The ranges of 94% to 98% and 92% to 96% are for most other acutely ill adults. A range of 85% to 88% is lower than recommended for COPD. The nurse still obtains a written order.

24. [CORE] A patient has a 28% Venturi mask. SpO2 has fallen from 90% to 86%, below the ordered range of 88% to 92%. Which statement about adjusting this device is accurate?

a. Turning up the flow will deliver a higher oxygen concentration.
b. A different valve is needed to change the oxygen concentration.
c. The mask must run at 15 L/min to work correctly.
d. Venturi masks deliver an oxygen concentration that varies with each breath.

Answer: b — The colour-coded valve sets the concentration in a Venturi mask, so the valve is changed, per order or directive, to increase FiO2 (section 12.4). Increasing the flow does not raise the concentration delivered. Fifteen litres per minute is the flow for a non-rebreather mask, not a 28% Venturi. A Venturi mask is a high-flow device that delivers a fixed concentration, not a variable one.

25. [CORE] A nurse watches a patient use an incentive spirometer on day 1 after surgery. Which action shows that the patient needs more teaching?

a. Holding the device upright while sitting up
b. Breathing out normally, then sealing the lips around the mouthpiece
c. Breathing in quickly and forcefully to make the indicator jump
d. Keeping the lungs inflated for at least 5 seconds at full inspiration

Answer: c — The patient should breathe in slowly and steadily toward the target, not quickly and forcefully (section 12.5). Holding the device upright, breathing out normally before sealing the lips, and keeping the lungs inflated for at least 5 seconds at full inspiration are all correct technique.

26. [CORE] A nurse is preparing to suction a patient's tracheostomy. Which action follows current suctioning guidance?

a. Instilling 5 mL of normal saline to thin secretions
b. Applying suction for up to 30 seconds per pass
c. Suctioning every 2 hours whether or not secretions are present
d. Giving extra oxygen before suctioning

Answer: d — The AARC guideline recommends preoxygenation before suctioning (section 12.6). Routine saline instillation should generally be avoided. Suction should be applied for no more than 15 seconds. Suctioning is done when assessment shows a need, not on a fixed schedule.

27. [CORE] In an Ontario public hospital, an RPN caring for a patient with a stable, long-standing tracheostomy hears coarse secretions in the tube. Which statement about the RPN's authority is accurate?

a. The RPN may suction the tracheostomy if there is an order or medical directive and the RPN is competent to do so.
b. The RPN may initiate suctioning independently because it is routine care.
c. Only an RN or an RT may suction a tracheostomy in Ontario.
d. The RPN needs a physician to delegate the act before each suctioning episode on the unit.

Answer: a — Putting an instrument into an artificial opening or beyond the larynx is a controlled act that RPNs are authorized to perform with an order or directive; competence and employer policy also apply (section 12.6, Scope in Practice box). Nurses cannot initiate controlled acts in public hospitals. RPNs are not excluded by law. Delegation is not needed because the act is already authorized to nurses; an order or directive is the authorizing mechanism.

28. [CORE] A patient has an oxygen order for nasal cannula at 1 to 4 L/min to keep SpO2 at 92% to 96%. The patient is on 4 L/min, is comfortable, and has an SpO2 of 99%. What should the nurse do?

a. Leave the flow at 4 L/min because a higher saturation is safer.
b. Lower the flow within the order and recheck SpO2 after about 5 minutes.
c. Stop the oxygen completely and recheck the next day.
d. Change to a simple face mask at 4 L/min for more comfort.

Answer: b — SpO2 is above the ordered range, so the nurse turns the flow down within the order and reassesses after about 5 minutes on the new setting (section 12.4). Liberal oxygen is linked to higher mortality and hides deterioration. Stopping oxygen abruptly without stepwise weaning and monitoring is unsafe. A simple face mask must not run below 5 L/min because of carbon dioxide rebreathing.

29. [CORE] A patient after abdominal surgery has crackles at the bases and a weak cough because of incisional pain. Which nursing action best supports airway clearance?

a. Asking for chest physiotherapy every 4 hours
b. Keeping the patient on bed rest until the crackles clear
c. Teaching huff coughing with a pillow over the incision, after pain is controlled
d. Suctioning the patient's nose and throat every 2 hours to keep the airway clear

Answer: c — Effective pain control and huff coughing with splinting help the patient clear secretions with less pain (section 12.5). Chest physiotherapy is not routine postoperative care. Early mobility, not bed rest, is recommended after surgery. Suctioning is used only when the patient cannot clear secretions despite their best cough, not on a schedule.

30. [CORE] Nasotracheal suctioning is being considered for a patient who cannot clear secretions. Which finding would make the nurse question the order?

a. Gurgling sounds on breathing
b. A facial fracture from a fall the day before
c. An SpO2 of 91% on room air
d. A weak cough after a stroke

Answer: b — Acute head, facial or neck injury is a contraindication to nasotracheal suctioning (section 12.5). Gurgling breath sounds and a weak cough are indications for suctioning, not reasons to avoid it. A modest SpO2 drop is a reason to give oxygen and monitor closely, not a contraindication.

31. [CORE] A patient who had a total laryngectomy 2 weeks ago becomes distressed, and the SpO2 is falling. How should the nurse give oxygen?

a. By non-rebreather mask over the mouth and nose
b. By nasal cannula at 4 L/min
c. By bag-valve mask over the mouth and nose
d. Directly to the neck stoma

Answer: d — After a laryngectomy, the patient is a neck breather, with no connection between the upper airway and the lungs, so oxygen and any ventilation must be given at the stoma (section 12.6). Masks, cannulas and bag-valve ventilation over the mouth and nose cannot reach the lungs.

32. [CORE] Which statement best explains why a target SpO2 range, rather than "as much oxygen as possible", is ordered for acutely ill adults?

a. Too little oxygen and too much oxygen can both harm patients.
b. Higher SpO2 values are always more accurate on a pulse oximeter.
c. Oxygen is expensive, so hospitals limit its use.
d. A target range is needed only for patients with COPD.

Answer: a — Hypoxemia harms tissues, and liberal oxygen in acutely ill adults has been linked to higher mortality and can hide deterioration (section 12.4). Oximeter accuracy does not improve at higher values. Cost is not the reason for target ranges. Target ranges are recommended for all patients, with a lower range for those at risk of hypercapnia.

33. [RN] A patient with pneumonia is on a high-flow nasal cannula at 50 L/min. Over 2 hours, the FiO2 needed to keep SpO2 in range has risen from 0.40 to 0.60. What is the priority?

a. Document the change and continue to titrate within the order.

b. Switch to a simple face mask to give the patient a break.

c. Turn off the heated humidifier to reduce the work of breathing.

d. Escalate for urgent medical and critical care review.

Answer: d — A rising oxygen requirement, especially an FiO2 of 0.50 or more, calls for urgent senior and intensive care review (section 12.4; Barnett et al., 2022). Titrating without escalating misses deterioration. A simple face mask delivers an FiO2 of about 0.60 at most and would reduce support. Turning off the humidifier removes a key feature of HFNC and does not reduce work of breathing.

34. [RN] A patient with a cuffed tracheostomy is ready to try a speaking valve after assessment by the SLP and RT. What must the nurse confirm before placing the valve?

a. The cuff is fully deflated.

b. The cuff is inflated to its usual pressure.

c. The inner cannula has been removed and discarded.

d. Oxygen has been turned off.

Answer: a — A speaking valve lets air in but not out through the tube, so exhaled air must pass around the tube and up through the larynx. The cuff must be completely deflated first; with the cuff inflated, the patient cannot breathe out (section 12.6; Hess & Altobelli, 2014; Mitchell et al., 2013). The inner cannula is managed according to the tube type and product instructions. Oxygen can be given with a speaking valve if the patient needs it.

35. [RN] A patient with COPD has an order for oxygen titrated to SpO2 88% to 92% under a unit directive. On 3 L/min by nasal cannula, SpO2 is 97%, and the patient is newly drowsy and hard to rouse. What should the nurse do?

a. Stop the oxygen immediately and recheck SpO2 and level of consciousness in 1 hour.

b. Increase the oxygen to raise SpO2 to 98%.

c. Reduce the oxygen to reach the target range, call for urgent medical review and anticipate a blood gas.

d. Encourage sleep and reassess at the next routine vital signs.

Answer: c — A high SpO2 and new drowsiness in a patient at risk of hypercapnia suggest oxygen-related carbon dioxide retention. The nurse titrates down to the target range, escalates and anticipates a blood gas (section 12.4). Stopping oxygen abruptly can cause life-threatening rebound hypoxemia. More oxygen would worsen the problem. Waiting until routine vital signs delays care for a deteriorating patient.

13 Lower Respiratory Infections and Lung Cancer

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Explain how pneumonia, influenza, COVID-19, RSV, tuberculosis, lung cancer and pleural effusion develop, and link each to its manifestations.
2. Recognize pneumonia in adults and older adults, including atypical presentations, and escalate signs of sepsis and respiratory failure.
3. Use diagnostic findings (chest imaging, cultures, rapid tests, TB tests and laboratory values in SI units) in nursing care.
4. Apply infection prevention and control, including airborne precautions for TB and precautions for respiratory viruses.
5. Support safe antimicrobial, antiviral and TB treatment, including adherence and adverse effects.
6. Care for patients with lung cancer through diagnosis, surgery, radiation and systemic therapy.
7. Teach prevention: vaccination, smoking cessation and radon testing.
8. Describe TB in Canada with a distinctions-based, strengths-based lens, including Inuit Nunangat.
9. Distinguish RN and RPN roles in these settings using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 6	Clinician; Scholar	Foundations of Practice
4, 5, 7	Educator; Advocate; Collaborator	Foundations of Practice; Collaborative Practice
8, 9	Advocate; Professional	Ethical Practice; Legal Practice

Introduction

Lower respiratory infections fill medical units every winter, and they also develop in patients admitted for other reasons. In 2023–2024, pneumonia was the fourth most common reason for a hospital stay in Canada. It accounted for 66,128 hospitalizations, or 2.2% of all stays, with an average acute stay of 6.9 days. Only giving birth, chronic obstructive pulmonary disease (COPD) and bronchitis, and heart failure ranked higher (Canadian Institute for Health Information [CIHI], 2025). Influenza and pneumonia together are among the 10 leading causes of death in Canada (National Advisory Committee on Immunization [NACI], 2025).

This chapter is the book's home for lower respiratory infections and lung cancer. Section 13.1 covers community-acquired pneumonia, section 13.2 hospital-acquired and aspiration pneumonia, and section 13.3 influenza, COVID-19 and respiratory syncytial virus (RSV) in adults. Section 13.4 covers tuberculosis, section 13.5 lung cancer, and section 13.6 pleural effusion and empyema. Related topics live in other chapters:

- infection prevention and control (IPAC), sepsis and antimicrobial stewardship (Chapter 4);
- early warning scores and rapid response (Chapter 6);
- older adults and delirium (Chapter 8);
- cancer care in general (Chapter 9);
- respiratory assessment, oxygen therapy and airway clearance (Chapter 12);
- asthma, COPD and smoking cessation (Chapter 14);
- acute respiratory failure, mechanical ventilation and chest tubes (Chapter 15).

13.1 Community-Acquired Pneumonia

How Pneumonia Develops

Pneumonia is an acute infection of the lung tissue, the alveoli and smallest airways, that sets off inflammation there. **Community-acquired pneumonia (CAP)** starts outside hospital. The 2019 guideline from the American Thoracic Society and the Infectious Diseases Society of America (ATS/IDSA) dropped the label "health care-associated pneumonia"; local data now guide the judgment of resistance risk (Metlay et al., 2019). The most recent national Canadian CAP guideline, from the Canadian Infectious Disease Society and the Canadian Thoracic Society, dates from 2000 (Mandell et al., 2000). Canadian hospital stewardship guidance, such as Sinai Health's in Toronto, cites the ATS/IDSA guideline (Sinai Health, n.d.), and this chapter follows it.

Often no cause is found: in a large United States study of adults admitted with CAP, testing identified one in only 38% of patients. Viruses were found more often than bacteria, and the most common single causes were human rhinovirus, influenza virus and *Streptococcus pneumoniae* (Jain et al., 2015). In Canadian adults, pneumonia caused by *S. pneumoniae* (pneumococcus), with bacteria in the bloodstream, is the most common form of invasive pneumococcal disease (NACI, 2024a). Other causes include:

- influenza virus, the virus that causes COVID-19, and RSV (section 13.3);
- **atypical bacteria**, such as *Legionella*, which need special tests to detect (Metlay et al., 2019). In Ontario, the risk of *Legionella* is highest from June to November (Sinai Health, n.d.);
- less often, *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), and *Pseudomonas aeruginosa* (Metlay et al., 2019).

Organisms usually reach the alveoli by inhalation or by aspiration of small amounts of throat secretions. When they overcome the lung's defences, the inflammatory response (Chapter 4, section 4.1) fills the air spaces with fluid, white blood cells and fibrin. The lung becomes solid, a change called **consolidation**. Blood flowing past these airless alveoli picks up no oxygen, and hypoxemia follows (Chapter 12, section 12.1). Inflamed pleura cause **pleuritic chest pain**, a sharp pain that worsens with deep breaths or coughing (effusion: section 13.6).

Who Is at Risk

Risk climbs steeply with age. In the United States study, the yearly rate of CAP needing hospital care was 24.8 per 10,000 adults overall, 63.0 per 10,000 at ages 65 to 79 and 164.3 per 10,000 at 80 and older (Jain et al., 2015). Working-age adults are not spared: in Canada, pneumonia hospitalizations among adults aged 18 to 64 rose from 14,937 in 2022–2023 to 17,447 in 2023–2024, nearly 17% (CIHI, 2025).

Chronic heart, lung, liver or kidney disease, diabetes, alcohol use disorder, cancer and asplenia are comorbidities that change antibiotic choice (Metlay et al., 2019). NACI adds these groups at higher risk of invasive pneumococcal disease (NACI, 2024a):

- people with weakened immune systems, including people living with human immunodeficiency virus (HIV);
- people who smoke, especially after age 50;
- people who misuse alcohol, use cocaine or inject drugs;
- residents of long-term care and other residential care;
- people who are unhoused.

In surveillance in Toronto and Peel Region from 2014 to 2023 (excluding 2020 and 2021), the overall rate of invasive pneumococcal disease in adults aged 18 to 49 was 2.5 per 100,000, but among unhoused adults of the same ages it was 66 per 100,000 (NACI, 2024a). NACI also notes a higher risk of severe pneumococcal disease among First Nations, Inuit and Métis people, arising from intersecting factors (NACI, 2024a). These factors are structural, such as crowded housing and distance from care, not Indigenous identity (Chapter 2). Anything that raises aspiration risk also raises pneumonia risk (section 13.2).

Recognizing Pneumonia

The classic picture is new cough, sputum, fever or chills, shortness of breath and pleuritic pain, with a rising respiratory and heart rate. Over consolidated lung, the nurse may hear crackles or bronchial breath sounds (Chapter 12, section 12.2). Oxygen saturation

measured by pulse oximetry (SpO2) often falls. A careful full-minute count of the respiratory rate matters, because a rising rate is an early warning sign (Chapter 6).

Older adults often lack these signs; new confusion, a fall or loss of function may be the first clue (Chapter 4, section 4.2; Lifespan Considerations box). On darker skin, pallor and cyanosis are harder to see, so the nurse checks the lips, oral mucosa, conjunctivae and nail beds, and remembers that pulse oximetry can overestimate saturation on darker skin (Chapter 12, sections 12.2 and 12.3).

Pneumonia can lead to sepsis. A rising respiratory rate, new confusion, falling blood pressure, a racing pulse, mottled skin or falling urine output calls for sepsis screening and escalation (Chapter 4, section 4.6; Chapter 6).

Diagnostics

The diagnosis rests on clinical findings plus a new infiltrate on chest imaging (Metlay et al., 2019; Figure 13.1). The ATS/IDSA guideline does not recommend routine cultures for patients treated at home. In hospital, it advises pretreatment sputum and blood cultures for patients with the following (a strong recommendation for the first two groups, a conditional one for the last two):

- severe CAP;
- planned empirical treatment for MRSA or *P. aeruginosa*;
- previous infection with either organism;
- a hospital stay with intravenous (IV) antibiotics in the past 90 days (Metlay et al., 2019).

The nurse collects ordered cultures before the first antibiotic dose whenever this causes no delay (Chapter 4, section 4.5).

- **Urine antigen tests:** pneumococcal and *Legionella* tests are suggested for severe CAP, and the *Legionella* test also for an outbreak or recent travel (Metlay et al., 2019).
- **Viral testing:** when influenza is circulating, the guideline recommends a rapid molecular influenza test (Metlay et al., 2019).
- **Blood work:** the white blood cell (WBC) count, in $\times 10^9$/L, and C-reactive protein (CRP) are trended (Chapter 4, section 4.2); reference ranges vary by laboratory. A procalcitonin result does not decide whether to start antibiotics in confirmed CAP (Metlay et al., 2019).
- **Sepsis work-up:** lactate, creatinine and urea are added when sepsis is suspected (Chapter 4, section 4.6).
- **Oxygenation:** SpO2 is trended; an arterial blood gas is drawn for severe hypoxemia or suspected carbon dioxide retention (Chapter 12, section 12.3).

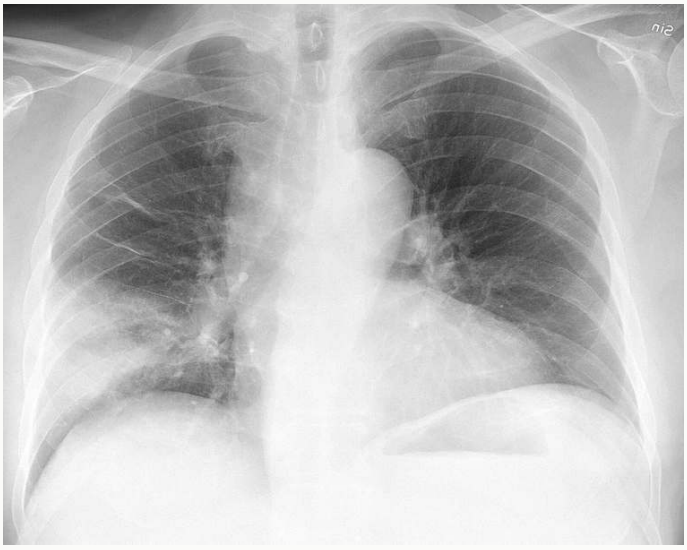

Figure 13.1 Chest X-ray of lobar pneumonia. Consolidation fills the right middle lobe, the white area beside the right heart border (on the viewer's left).

Nursing Care

Nursing care follows the clinical judgment model (Chapter 1, section 1.4).

- **Recognize and analyze cues.** The nurse trends vital signs, SpO2, oxygen need, mental status, intake and urine output, and calculates the early warning score (Chapter 6). A rising oxygen need is a cue even when the SpO2 looks acceptable.
- **Prioritize hypotheses.** Worsening hypoxemia and sepsis come first; dehydration, delirium and falls follow.
- **Give oxygen to a target.** The nurse titrates oxygen to the prescribed SpO2 range and asks for a range when none is ordered (Chapter 12, section 12.4).
- **Give the first antibiotic dose promptly.** No guideline sets one deadline for every patient with CAP, but for septic shock or probable or definite sepsis, antimicrobials are given immediately, ideally within 1 hour of recognition (Prescott et al., 2026;

Chapter 4, section 4.6).

- **Support fluids and nutrition.** Fever and fast breathing increase fluid losses. The nurse gives IV fluids as ordered, watches for overload in heart or kidney disease (Chapter 3) and offers small, frequent meals.
- **Clear the airway and mobilize.** Sitting upright, deep breathing, coughing and early mobility help clear secretions (Chapter 12, section 12.5). Analgesia for pleuritic pain makes deep breathing possible (Chapter 5).
- **Promote comfort.** Antipyretics as ordered, mouth care and rest periods help.
- **Prevent spread.** Droplet and contact precautions are added while a respiratory virus is suspected (section 13.3; Chapter 4, section 4.3).
- **Evaluate outcomes.** Clinical stability supports the switch to oral therapy and discharge. An IDSA clinical pathway defines it as at least five of the following, or a return to baseline (Infectious Diseases Society of America [IDSA], n.d.):
- temperature 38 °C or lower;
- heart rate 100 beats/min or lower;
- respiratory rate 24 breaths/min or lower;
- SpO2 of 90% or higher;
- baseline mental status;
- systolic blood pressure of 90 mm Hg or higher.

The patient must also tolerate oral medications. The nurse who sees these signs prompts a review (Chapter 4, section 4.5).

Before discharge, the nurse teaches the patient to take the antibiotic as prescribed and to return for worsening breathlessness, new confusion or returning fever, and checks follow-up and vaccine status. A routine follow-up chest X-ray is not recommended; lung cancer screening is offered when clinically indicated (Metlay et al., 2019; Chapter 9).

Antimicrobials

Antibiotic choice depends on the care setting, severity, comorbidities and local resistance. The ATS/IDSA guideline recommends these approaches (Metlay et al., 2019):

- **Outpatients without comorbidities:** amoxicillin, or doxycycline. A macrolide such as azithromycin is used alone only where pneumococcal resistance to macrolides is low.
- **Outpatients with comorbidities:** amoxicillin–clavulanate or a cephalosporin, combined with a macrolide or doxycycline. Another option is a **respiratory fluoroquinolone** (levofloxacin or moxifloxacin) alone.
- **Inpatients with non-severe CAP:** a beta-lactam such as ceftriaxone plus a macrolide, or a respiratory fluoroquinolone alone.
- **Severe CAP:** a beta-lactam plus either a macrolide or a respiratory fluoroquinolone.
- **MRSA or *P. aeruginosa* coverage:** added only when locally validated risk factors are present.

Hospitals adapt these options: one Toronto stewardship program uses amoxicillin or ampicillin for lower-risk patients, and amoxicillin–clavulanate or ceftriaxone, with azithromycin considered, for higher-risk patients (Sinai Health, n.d.).

Before the first dose, the nurse asks what happened with any reported drug allergy and records the reaction exactly; most penicillin allergy labels do not hold up when assessed (Ontario Medical Association [OMA], 2025; Chapter 4, section 4.5). Stewardship continues:

- therapy is narrowed when cultures exclude resistant organisms (Metlay et al., 2019);
- courses are short: the Toronto program stops after 3 days if the patient is afebrile and stable by day 3, and extends to 5 or 7 days for slower responses (Sinai Health, n.d.);
- the nurse asks for the planned stop date (Chapter 4, section 4.5).

Prevention

- **Vaccination:** pneumococcal, influenza, COVID-19 and RSV vaccines protect adults' lungs (section 13.3, Patient Education box).
- **Smoking cessation:** smoking raises pneumococcal risk (NACI, 2024a; Chapter 14).

- **Oral health:** poor oral hygiene and gum disease are linked to aspiration pneumonia (Son et al., 2017).
- **Everyday measures:** hand hygiene, covering coughs and staying home when sick limit the spread of respiratory viruses (Public Health Agency of Canada [PHAC], 2026a).

LIFESPAN CONSIDERATIONS

Pneumonia in Older Adults

- **Older adults:** pneumonia needing hospital care is far more common after 65, and more common again after 80 (Jain et al., 2015). It often shows up as confusion, a fall, poor appetite or a sudden loss of function rather than fever and cough. The nurse treats any new change in thinking or function as a possible sign of infection and checks for delirium (Chapter 8, section 8.2). Dysphagia, frailty and sedating drugs raise the risk of aspiration. Bed rest quickly costs strength, so mobilizing early with help protects function and lowers the risk of hospital-associated disability (Chapter 8, section 8.1). Older adults lose fluid easily with fever, yet many also have heart or kidney disease, so fluid balance needs careful watching. A medication review matters too: some antimicrobials and antivirals interact with common drugs (section 13.3).
- **Younger adults:** risk rises with smoking, alcohol or drug use, unstable housing and chronic disease (NACI, 2024a). Pregnant people with influenza or COVID-19 are a higher-risk group for severe illness (NACI, 2025, 2026a).

CLINICAL JUDGMENT

From Pneumonia to Sepsis

Names and details are fictional; this is a composite story.

Mr. Harold Pelletier, 74, was admitted to a medical unit today with community-acquired pneumonia and received his first IV antibiotic dose at 1600. At 2000: temperature 38.2 °C, heart rate 96 beats/min, respiratory rate 20 breaths/min, blood pressure 128/74 mm Hg, SpO2 94% on 2 L/min oxygen; alert and chatting with his daughter.

- **Recognize cues:** at 0100 his respiratory rate is 30 breaths/min, heart rate 118 beats/min, blood pressure 92/54 mm Hg, temperature 39.1 °C and SpO2 89% on 2 L/min. He is trying to climb out of bed and does not know where he is. His urinal holds 40 mL since 2000.
- **Analyze cues:** fast breathing, low blood pressure and new confusion together suggest organ dysfunction.
- **Prioritize hypotheses:** the most urgent explanation is sepsis from pneumonia, with worsening hypoxemia. Delirium is a sign of it.
- **Generate solutions:** support oxygenation, escalate at once, prepare for a sepsis assessment and keep him safe.
- **Take action:** the nurse stays with Mr. Pelletier, raises the head of the bed and increases oxygen within the ordered range. The nurse calculates the early warning score, which meets the hospital's trigger for the rapid response team, and calls using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6, section 6.2). The nurse asks whether a lactate and repeat cultures are needed, reports when the next antibiotic dose is due, prepares for IV fluids and keeps the bed low. A registered practical nurse (RPN) would take the same immediate actions and notify the registered nurse (RN) and the team under the same employer policy.
- **Evaluate outcomes:** the nurse rechecks vital signs, SpO2, mental status and urine output as often as the team orders, and reports any further fall in blood pressure (Chapter 4, section 4.6).

GOING DEEPER

Pneumonia Severity Scores

Required for RN students; optional for PN students.

Severity scores help the team decide where a patient with CAP should be treated: at home, on a ward or in critical care. Two are widely used.

CURB-65 was built from three hospital cohorts in the United Kingdom, New Zealand and the Netherlands (Lim et al., 2003). Its name lists its five criteria, each worth one point:

- **C**onfusion;
- **U**rea above 7 mmol/L;
- **R**espiratory rate of 30 breaths/min or more;
- **B**lood pressure low: systolic under 90 mm Hg, or diastolic of 60 mm Hg or lower;
- age **65** years or older.

In the original study, death within 30 days was uncommon at scores of 0 to 2 (from under 1% to about 3%). It rose to 17% at a score of 3 and to over 40% at scores of 4 and 5. The authors proposed using the score to sort patients into management groups (Lim et al., 2003).

The **Pneumonia Severity Index (PSI)** was derived from more than 14,000 inpatients. It sorts patients into five risk classes using age, coexisting diseases, and vital signs and laboratory results that are abnormal when the patient first presents (Fine et al., 1997). Very few patients in the three lowest classes died, which helped identify people who could safely be treated at home. PSI needs more data than CURB-65, so it is usually calculated with an electronic tool.

The ATS/IDSA guideline recommends using a validated rule together with clinical judgment. It prefers PSI over CURB-65 (Metlay et al., 2019). Neither score sees everything. A patient with a low score may still need admission for hypoxemia, inability to take oral drugs, delirium or no safe place to recover. CURB-65 does not include oxygenation at all. Scores support the team's decision; they never replace assessment and reassessment.

13.2 Hospital-Acquired and Aspiration Pneumonia

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia (HAP) is pneumonia that was not incubating at admission and appears 48 hours or more after admission. **Ventilator-associated pneumonia (VAP)** is pneumonia that develops more than 48 hours after endotracheal intubation (Kalil et al., 2016). VAP belongs to critical care and is covered in Chapter 15. Pneumonia in patients who are not on a ventilator gets less attention than VAP. A systematic review notes that it occurs more often, costs more and is just as dangerous (Mitchell et al., 2019), and it roughly doubles the time to discharge (Klompas et al., 2022).

Many hospital routines raise the risk of HAP:

- bed rest and immobility;
- sedating drugs and reduced consciousness;
- dysphagia, tube feeding and poor oral hygiene (Son et al., 2017);
- surgery, especially of the chest or abdomen (Chapter 7, section 7.6).

The likely organisms differ from those in CAP. Empirical treatment often covers *S. aureus*, *P. aeruginosa* and other gram-negative bacilli, some of them resistant. In the guideline's analysis, IV antibiotics in the previous 90 days was the one risk factor for resistant organisms in HAP that stood out (Kalil et al., 2016). Each hospital produces a local antibiogram, a summary of how its own bacteria respond to antibiotics, and empirical choices follow it. Therapy is narrowed once cultures return, and about 7 days of treatment is recommended for most patients (Kalil et al., 2016). Antibiotic-resistant organisms are covered in Chapter 4, section 4.4. Table 13.1 compares CAP and HAP.

Table 13.1 Community-acquired and hospital-acquired pneumonia compared (Kalil et al., 2016; Metlay et al., 2019; Mitchell et al., 2019; NACI, 2024a; original wording)

Feature	Community-acquired	Hospital-acquired
Definition and timing	Starts outside hospital, including in long-term care	Not incubating at admission; starts 48 hours or more after admission
Setting	Treated at home, on a ward or in critical care, depending on severity	Develops on a hospital unit; pneumonia after more than 48 hours on a ventilator is VAP (Chapter 15)
Likely organisms	Respiratory viruses, S. pneumoniae and atypical bacteria; often no cause found	S. aureus (including MRSA), P. aeruginosa and other gram-negative bacilli, more often resistant
Main risk factors	Older age, smoking, chronic heart, lung, liver or kidney disease, diabetes, weakened immunity, alcohol or drug use, unstable housing	Immobility, sedation or reduced consciousness, dysphagia, tube feeding, poor oral hygiene, recent surgery; IV antibiotics in the past 90 days raise the risk of resistant organisms
First-line approach	Narrower agents chosen by severity and comorbidities; MRSA or Pseudomonas coverage only with local risk factors	Broader coverage guided by the local antibiogram, then narrowed; about 7 days for most patients

Feature	Community-acquired	Hospital-acquired
Prevention focus	Vaccination, smoking cessation, oral health, hand hygiene	Oral care, swallowing screens, early mobility, sitting upright, lighter sedation, hand hygiene and stopping viral spread on the unit

Prevention on the Unit

HAP prevention is largely nursing work, and the evidence keeps growing. A systematic review of 15 studies found that most programs focused on oral care, and that most oral care studies reported less HAP. Programs that screened swallowing after stroke, or that got patients moving early, also reported fewer cases. The studies varied widely in quality, however, and the authors called for well-designed, nurse-led trials (Mitchell et al., 2019). Nurses can act on this evidence now:

- **Oral care:** brush the teeth, gums and tongue, and clean dentures, on the regular schedule set by unit policy, with help for patients who cannot do it themselves. In ventilated patients, toothbrushing without chlorhexidine is recommended, and routine chlorhexidine oral care is not (Klompas et al., 2022).
- **Swallowing screens:** screen patients at risk, such as those with a stroke, before giving the first food, fluid or oral medication. Refer to speech-language pathology as policy directs (Mitchell et al., 2019; Chapter 31).
- **Early mobility:** sit patients up and walk them as soon as it is safe (Mitchell et al., 2019).
- **Position upright:** sit patients up for meals and keep the head of the bed raised during tube feeding to reduce reflux and aspiration (Son et al., 2017).
- **Minimize sedation:** use the lightest effective sedation and watch closely after sedating drugs (Son et al., 2017).
- **Deep breathing:** encourage deep breathing and coughing. Incentive spirometry is used together with these measures and early mobility, not alone (Chapter 12, section 12.5).
- **Hand hygiene and viral prevention:** clean hands before and after patient contact, and use droplet and contact precautions for respiratory viruses (section 13.3).

Aspiration Pneumonia and Pneumonitis

Aspiration is the passage of material from the mouth, throat or stomach into the airways. It can cause two different problems (Son et al., 2017).

- **Aspiration pneumonitis** is a chemical injury caused by inhaling a large volume of stomach contents, which are usually sterile. It typically follows vomiting in a person with reduced consciousness, for example after sedation, poisoning or trauma. The event may be witnessed, and hypoxemia comes on within hours. The injury may settle within about 48 hours. Care is supportive, and antibiotics are not routinely required unless infection follows.
- **Aspiration pneumonia** is an infection that develops after a person breathes in mouth and throat secretions carrying bacteria. It usually occurs in a person with dysphagia, often an older adult, and the aspiration is usually not witnessed.

Risk factors include dysphagia after stroke (Chapter 31) or with dementia or Parkinson disease, reduced consciousness, tube feeding, reflux and poor oral health (Son et al., 2017). On imaging, aspiration tends to affect the parts of the lung that are lowest at the time it happens. In a patient lying flat, that means the back of the lungs (Son et al., 2017).

The nurse watches for coughing or choking with meals or medications, a change in voice after swallowing, food left in the mouth, and new fever, crackles or hypoxemia. When aspiration is witnessed, the nurse:

- stops any feeding;
- positions the patient upright or on the side;
- suctions the mouth and throat as needed (Chapter 12, section 12.5);
- gives oxygen to target and escalates.

The ATS/IDSA guideline suggests not adding routine anaerobic antibiotic coverage for suspected aspiration pneumonia unless a lung abscess or empyema is suspected (Metlay et al., 2019; section 13.6). Prevention rests on the measures listed above, together with the diet textures the speech-language pathologist recommends.

13.3 Influenza, COVID-19 and RSV

How They Spread and How to Protect Others

Influenza, **COVID-19** and infection with **respiratory syncytial virus (RSV)** are acute viral respiratory illnesses (Figure 13.2). COVID-19 is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). All three spread through respiratory particles and through contact with secretions on hands and surfaces.

- **Influenza:** adults can spread it from about 1 day before symptoms start to about 5 days after (NACI, 2025).
- **RSV:** people are infectious for about 8 days on average, and sometimes for up to 3 weeks (PHAC, 2026a).
- **COVID-19:** people who have no symptoms yet, or who never develop them, can spread the virus (Public Health Ontario [PHO], 2023).

Ontario guidance places patients with influenza, RSV or COVID-19 on droplet and contact precautions in a single room. Staff wear a gown, gloves, a mask and eye protection (Provincial Infectious Diseases Advisory Committee [PIDAC], n.d.). Precautions start when the illness is suspected, not when the test result returns. Before each interaction, the nurse's point-of-care risk assessment guides any added protection, such as a fit-tested N95 respirator for aerosol-generating medical procedures. Respirator rules for COVID-19 have changed over time and still vary between hospitals, so the nurse follows current policy and the sign on the door. Personal protective equipment is taught in full in Chapter 4, section 4.3.

Nurses also protect patients by staying home when ill and by keeping their own vaccines up to date. NACI names health care workers among the groups for which it particularly recommends influenza and COVID-19 vaccines; for influenza, one reason is that they can pass the infection to patients at high risk (NACI, 2025, 2026a).

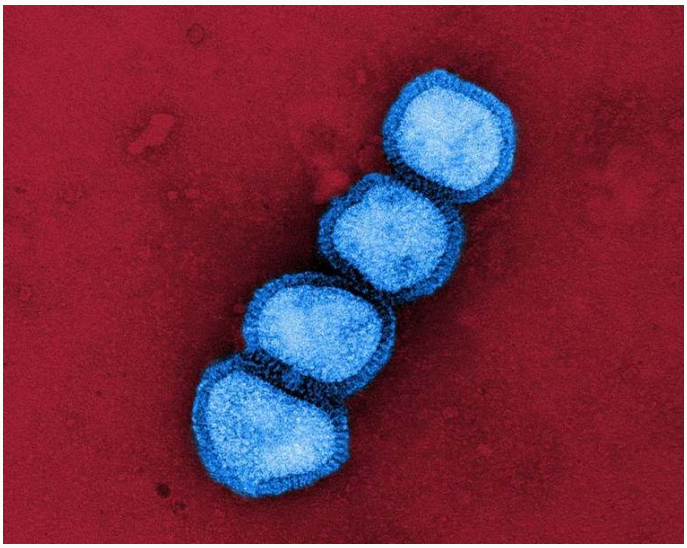

Figure 13.2 Influenza A (H1N1) virus particles, coloured blue, seen with a transmission electron microscope.

Recognizing Illness and Complications

Influenza classically begins suddenly with fever, cough and muscle aches. Headache, chills, loss of appetite, fatigue and sore throat are also common, and most people recover in about 7 to 10 days (NACI, 2025). RSV causes a runny nose, cough, sneezing, fever and wheezing. In severe cases, it causes pneumonia or other lower respiratory tract disease (PHAC, 2026a). COVID-19 shares many of these symptoms. Because the three look alike at the bedside, testing is needed to tell them apart.

Complications are what bring adults into hospital:

- respiratory failure;
- viral pneumonia, or a bacterial pneumonia that follows the viral illness;
- delirium;
- worsening of chronic conditions (NACI, 2025).

The risk of heart attack and stroke also rises significantly in the first 15 days after influenza (NACI, 2025). Older adults carry most of the burden. In 2023–2024, adults 65 and older accounted for 45% of the hospitalizations and 71% of the deaths associated with influenza in Canada (NACI, 2025). In pooled Canadian surveillance of adults admitted to hospital with respiratory illness, RSV hospitalization rates climbed from 43.7 per 100,000 at ages 60 to 69 to 282.5 per 100,000 at age 80 and older. About 10% of older

adults admitted with RSV needed intensive care. In a Canadian study of adults 50 and older admitted with RSV over the 2012–2015 seasons, 98.1% had at least one chronic condition (NACI, 2024b).

Other groups at higher risk include adults with chronic heart, lung, kidney or metabolic disease, people with weakened immunity, pregnant people, residents of long-term care, and First Nations, Inuit and Métis people. For Indigenous Peoples, this risk reflects intersecting structural and social determinants of health, such as crowded housing and access to care, not biology (NACI, 2025, 2026a, 2026b; Chapter 2).

Testing and Treatment

Testing uses molecular tests, such as polymerase chain reaction (PCR), or rapid tests. When influenza is circulating, the ATS/IDSA guideline recommends a rapid molecular test for patients with pneumonia (Metlay et al., 2019). For COVID-19, a PCR, rapid molecular or rapid antigen test can confirm infection (Ontario Health, 2024).

An **antiviral** is a drug that stops a virus from multiplying. Antivirals for influenza and COVID-19 work best when started early, so the nurse gives the first dose without delay once it is ordered. Table 13.2 summarizes the three viruses.

- **Influenza:** Ontario Health (2025) recommends oseltamivir as first-line treatment for severe or worsening influenza, no matter how long the patient has had symptoms or whether risk factors are present. For milder illness, treatment may be considered when risk factors are present, ideally within 48 hours after symptoms begin. Treatment does not wait for a test result when influenza is circulating. For milder illness, inhaled zanamivir is an alternative, and baloxavir is generally reserved for patients who cannot take oseltamivir or zanamivir. Oseltamivir doses are adjusted for kidney function. Its most common side effects are nausea and vomiting (Ontario Health, 2025).
- **COVID-19: nirmatrelvir–ritonavir** is used to treat adults who have mild to moderate COVID-19 and are at high risk of severe disease. It is not started in patients who already need hospital care for severe or critical COVID-19. It must begin within 5 days of symptom onset (Pfizer Canada ULC, 2026). Ontario Health (2024) recommends it for adults 65 and older and for immunocompromised adults, and suggests considering it for other higher-risk adults. Remdesivir, started within 7 days of onset, is the alternative when nirmatrelvir–ritonavir cannot be used (Ontario Health, 2024).
- **RSV:** no antiviral drug specifically treats RSV. Care is supportive, and severe cases may need admission for oxygen (PHAC, 2026a).

Ritonavir is a strong inhibitor of the liver enzyme CYP3A4, so it can raise other drugs to dangerous levels (Ontario Health, 2024). The product monograph carries a serious warning about drug interactions. It lists drugs that must not be combined with nirmatrelvir–ritonavir, including some antiarrhythmics, some statins and some anticoagulants. Strong enzyme inducers, such as some anticonvulsants, rifampin and St. John's wort, make the antiviral less effective (Pfizer Canada ULC, 2026). Before the first dose, the nurse makes sure the prescriber or pharmacist has a complete list of the patient's medications, including prescription, over-the-counter, recreational and natural health products. Ritonavir can also make combined hormonal contraceptives less effective, so the patient is taught to use another effective method or an added barrier method (Pfizer Canada ULC, 2026).

Supportive care is the same for all three viruses:

- oxygen to target;
- fluids;
- fever and symptom control;
- rest, then early mobility;
- monitoring for bacterial pneumonia and for worsening of chronic disease.

Older adults need the same watchfulness as in pneumonia. Delirium is a recognized complication of influenza (NACI, 2025), and a rising respiratory rate, a rising oxygen need or new confusion calls for the escalation steps in section 13.1. Teaching for nirmatrelvir–ritonavir covers its most common side effects, a changed sense of taste and diarrhea. If a patient is admitted to hospital after starting treatment, the full 5-day course may be completed at the health care team's discretion. Patients are taught to report a rash or other signs of an allergic reaction at once, because the drug is stopped for a significant hypersensitivity reaction (Pfizer Canada ULC, 2026).

Some people have lasting symptoms after COVID-19. The World Health Organization (WHO) defines **post-COVID-19 condition** (long COVID) as symptoms that continue more than 3 months after confirmed or probable infection with SARS-CoV-2, last at least 2 months and have no other explanation. Fatigue, shortness of breath, sleep problems, palpitations, anxiety and depression are common (Quinn et al., 2023). The nurse takes these symptoms seriously and helps the patient connect with primary care.

Table 13.2 Influenza, COVID-19 and RSV in adults at a glance (NACI, 2025, 2026a, 2026b; Ontario Health, 2024, 2025; PHAC, 2026a; PHO, 2023; PIDAC, n.d.; original wording)

Feature	Influenza	COVID-19	RSV
Usual spread	Respiratory particles and contact with secretions; adults contagious from about 1 day before to 5 days after symptoms begin	Respiratory particles and contact; people without symptoms can spread it	Respiratory particles and contaminated surfaces; infectious for about 8 days on average
Precautions in hospital (Ontario; may vary by province and policy)	Droplet and contact, single room	Droplet and contact, single room; respirator rules set by hospital policy	Droplet and contact, single room
Who is at higher risk	Adults 65 and older, chronic conditions, pregnancy, long-term care residents, First Nations, Inuit and Métis communities	Adults 65 and older, chronic conditions, weakened immunity, pregnancy, long-term care residents	Adults 75 and older, chronic heart and lung disease, weakened immunity, long-term care residents
Antiviral treatment in Canada	Oseltamivir first-line for severe illness; inhaled zanamivir or baloxavir in selected cases	Nirmatrelvir–ritonavir within 5 days for high-risk adults; remdesivir as the alternative	No specific antiviral; supportive care
Adult vaccine (NACI)	Every year for everyone 6 months and older	Yearly for adults at higher risk, with a second yearly dose for some; other adults may receive it	One dose for adults 75 and older and for some younger adults at high risk

PATIENT EDUCATION

Vaccines That Protect Adults' Lungs

- **Influenza:** NACI recommends a flu vaccine every year for everyone 6 months and older, unless a contraindication applies (NACI, 2025). In Ontario, it is publicly funded. For the 2026–2027 season, pharmacies offer it to the general public aged 2 and older from October 26, 2026, with high-dose and adjuvanted vaccines for people 65 and older (Ontario Ministry of Health, 2026a).
- **COVID-19:** starting in fall 2026, NACI strongly recommends a yearly dose for adults 65 and older and for other higher-risk groups. A second yearly dose is recommended for people 80 and older, residents of long-term care and some others (NACI, 2026b).
- **Pneumococcal:** NACI recommends one dose of Pneu-C-20 or Pneu-C-21 for all adults 65 and older and for adults under 65 at increased risk, whatever vaccines they had before (NACI, 2024a). Ontario funds Pneu-C-21 at 65 and older and Pneu-C-20 for high-risk adults aged 18 to 64 (Ontario Ministry of Health, 2026b).
- **RSV:** NACI recommends one dose for all adults 75 and older and for some higher-risk younger adults (NACI, 2026a). Ontario funds it for all adults 75 and older and for adults aged 60 to 74 in certain high-risk groups (Ontario Ministry of Health, 2026c).

Programs differ in other provinces and territories, and they change from season to season. The nurse checks current local eligibility and encourages patients to keep a record of their vaccines.

13.4 Tuberculosis

Tuberculosis is curable and preventable, yet it still causes illness and death in Canada, and its burden falls unequally for social and historical reasons. Pneumonia and viral respiratory infections were covered in sections 13.1 to 13.3.

How TB Develops

Tuberculosis (TB) is an infection caused by the bacterium *Mycobacterium tuberculosis* (Figure 13.3). It spreads through the air. When a person with TB in the lungs or larynx coughs or sneezes, they release droplet nuclei, particles about 1 to 5 microns across that stay in the air and travel on air currents and through ducts. Almost all spread happens indoors (Long et al., 2022).

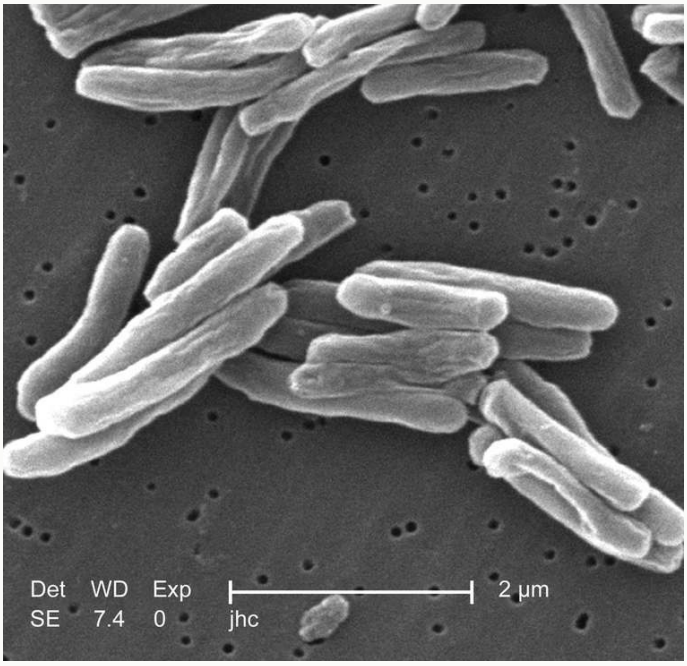

Figure 13.3 Mycobacterium tuberculosis bacteria seen with a scanning electron microscope, magnified about 15,500 times.

After someone breathes in the bacteria, the immune system usually contains them. The bacteria stay alive but inactive. The Canadian Tuberculosis Standards call this state **TB infection**; older sources and some chapters of the Standards still say *latent TB infection* (LTBI) (Alvarez et al., 2022; Campbell et al., 2022). In Nunavut, it is sometimes called "sleeping TB" (Government of Nunavut, 2026). A person with TB infection has no symptoms and cannot spread TB.

TB disease (active TB) develops when the bacteria multiply and cause illness. About 90% to 95% of people with TB infection never develop disease (Long et al., 2022). The risk is highest in the first 2 to 3 years after infection (Campbell et al., 2022). The Standards rank risk factors for progression:

- **Very high:** HIV (Chapter 21), recent contact with infectious TB, and silicosis.
- **High:** stage 4 or 5 chronic kidney disease (Chapter 27); transplant; immunosuppressing drugs such as tumour necrosis factor (TNF) inhibitors or corticosteroids; some cancers; and fibronodular scarring on chest X-ray.
- **Moderate:** diabetes (Chapter 22), heavy alcohol use and heavy smoking (Campbell et al., 2022).

Young children are also at high risk (Long et al., 2022). Table 13.3 compares the two states.

Table 13.3 TB infection and TB disease compared (Canadian Tuberculosis Standards, 8th edition; original wording)

Feature	TB infection	TB disease
What the bacteria are doing	Alive but held in check by the immune system	Multiplying and damaging tissue, most often the lungs
How the person feels	Well; no symptoms	Usually unwell: cough, fever, night sweats, weight loss, fatigue
Can the person spread TB?	No	Yes, when TB is in the lungs or larynx, especially with cough, cavities or a positive smear
Skin test or blood test	Usually positive	Usually positive, but a negative result does not rule out disease
Chest X-ray	Usually normal, or old scarring only	Often abnormal; X-ray alone cannot confirm TB
Sputum smear and culture	Negative, or not needed	Culture grows M. tuberculosis; smear may be positive
Treatment	Preventive treatment with one or two drugs for months	Several drugs together for at least 6 months
Public health	Reporting rules vary by province or territory	Reportable in every Canadian jurisdiction; contacts are traced

TB in Canada

In 2023, Canada reported 2,217 cases of TB disease, a rate of 5.5 per 100,000 population, up from 4.6 per 100,000 in 2014; men aged 65 and older had the highest rate of any age and sex group, at 8.2 per 100,000 (PHAC, 2025). Surveillance data for 2024 show the same sharp gaps. People born outside Canada accounted for 82.9% of people with TB disease, and incidence was 186.9 per 100,000 among Inuit, 13.5 among First Nations, 1.3 among Métis and 0.4 among non-Indigenous people born in Canada (PHAC, 2026b). First Nations data belong to First Nations under the principles of OCAP® (First Nations Information Governance Centre, n.d.; Chapter 2).

These gaps have structural causes, not biological ones. Crowded housing raises the risk both of becoming infected and of progressing to disease (Mounchili et al., 2022). Inuit leaders and the federal government have named poverty, food insecurity and inadequate housing as drivers of TB in Inuit Nunangat (Inuit Tapiriit Kanatami [ITK], 2019), and ITK has said that limits on staffing, accommodation and space for non-local health workers stretch northern resources beyond capacity (ITK, 2025). These conditions grew out of colonial policies; Chapter 2 discusses this history and culturally safe care.

CANADIAN CONTEXT

TB and Inuit-Led Elimination

In December 2018, Inuit Tapiriit Kanatami (ITK), the national organization representing Inuit, released the Inuit Tuberculosis Elimination Framework. It builds on a joint commitment made by Inuit and the Government of Canada in March 2018: to end TB among Inuit across Inuit Nunangat by 2030 and, as an interim step, to cut the reported active TB rate by 50% or more by 2025 (Indigenous Services Canada, 2018).

- **Inuit-led priorities:** the Framework's six areas include reducing poverty and improving social conditions, mobilizing communities and developing Inuit-specific solutions. Each of the four Inuit regions wrote its own action plan, with community-wide screening, regional TB committees and education (ITK, 2019).
- **Where things stand:** in March 2025, ITK reported that TB incidence among Inuit in Inuit Nunangat had climbed from 182.9 (2016) to 268.6 (2023) per 100,000 people, and that the rate among Inuit living in Inuit Nunangat is 300 times the rate among non-Indigenous people born in Canada. ITK said the 2025 milestone would not be met, noted that pandemic priorities had pulled attention away from TB work, and asked Canada and the federal parties seeking to form government to identify the funding needed to reach the 2030 goal (ITK, 2025). These ITK figures describe Inuit in Inuit Nunangat; the PHAC rate in section 13.4 (186.9 per 100,000 in 2024) describes Inuit across Canada.
- **Signs of progress:** in March 2026, the Government of Nunavut and Nunavut Tunngavik Inc. (NTI) reaffirmed their shared aim of a Nunavut free of TB by 2030. They reported that fewer people in Nunavut have had active TB in recent years, partly because more people are being screened and treated for TB infection ("sleeping TB"). NTI has funded hamlets to lead local responses to outbreaks, and both partners named housing, food security and health care access as part of the work (Government of Nunavut, 2026).

Recognizing TB

TB disease in the lungs usually develops slowly. Common symptoms are a cough that lasts for weeks (public health guidance uses three weeks or more), sputum, coughing up blood (**hemoptysis**), fever, night sweats, loss of appetite, weight loss, fatigue and chest pain (Windsor-Essex County Health Unit, 2024). Some people have few respiratory symptoms (B. L. Johnston et al., 2022).

The Standards advise considering TB in anyone with subacute or chronic respiratory symptoms, even if a different cause seems more probable (B. L. Johnston et al., 2022). The nurse asks about birth in or travel to places where TB is common; contact with TB; past TB or TB treatment; shelters or crowded housing; the risk factors above; and the date the cough began, which public health uses to set the infectious period (Rea et al., 2022). A weeks-long cough plus one of these factors is a cue to mask the patient and start airborne precautions while TB is ruled out.

Testing

Two tests show whether a person has been infected:

- **Tuberculin skin test (TST):** purified protein derivative is injected into the skin of the inner forearm. A trained nurse measures the induration (firm swelling) 48 to 72 hours later in millimetres. Bacille Calmette-Guérin (BCG) vaccine can cause a false-positive result (Campbell et al., 2022).

- **Interferon-gamma release assay (IGRA):** a blood test that measures interferon-gamma released by T cells exposed to proteins specific to *M. tuberculosis*. BCG does not affect it. It is preferred for people who had BCG after infancy or are unlikely to return for a TST reading (Campbell et al., 2022).

A positive result on either test does not show whether the person has TB infection or TB disease (Campbell et al., 2022). A positive result is followed by a symptom review and a chest X-ray (Windsor-Essex County Health Unit, 2024).

Figure 13.4 A room pressure monitor beside a negative-pressure isolation room. The green "normal" display shows that air is flowing into the room; the nurse checks it as policy directs and reports an alarm. (credit: “Joondalup Hospital negative pressure room” by Orderinchaos/Wikimedia Commons, CC BY-SA 4.0)

Diagnosing TB disease relies on sputum. At least three specimens are collected; the Standards recommend collecting them on one day, spaced at least 1 hour apart (Behr et al., 2022). Each is tested by:

- **Smear microscopy:** a stain looks for acid-fast bacilli. It is fast but misses many cases, and other mycobacteria also stain positive.
- **Culture:** the reference standard; results take 2 to 8 weeks. Drug susceptibility testing is done on the first positive culture.
- **Nucleic acid amplification test (NAAT):** detects the genetic material of *M. tuberculosis* much faster than culture, and some NAATs can flag rifampin resistance. A negative NAAT alone does not rule out TB (Behr et al., 2022).

A chest X-ray is part of every work-up, but it cannot confirm TB on its own (Behr et al., 2022).

The nurse teaches the patient to cough deeply and bring up sputum from the lungs, not saliva. When a patient cannot, sputum may be induced with nebulized 3% hypertonic saline (Behr et al., 2022). Induction creates infectious aerosols, so it is done in an airborne infection isolation room or a sputum booth that meets the same ventilation standard (B. L. Johnston et al., 2022), following employer policy.

Airborne Precautions

Airborne precautions are taught in full in Chapter 4. For TB, the Standards call for:

- an **airborne infection isolation room (AIIR)**, a single room under negative pressure so that air flows in from the hallway and is exhausted outdoors or filtered, with at least 12 air changes per hour; airflow is checked daily while the room is in use (Figure 13.4);
- a Health Canada-approved, fit-tested **N95 respirator** (or equivalent) for every health care worker who provides care to, transports or is in direct contact with the patient;
- a medical mask on the patient whenever they leave the AIIR (B. L. Johnston et al., 2022).

For suspected TB, precautions can stop after three consecutive negative sputum smears and another diagnosis that explains the illness. Confirmed TB that is not rifampin resistant needs clinical improvement and at least 2 weeks of effective treatment, plus three consecutive negative smears if the smear was positive. Rifampin-resistant TB needs at least 4 weeks of effective treatment, clinical improvement and further criteria, including susceptibility results and negative smears (B. L. Johnston et al., 2022).

CLINICAL SAFETY

Airborne Isolation and N95 Fit

- **Mask the patient first.** A patient with a weeks-long cough and TB risk factors wears a medical mask from triage onward and is moved to an AIIR as soon as possible (B. L. Johnston et al., 2022).
- **Wear the respirator you were fitted for.** Fit testing matches a person to a specific make, model and size of N95. A different model may not seal (B. L. Johnston et al., 2022) (Figure 13.5).
- **Seal check every time.** The nurse performs a user seal check each time the respirator goes on (B. L. Johnston et al., 2022).
- **Keep the room working.** The door stays closed and the airflow indicator is checked per policy. If the room is not under negative pressure, the nurse reports it at once (Chapter 4).
- **Plan transport.** The receiving department is told in advance, the patient wears a medical mask and staff wear N95s (B. L. Johnston et al., 2022).

Treatment and Adherence

TB infection. Treating TB infection prevents disease. The Standards recommend either 4 months of daily rifampin or 12 once-weekly doses of isoniazid with rifapentine; 9 months, or if needed 6 months, of daily isoniazid is the alternative when rifamycins cannot be used (Alvarez et al., 2022). Health Canada has not approved rifapentine (Alvarez et al., 2022). Instead, it appears on Health Canada's List of Drugs for an Urgent Public Health Need for treating TB infection, together with isoniazid, in people at high risk of progression. The Public Health Agency of Canada notified Health Canada on November 28, 2025, for use in all jurisdictions; this kind of notification lets a listed drug be brought into Canada and sold in the notifying jurisdiction for 1 year (Health Canada, 2026). The weekly regimen is generally given as directly observed therapy (Alvarez et al., 2022).

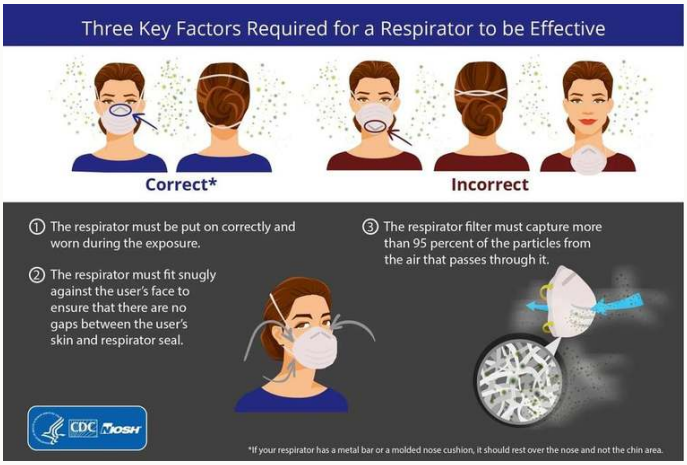

Figure 13.5 Three things an N95 respirator needs to protect the wearer: it is put on and worn correctly, it seals snugly against the face, and its filter captures more than 95% of particles. (credit: "Three Key Factors Required for a Respirator to be Effective" by Centers for Disease Control and Prevention/NIOSH, public domain)

Drug-susceptible TB disease. Standard treatment has two phases. In the first 2 months, the patient takes isoniazid, rifampin, pyrazinamide and ethambutol daily; ethambutol can stop once tests show the strain is fully susceptible. For the next 4 months, the patient takes isoniazid and rifampin. Some people need a longer continuation phase (J. C. Johnston et al., 2022). Sputum is tested regularly until it turns negative.

Supporting adherence. Missed or erratic doses can lead to treatment failure and drug resistance (Brode et al., 2022). In **directly observed therapy (DOT)**, a trained person watches the patient take each dose. The Standards recommend DOT for intermittent regimens and higher-risk groups, decided with the patient, and favour DOT in the community; video-observed therapy may be an option. Care is patient-centred: professional interpreters, non-stigmatizing language and practical supports such as reminders, home visits, blister packs and transportation (J. C. Johnston et al., 2022). In Ontario, TB drugs are free to the patient (Ontario Ministry of Health, 2025). Baseline and monthly monitoring includes liver tests, blood counts, weight and, with ethambutol, vision (J. C. Johnston et al., 2022).

Drug-resistant TB. Multidrug-resistant TB (MDR-TB) is resistant to at least isoniazid and rifampin. Resistance can be acquired through inadequate treatment or missed doses, or a person can be infected with a resistant strain (Brode et al., 2022). In 2023, 1.6% of tested samples in Canada were MDR-TB (PHAC, 2025). Treatment uses several second-line drugs for many months under an experienced team, with DOT (Brode et al., 2022).

Reporting and contact tracing. TB disease is reportable in every Canadian jurisdiction (Rea et al., 2022). In Ontario, nurses, physicians, pharmacists and others have a duty to report under the *Health Protection and Promotion Act*. Within 24 hours of being notified, the board of health contacts the person with suspected or confirmed respiratory TB, directs respiratory isolation, identifies

high-priority contacts within 48 hours and provides DOT (Ontario Ministry of Health, 2025). Contacts are tested in widening circles, starting with the household (Rea et al., 2022). The nurse reassures patients that public health protects their privacy (Chapter 1).

MEDICATIONS

Drugs for TB

Drugs are always given in combination for TB disease; never as a single drug.

- **Isoniazid:** can injure the liver and cause peripheral neuropathy. Pyridoxine (vitamin B6) is added for people at risk, such as those with diabetes, kidney disease, HIV, malnutrition or substance use, and during pregnancy (J. C. Johnston et al., 2022).
- **Rifampin:** can turn urine, saliva, sweat, tears and other body fluids red or orange and can permanently stain soft contact lenses (Valeant Canada, 2019). It speeds the breakdown of many drugs, such as warfarin, methadone and phenytoin. The Standards advise monitoring these interactions early (within 1 to 2 weeks of starting rifampin) and again after it stops, because the effect wears off over about 2 weeks (J. C. Johnston et al., 2022). It can make estrogen-containing hormonal contraceptives less effective (Valeant Canada, 2019).
- **Pyrazinamide:** a common cause of liver injury (J. C. Johnston et al., 2022).
- **Ethambutol:** can damage the optic nerve. Vision and colour vision are tested at baseline and monthly (J. C. Johnston et al., 2022).
- **Rifapentine with isoniazid (weekly):** may cause a flu-like reaction (Alvarez et al., 2022).

Teach: report yellow skin or eyes, dark urine, nausea, abdominal pain, rash, numbness or tingling, or any change in vision; ask before taking any new drug; do not stop early.

13.5 Lung Cancer

Lung cancer is the leading cause of cancer death in Canada. This section covers its causes, main types, recognition and treatment, and the nursing care that helps people live as well as possible through it. Cancer biology, staging, screening and cancer treatments in general are in Chapter 9; palliative care is in Chapter 10.

Lung Cancer in Canada

An estimated 32,900 people in Canada will be diagnosed with lung cancer in 2026, and 19,300 will die of it. It is the most commonly diagnosed cancer (excluding non-melanoma skin cancer) and accounts for about 22% of all cancer deaths, more than any other cancer in men or women. Incidence has fallen in men since the early 1990s and in women since 2016, and death rates are now falling in both sexes; differences between men and women in these trends likely reflect past patterns of tobacco use (Brenner et al., 2026; Canadian Cancer Society, 2026).

Smoking is the leading cause of lung cancer (Health Canada, 2024). Other risk factors include second-hand smoke; work exposures such as asbestos, arsenic, chromium, beryllium and nickel; radiation to the chest; air pollution; a family history of lung cancer; HIV infection; and increasing age (PDQ Adult Treatment Editorial Board, 2025a).

Radon is a radioactive gas, with no colour or smell, released when uranium in soil and rock breaks down (Figure 13.6). It can build up in homes (Health Canada, 2018). Radon is the second leading cause of lung cancer in Canada after smoking and the leading cause in people who don't smoke; it accounts for an estimated 16% of lung cancer deaths. At Health Canada's guideline level, the estimated lifetime risk of lung cancer from radon is about 2% for people who don't smoke but about 17% for people who smoke (Health Canada, 2024). Health Canada recommends a long-term radon test of at least 3 months, ideally in fall or winter, and action to lower levels above the Canadian guideline of 200 becquerels per cubic metre as soon as possible (Health Canada, 2018). Nurses can include radon testing in patient teaching.

Lung cancer also occurs in people who have never smoked; the gene changes that guide targeted therapy (see the Going Deeper box) are more common in this group (PDQ Adult Treatment Editorial Board, 2025a). Every patient deserves care free of blame. Data on lung cancer among First Nations, Inuit and Métis Peoples are best drawn from Indigenous-governed sources, and First Nations data are used under OCAP® (Chapter 2).

Types and Spread

Lung cancers are grouped by how the cells look under the microscope:

- **Non-small cell lung cancer (NSCLC):** any lung cancer other than small cell. Adenocarcinoma (about 40% of lung cancers) is now the most common type and usually starts in the outer lung. Squamous cell carcinoma (about 25%) usually arises in the large central airways and is strongly linked with smoking. Large cell carcinoma makes up about 10% (PDQ Adult Treatment Editorial Board, 2025a).
- **Small cell lung cancer (SCLC):** about 15% of lung cancers. It grows quickly and has usually spread by the time it is found; only about 30% of people have limited-stage disease at diagnosis (PDQ Adult Treatment Editorial Board, 2025b).

Figure 13.6 Radon detectors from a home test kit. Because radon has no colour or smell, testing is the only way to know a home's level.

Lung cancer spreads to lymph nodes in the chest and to the brain, bones, liver and adrenal glands. Stage drives treatment; staging is explained in Chapter 9, as is lung cancer screening, including the Ontario Lung Screening Program.

Recognizing and Diagnosing

Early lung cancer often causes no symptoms. When symptoms appear, they include a new or worsening cough, hemoptysis, shortness of breath (dyspnea), chest pain, weight loss and fatigue. Pneumonia that does not resolve, a pleural effusion (section 13.6) or a collapsed lobe may be the first sign. A tumour pressing on nearby structures can cause hoarseness, difficulty swallowing, or swelling of the face and distended neck veins from compression of the superior vena cava. Spread to the brain can cause neurological changes, and spread to bone causes pain (PDQ Adult Treatment Editorial Board, 2025a). Swelling of the face and neck is an oncologic emergency (Chapter 9).

A **paraneoplastic syndrome** is a group of signs caused by substances a tumour releases, not by the tumour's physical presence. NSCLC can release a hormone-like protein (parathyroid hormone–related protein) that raises calcium (hypercalcemia), and it can cause finger clubbing (PDQ Adult Treatment Editorial Board, 2025a). Small cell cancer can cause the syndrome of inappropriate antidiuretic hormone (SIADH) with low sodium, cortisol excess (Cushing syndrome) and nerve and muscle syndromes such as Lambert-Eaton myasthenic syndrome (PDQ Adult Treatment Editorial Board, 2025b). Hypercalcemia and SIADH are explained in Chapters 9 and 23; sodium and calcium imbalances in Chapter 3. New confusion in a patient with lung cancer may be a metabolic cause and needs prompt assessment, not an assumption of delirium (Chapter 8).

Diagnosis begins with a chest X-ray and a computed tomography (CT) scan of the chest with contrast. A positron emission tomography (PET) scan helps show spread. Tissue is needed to confirm the type, through bronchoscopy, a needle biopsy guided by imaging, or sampling of chest lymph nodes (PDQ Adult Treatment Editorial Board, 2025a). Tumour tissue is also tested for biomarkers (see the Going Deeper box). The nurse prepares the patient for each procedure (Chapter 1 for consent), watches for bleeding and pneumothorax afterward (Chapter 15), and supports the patient through a frightening wait for results.

Treatment and Nursing Care

Treatment depends on the type, stage, biomarkers, the person's health and their goals (Table 13.4). Many patients receive more than one treatment.

Surgery offers the best chance of cure for early NSCLC (PDQ Adult Treatment Editorial Board, 2025a). A **lobectomy** removes one lobe; a segmentectomy removes a smaller portion; a pneumonectomy removes a whole lung. The enhanced recovery guideline for lung surgery recommends video-assisted thoracoscopic surgery (VATS), done through small incisions, for early-stage cancer. It also recommends quitting smoking 4 or more weeks before surgery; multimodal pain control including regional anesthesia to reduce

opioid use; getting out of bed within 24 hours; early eating and drinking; and both drug and mechanical prophylaxis against venous thromboembolism (Batchelor et al., 2019).

After lung surgery, the nurse:

- keeps pain controlled so the patient can breathe deeply and cough (Chapter 5);
- coaches deep breathing, coughing and incentive spirometry (Chapter 12) and helps the patient walk early;
- monitors the chest drain for air leak, drainage and function (Chapter 15);
- watches for pneumonia, atelectasis and respiratory failure, and for new atrial fibrillation, which occurs in about 12% of patients after lung resection (Batchelor et al., 2019);
- recognizes and escalates deterioration using early warning scores and SBAR (Chapter 6; postoperative complications in Chapter 7, section 7.6).

Radiation to the chest can inflame the esophagus. Painful or difficult swallowing often lasts several weeks after treatment; care focuses on pain relief and keeping up nutrition and fluids. **Radiation pneumonitis**, inflammation of the lung, usually appears in the first weeks to months after radiation begins, with cough, dyspnea and fever. Severe cases can be fatal (Billiet et al., 2014). Patients are taught to report new or worse breathing symptoms even after treatment ends.

Systemic therapy includes chemotherapy, targeted therapy and immunotherapy (Chapter 9). **Immunotherapy** with immune checkpoint inhibitors releases a brake on T cells so they attack the cancer. These T cells can also attack healthy organs, causing immune-related adverse effects: pneumonitis, colitis, hepatitis, kidney inflammation, skin reactions and hormone disorders such as thyroid and adrenal problems or type 1 diabetes. These effects can appear even after the last dose (Merck Canada, 2019). A patient on immunotherapy who reports new cough, dyspnea or diarrhea needs prompt assessment and a call to the oncology team.

Symptom care. Dyspnea, cough, pain and fatigue are common. The nurse assesses each symptom, gives ordered treatments, positions the patient upright, teaches energy conservation and pacing, and involves the interprofessional team. Coughing up a large amount of blood is an emergency: the nurse stays with the patient, calls for help at once and follows Chapter 6. Palliative care can start at diagnosis, alongside treatment aimed at the cancer (Chapter 10).

Teaching and transitions. Before discharge, the nurse confirms that the patient knows which symptoms to report after radiation or immunotherapy, even weeks later. Patients taking an oral targeted drug at home, such as osimertinib, learn to take it at the same time each day, to swallow tablets whole and to care for their skin and nails (Cancer Care Ontario, 2023). Smoking cessation support continues after surgery (Chapter 14), and the family can be encouraged to test their home for radon. Older adults face a higher risk of atrial fibrillation after lung resection (Batchelor et al., 2019), so the nurse checks pulse rhythm and teaches what palpitations or new dizziness may mean.

Table 13.4 Lung cancer treatments and nursing focus (Batchelor et al., 2019; Billiet et al., 2014; Cancer Care Ontario, 2023; Merck Canada, 2019; original wording)

Treatment	What it involves	Main risks	Nursing focus
Surgery	Removing a segment, lobe or whole lung, often by VATS	Pneumonia, atelectasis, air leak, atrial fibrillation, venous thromboembolism	Pain control, breathing exercises, walking within 24 hours, chest drain checks, early escalation
Radiation	High-energy beams aimed at the tumour over several weeks	Esophagitis with painful swallowing; pneumonitis weeks to months later; fatigue	Swallowing and nutrition, pain relief, teaching to report new cough or dyspnea
Chemotherapy	Drugs that kill dividing cells, often given with radiation or immunotherapy	Low blood counts and infection, nausea, fatigue (Chapter 9)	Infection prevention, symptom control, safe handling of hazardous drugs
Targeted therapy	Oral drugs aimed at a specific gene change in the tumour	Rash, diarrhea, nail and skin changes; rarely lung inflammation or heart effects	Skin care teaching, hydration, reporting new breathlessness, adherence at home

Treatment	What it involves	Main risks	Nursing focus
Immunotherapy	Checkpoint inhibitors that help T cells attack the cancer	Immune attack on lungs, bowel, liver, skin or glands, even after treatment ends	Teaching early reporting, baseline and follow-up assessment, prompt referral

GOING DEEPER

Biomarkers and Targeted Therapy in Lung Cancer

Required for RN students; optional for PN students.

Many NSCLCs, especially adenocarcinomas, carry gene changes that drive their growth. Tumour tissue is tested for these **biomarkers** before treatment is chosen. Changes in the epidermal growth factor receptor (EGFR) gene and rearrangements of the anaplastic lymphoma kinase (ALK) gene are more common in adenocarcinomas of people who never smoked. Other targetable genes include ROS1, BRAF, KRAS, MET, RET, NTRK and HER2 (PDQ Adult Treatment Editorial Board, 2025a). Tumours are also tested for programmed death-ligand 1 (PD-L1), a protein that helps predict benefit from immunotherapy.

Targeted therapy. Osimertinib is an oral EGFR inhibitor used in Ontario for NSCLC with a confirmed EGFR mutation. Common effects are diarrhea, rash, dry skin and nail changes; serious effects include interstitial lung disease (about 4% of patients, median onset about 3 months), QT prolongation, heart muscle weakness and eye inflammation (keratitis). Monitoring includes blood counts, liver and kidney function, electrolytes, an electrocardiogram (ECG) at baseline and heart function (Cancer Care Ontario, 2023).

Immune checkpoint inhibitors. Pembrolizumab, marketed in Canada, blocks the programmed cell death protein 1 (PD-1) receptor on T cells. In its 2026 Canadian monograph, single-drug first-line use covers adults with metastatic NSCLC, or stage III disease when surgery or chemoradiation is not an option, whose tumours express PD-L1 (tumour proportion score of 1% or more) and have no EGFR or ALK change. Suspected immune-related pneumonitis needs imaging and corticosteroids are used for moderate or worse cases (Merck Canada, 2019). Moderate (grade 2) pneumonitis means holding the drug, and severe or recurrent moderate pneumonitis means stopping it for good (Merck Canada, 2026).

Nursing focus. The RN reviews baseline findings and teaches the patient which symptoms to report and how fast. At every contact, the RN asks about new cough, dyspnea, diarrhea, rash, fatigue and eye symptoms, and grades any effect so the oncology team can act. The RN also remembers that oral cancer drugs taken at home are hazardous drugs (Chapter 9).

13.6 Pleural Effusion and Empyema

The pleural space normally holds only a thin film of fluid. This section explains why fluid collects, how thoracentesis removes it and the nursing care around the procedure. Chest tubes and chest drainage are taught in Chapter 15.

Fluid Around the Lung

A **pleural effusion** is an abnormal collection of fluid in the pleural space. Effusions fall into two groups. A **transudate** is thin fluid pushed out by pressure or low protein in the blood; heart failure (Chapter 18) is a common cause, as are cirrhosis and nephrotic syndrome. An **exudate** is protein-rich fluid caused by inflammation or disease of the pleura itself, most often infection or cancer. The laboratory compares protein and lactate dehydrogenase (LDH) in the fluid and the blood to tell them apart (Roberts et al., 2023).

A **parapneumonic effusion** forms next to a pneumonia (sections 13.1 and 13.2). When the fluid becomes infected or frankly purulent, it is called **empyema**. A low fluid pH signals an infection that needs drainage (Roberts et al., 2023). A **malignant pleural effusion** is caused by cancer that involves the pleura, and it often returns after drainage (Roberts et al., 2023).

A large effusion compresses the lung. The patient may report dyspnea, cough or chest discomfort. On assessment, the nurse finds dullness to percussion, reduced or absent breath sounds and reduced chest expansion on the affected side (Chapter 12). Fever, chills and a pneumonia that is not improving suggest empyema. Ultrasound and chest imaging confirm the effusion.

Thoracentesis

Thoracentesis (pleural aspiration) is the removal of pleural fluid with a needle or small catheter (Figure 13.7). A diagnostic tap sends fluid for chemistry, cell counts, cytology and culture; a therapeutic tap relieves dyspnea. Thoracic ultrasound guidance is

mandatory except in an emergency, because it reduces the risk of pneumothorax and organ puncture (Asciak et al., 2023; Roberts et al., 2023).

Before. The nurse confirms that informed consent has been obtained by the practitioner doing the procedure (Chapter 1). The nurse records baseline vital signs, SpO2 and breath sounds, and checks for anticoagulants and antiplatelet drugs; for elective procedures, some are held for a set time beforehand, following policy and the practitioner's orders (Asciak et al., 2023). The patient usually sits upright, leaning forward over a padded bedside table.

During. The nurse helps the patient keep still, gives reassurance and watches the patient's face, breathing and SpO2. Fluid is drained slowly by syringe or gravity, not by wall suction or vacuum bottles. In general, no more than 1.5 L is removed at one time. Drainage stops early, even below that volume, if the patient reports chest tightness or pain, keeps coughing or becomes more breathless (Asciak et al., 2023). The patient may feel faint from a vasovagal response; the nurse watches for pallor, sweating and a falling heart rate or blood pressure.

After. The nurse checks vital signs, SpO2, breath sounds and the puncture site, and labels and sends specimens. A chest X-ray is not routine after an uncomplicated tap, but it is done if symptoms persist, the procedure was complicated or several attempts were needed (Asciak et al., 2023). The nurse acts at once on:

Figure 13.7 A packaged thoracentesis kit: a drainage bag and tubing, syringes, and the needle and catheter used to drain pleural fluid. (credit: "ThoracentesisEquip" by James Heilman, MD/Wikimedia Commons, CC BY-SA 4.0)

- sudden dyspnea, chest pain or falling SpO2, which suggest **pneumothorax**, the most common complication (Asciak et al., 2023; Chapter 15);
- cough, frothy sputum, crackles and hypoxemia, which suggest **re-expansion pulmonary edema**, a rare but potentially fatal complication that usually appears within the first hour (Asciak et al., 2023);
- bleeding, which is uncommon but can be life-threatening (Asciak et al., 2023).

When a Chest Tube or Other Procedure Is Needed

Pleural infection with a pH of 7.2 or less, or frank pus, needs a chest tube; a small-bore tube is used first. If drainage stops while infected fluid remains, medicines to break down clots and thick debris may be instilled into the pleural space, and some patients need surgery, preferably by VATS (Roberts et al., 2023). Antibiotics are given throughout (sections 13.1 and 13.2).

For a malignant effusion that keeps returning, patients without a trapped lung are offered a choice between an **indwelling pleural catheter**, a tunnelled tube that the patient or a family member drains at home, and **pleurodesis**, in which talc is placed in the pleural space to seal it shut. The choice rests with the patient (Roberts et al., 2023). Chest drainage care is in Chapter 15; home and community nursing support is part of planning the transition home.

SCOPE IN PRACTICE

Directly Observed Therapy, Thoracentesis and Reporting

Roles depend on **authority, competence and context** (Chapter 1, section 1.3). Employer policy and the province or territory also shape practice.

- **Thoracentesis:** performed by a physician, or by a nurse practitioner (NP) with the competence to do it where employer policy permits; CNO's practice standard lists performing a procedure below the dermis or a mucous membrane among the controlled

acts NPs are authorized to perform (College of Nurses of Ontario [CNO], 2026). RNs and practical nurses assist, monitor and recognize complications. RNs and RPNs cannot initiate controlled acts in Ontario's public hospitals (Chapter 1).

- **DOT:** in Ontario, the board of health keeps a system for DOT (Ontario Ministry of Health, 2025). Who observes the doses depends on the local program and employer policy.
- **Reporting:** TB is a disease of public health significance in Ontario (Windsor-Essex County Health Unit, 2024), and the duty to report it under the *Health Protection and Promotion Act* applies to nurses as well as physicians, pharmacists and others (Ontario Ministry of Health, 2025). The nurse follows the employer's reporting process, which often involves infection prevention and control.
- **Assignment:** an RPN may care for a patient in airborne isolation or after thoracentesis when the RPN has the competence and the context supports it. Assigning stable patients to RPNs is a common employer practice, not a CNO rule.
- **Deterioration:** every nurse who notices worsening acts at once and escalates (Chapter 6). The RPN consults the RN as the patient's needs change.

PRACTICE STORY

Stopping at the Right Moment

Names and details are fictional; this is a composite story.

Nurse: Mireille Gagnon, RPN. Years in practice: 6. Setting: medical unit, eastern Ontario.

Madame Lucie Thibodeau, 74, has lung adenocarcinoma that has spread to the pleura. She speaks mostly French, and I am one of the few francophone nurses on our unit, so I often take her assignment. That morning she told me, "Je n'arrive plus à respirer quand je marche." Her right side was dull to percussion with almost no breath sounds at the base.

The respirologist came to do a therapeutic thoracentesis with ultrasound at the bedside. My RN colleague, Kofi, was the resource nurse for the procedure and checked that her apixaban had been held as ordered. I explained each step in French, helped her lean over the padded table and stayed in front of her where she could see me.

At about 1.2 L she started to cough, and kept coughing. She squeezed my hand and said her chest felt tight. I said, "Doctor, she has a persistent cough and chest tightness." He stopped the drainage right away.

Afterward I sat her up and checked her every 15 minutes. Her SpO2 was 95% before the procedure. Forty minutes later it was 89%, her respiratory rate was 28 and I heard new fine crackles on the right. She was coughing up thin, pink-tinged sputum. I did not wait to see if it would settle. I called Kofi to the room, and we called the physician together while Kofi started oxygen under the existing order. The team treated her for suspected re-expansion pulmonary edema, and by morning she was back on room air.

Before I left, Madame Thibodeau asked whether she would need "the needle" every week. I told her honestly that I didn't know, and I asked the team to talk with her about an indwelling catheter or pleurodesis, in French, with her daughter present.

Reflect:

1. Which cues told Mireille that this was not simple post-procedure coughing, and why did timing matter?

2. Using authority, competence and context, explain why Mireille consulted the RN and called the physician rather than managing the change alone.

Chapter 13 Summary

Introduction

- Pneumonia was the fourth most common reason for a hospital stay in Canada in 2023–2024, with 66,128 hospitalizations.
- This chapter covers lower respiratory infections, tuberculosis, lung cancer and pleural disease; assessment and oxygen therapy are in Chapter 12.

13.1 Community-Acquired Pneumonia

- Pneumonia fills alveoli with exudate (consolidation), causing hypoxemia; viruses and S. pneumoniae are common causes, and often none is found.
- Risk rises steeply with age and with chronic disease, smoking, substance use, unstable housing and other structural conditions.
- Older adults may present with confusion, falls or loss of function rather than fever; sepsis cues call for immediate escalation.

- Cultures are collected before the first antibiotic dose when this causes no delay; antimicrobial choice follows severity, comorbidities and local resistance.
- Clinical stability guides the IV-to-oral switch and discharge; short courses and allergy assessment are part of stewardship.
- Severity scores such as CURB-65 and PSI support, but do not replace, clinical judgment.

13.2 Hospital-Acquired and Aspiration Pneumonia

- HAP appears 48 hours or more after admission; VAP is covered in Chapter 15.
- HAP organisms are more often resistant, and treatment follows the local antibiogram.
- Oral care, swallowing screens, early mobility, upright positioning and lighter sedation are core nursing prevention measures.
- Aspiration pneumonitis is a chemical injury from stomach contents; aspiration pneumonia is an infection, usually in a person with dysphagia.

13.3 Influenza, COVID-19 and RSV

- All three spread by respiratory particles and contact; in Ontario, they need droplet and contact precautions from the time illness is suspected.
- Complications include viral and bacterial pneumonia, delirium, worsening chronic disease and, after influenza, heart attack and stroke.
- Oseltamivir is first-line for severe influenza regardless of timing; nirmatrelvir–ritonavir is for high-risk adults with mild to moderate COVID-19 within 5 days and has serious drug interactions.
- RSV has no specific antiviral; care is supportive.
- NACI recommends influenza, COVID-19, pneumococcal and RSV vaccines for many adults; eligibility for public funding varies by province.

13.4 Tuberculosis

- TB spreads through airborne droplet nuclei, mostly indoors. TB infection causes no symptoms and is not contagious; TB disease causes illness and can spread.
- In 2023, Canada reported 2,217 TB cases (5.5 per 100,000). In 2024, rates were highest among Inuit, and 82.9% of people with TB disease were born outside Canada. Crowded housing, food insecurity, poverty and colonial history drive these gaps; Inuit-led elimination work targets 2030.
- TST and IGRA detect TB infection but not disease; sputum smear, culture and NAAT, with chest X-ray, diagnose TB disease.
- Suspected pulmonary TB needs an AIIR, fit-tested N95 respirators for staff and a medical mask for the patient outside the room.
- TB infection is treated with 4 months of rifampin or 12 weekly doses of isoniazid and rifapentine; drug-susceptible disease is treated with four drugs for 2 months, then isoniazid and rifampin for 4 months, supported by DOT and patient-centred care.
- TB disease is reportable in every jurisdiction; public health leads contact tracing.

13.5 Lung Cancer

- Lung cancer is the leading cause of cancer death in Canada; an estimated 32,900 people will be diagnosed and 19,300 will die of it in 2026.
- Smoking is the leading cause; radon is the second leading cause and the leading cause in people who never smoked. Health Canada recommends a long-term home radon test.
- NSCLC (mainly adenocarcinoma and squamous cell) is far more common than SCLC, which spreads early and causes paraneoplastic syndromes such as SIADH.
- Surgery, often by VATS, is the main curative option for early NSCLC; nursing care centres on pain control, early mobility, breathing exercises and early detection of complications.
- Radiation, chemotherapy, targeted therapy and immunotherapy each carry distinct risks, including radiation pneumonitis and immune-related pneumonitis, which may appear after treatment ends.

13.6 Pleural Effusion and Empyema

- Transudates usually come from pressure or low protein, as in heart failure; exudates from inflammation, infection or cancer. Empyema is infected pleural fluid.
- Thoracentesis is done under ultrasound guidance; no more than 1.5 L is removed at one time, and drainage stops if chest tightness, pain, persistent cough or worse breathlessness develop.
- After thoracentesis, the nurse watches for pneumothorax, re-expansion pulmonary edema and bleeding.
- Pleural infection with low pH or pus needs a chest tube; recurrent malignant effusion is managed with an indwelling pleural catheter or pleurodesis, by patient choice.

Key Terms (42)

airborne infection isolation room (AIIR): A single room under negative pressure, with air exhausted outdoors or filtered, used for patients with diseases spread by the airborne route.

antimicrobial stewardship: coordinated efforts to use antimicrobials only when needed, with the right drug, dose, route and duration.

antiviral: a drug that stops a virus from multiplying, such as oseltamivir for influenza or nirmatrelvir–ritonavir for COVID-19.

aspiration: the passage of material from the mouth, throat or stomach into the airways.

aspiration pneumonia: a lung infection that follows the breathing in of mouth and throat secretions that carry bacteria, usually in a person with dysphagia.

aspiration pneumonitis: a chemical lung injury caused by breathing in a large volume of stomach contents, usually in a person with reduced consciousness.

atypical bacteria: bacteria such as Legionella that cause pneumonia but need special tests, such as urine antigen tests or selective cultures, to detect.

blood culture: a blood sample placed in culture bottles to detect and identify bacteria or fungi in the bloodstream, collected before the first antibiotic dose when possible.

community-acquired pneumonia (CAP): pneumonia that begins outside hospital, including in long-term care.

consolidation: the filling of alveoli with fluid, cells and debris so that part of the lung becomes solid and airless.

COVID-19: the respiratory illness caused by the SARS-CoV-2 virus.

CURB-65: a five-item pneumonia severity score (confusion, urea, respiratory rate, blood pressure, age 65 or older) that helps decide where a patient should be treated.

directly observed therapy (DOT): A method in which a trained person watches a patient take each dose of medication, used to support completion of TB treatment.

drug-resistant TB: TB caused by bacteria resistant to one or more TB drugs; multidrug-resistant TB is resistant to at least isoniazid and rifampin.

empyema: Infected fluid or pus in the pleural space.

exudate: Protein-rich pleural fluid caused by inflammation or disease of the pleura, such as infection or cancer.

hospital-acquired pneumonia (HAP): pneumonia that was not incubating at admission and appears 48 hours or more after admission.

immunotherapy: Cancer treatment, such as immune checkpoint inhibitors, that helps the immune system attack cancer cells.

influenza: an acute respiratory illness caused by influenza viruses, classically with sudden fever, cough and muscle aches.

interferon-gamma release assay (IGRA): A blood test that detects TB infection by measuring interferon-gamma released by T cells exposed to M. tuberculosis proteins; not affected by BCG vaccine.

lobectomy: Surgical removal of one lobe of a lung.

N95 respirator: A fit-tested respirator that filters small airborne particles, worn by health care workers caring for patients with airborne infections such as TB.

non-small cell lung cancer (NSCLC): The group of lung cancers other than small cell, including adenocarcinoma, squamous cell carcinoma and large cell carcinoma.

nucleic acid amplification test (NAAT): A rapid laboratory test that detects the genetic material of M. tuberculosis in a specimen and can identify rifampin resistance.

paraneoplastic syndrome: Signs and symptoms caused by substances a tumour releases, such as hormones, rather than by the tumour's direct spread.

pleural effusion: An abnormal collection of fluid in the pleural space.

pleuritic chest pain: sharp chest pain that worsens with deep breathing or coughing, caused by inflammation of the pleura.

pneumonia: an acute infection of the lung tissue (alveoli and smallest airways) that causes inflammation and fills air spaces with fluid and cells.

Pneumonia Severity Index (PSI): a pneumonia prediction rule that sorts patients into five risk classes using age, coexisting diseases, vital signs and laboratory values.

post-COVID-19 condition: in the WHO definition, symptoms that continue more than 3 months after SARS-CoV-2 infection, last at least 2 months and have no other explanation.

radon: A colourless, odourless radioactive gas from the breakdown of uranium in soil and rock; the second leading cause of lung cancer in Canada.

re-expansion pulmonary edema: A rare, potentially fatal fluid build-up in a lung that re-expands quickly after removal of pleural fluid or air.

respiratory fluoroquinolone: a fluoroquinolone antibiotic, such as levofloxacin or moxifloxacin, that is active against the common bacterial causes of pneumonia.

respiratory syncytial virus (RSV): a common respiratory virus that can cause severe lower respiratory tract disease in older adults and people with chronic conditions.

small cell lung cancer (SCLC): A fast-growing lung cancer, about 15% of cases, that has usually spread by the time it is diagnosed.

TB disease: Active illness from M. tuberculosis multiplying in the body; TB disease in the lungs or larynx can spread to others.

TB infection: A state in which M. tuberculosis is alive but held in check by the immune system; the person has no symptoms and cannot spread TB (formerly called latent TB infection).

thoracentesis: Removal of fluid from the pleural space with a needle or small catheter, for diagnosis or relief of symptoms.

transudate: Low-protein pleural fluid caused by pressure or low blood protein, as in heart failure.

tuberculin skin test (TST): A test in which purified protein derivative is injected into the skin and the induration is measured 48 to 72 hours later to detect TB infection.

tuberculosis (TB): An infection caused by Mycobacterium tuberculosis that spreads through the air and most often affects the lungs.

ventilator-associated pneumonia (VAP): pneumonia that develops more than 48 hours after endotracheal intubation.

Licensure Review & Clinical Judgment Questions (35)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Lucille Arsenault (Questions 1–4): Lucille Arsenault, 82, lives alone in a seniors' apartment in Belleville, Ontario. Her son brought her to the emergency department because she fell twice yesterday and "isn't herself." A chest X-ray shows a new right lower lobe infiltrate, and she is admitted to a medical unit with community-acquired pneumonia. Her temperature is 37.4 °C, heart rate 104 beats/min, respiratory rate 26 breaths/min, blood pressure 118/70 mm Hg and SpO2 91% on room air. An RPN is caring for her, with an RN on the team.

1. [CORE] Mrs. Arsenault's son says, "It can't be pneumonia. She doesn't even have a fever." Which response by the nurse is most accurate?

a. "In older adults, pneumonia often shows up as confusion or falls, and the temperature may be only slightly raised."

b. "A temperature of 37.4 °C means the infection is viral rather than bacterial, so she will not need any antibiotics."

c. "The X-ray result is probably an error, because pneumonia in any adult always causes a high fever."

d. "Her temperature will go up once the antibiotic starts to work."

Answer: a — Older adults often present with confusion, falls or loss of function, and fever may be mild or absent (a) (section 13.1, Lifespan Considerations box). Temperature does not tell a viral cause from a bacterial one (b). Pneumonia does not always cause a high fever, and the infiltrate on imaging supports the diagnosis (c). Antibiotics treat the infection; they do not raise the temperature (d).

2. [CORE] The prescriber orders two sets of blood cultures and a first dose of IV ceftriaxone for Mrs. Arsenault. The antibiotic has arrived on the unit, and the person who draws the cultures can come in 10 minutes. What should the nurse do?

a. Give the antibiotic now and have the cultures drawn on the morning blood rounds

b. Ask the prescriber to cancel the cultures, since the antibiotic is ready

c. Have the cultures drawn in the next few minutes, then give the antibiotic right away

d. Hold the antibiotic until a sputum specimen is also obtained, however long that takes

Answer: c — Cultures are collected before the first dose when this can be done quickly, because antibiotics can sterilize specimens (c) (section 13.1; Chapter 4, section 4.5). Drawing cultures the next morning, after the antibiotic, lowers their yield (a). Cancelling ordered cultures is not the nurse's decision, and it gives up useful information (b). The dose is not delayed indefinitely for a sputum specimen that may be hard to obtain (d).

3. [CORE] At 0300 on day 2, Mrs. Arsenault's respiratory rate is 30 breaths/min, blood pressure 94/58 mm Hg and SpO2 88% on 2 L/min oxygen. She no longer follows simple commands. Which action should the RPN take first?

a. Recheck her vital signs in 1 hour so the trend can be confirmed before anyone is called

b. Give the as-needed sedative that is ordered for agitation so that she can rest

c. Record the findings in detail and report them to the RN and prescriber at morning rounds

d. Stay with her, raise the oxygen within the ordered range and escalate now

Answer: d — Rapid breathing, falling blood pressure, hypoxemia and new confusion suggest sepsis and worsening respiratory status. Any nurse acts at once and escalates, and the RPN involves the RN and the rapid response pathway as policy directs (d) (section 13.1, Clinical Judgment box; Chapter 6). Waiting an hour (a) or until rounds (c) delays care. A sedative could mask confusion and depress breathing (b).

4. [CORE] Mrs. Arsenault is ready for discharge. Which statement shows that she understands the teaching?

a. "I will stop my antibiotic as soon as I feel better."

b. "I will ask my pharmacist which pneumonia and RSV vaccines I am due for."

c. "I will need a chest X-ray every month for the next year to check my lungs."

d. "I should stay in bed for two weeks to let my lungs rest."

Answer: b — At 82, she is in the age groups for which NACI recommends pneumococcal and RSV vaccines, so checking her vaccine status is appropriate (b) (section 13.3, Patient Education box). The course is taken as prescribed (a). A routine follow-up chest X-ray is not recommended after recovery (c). Bed rest causes deconditioning; gradual activity is encouraged (d).

5. [CORE] Why does a patient with lobar pneumonia develop hypoxemia?

a. Inflammation narrows the trachea and blocks the flow of air to both lungs.

b. Blood flows past alveoli filled with fluid and cells, so it does not pick up oxygen.

c. Fever lowers the amount of hemoglobin available to carry oxygen in the blood.

d. The infection stops the respiratory centre in the brainstem from triggering breaths.

Answer: b — In consolidation, alveoli fill with exudate, so blood passing them leaves the lung without picking up oxygen (b) (section 13.1; Chapter 12, section 12.1). Pneumonia affects the lung tissue, not the trachea (a). Fever does not lower hemoglobin (c). The drive to breathe usually increases, which is why the respiratory rate rises (d).

6. [CORE] Before the first dose of amoxicillin, a patient with community-acquired pneumonia says, "I'm allergic to penicillin. It gave me an upset stomach once." What should the nurse do?

a. Give the amoxicillin as ordered, because an upset stomach is a side effect rather than a true allergy

b. Remove the penicillin allergy from the health record, since the reaction was not an allergy

c. Hold all antibiotics until an allergist can see the patient and test for penicillin allergy

d. Record the exact reaction and discuss it with the prescriber or pharmacist before the dose

Answer: d — The nurse documents what actually happened and shares it, so the prescriber or pharmacist can assess the label (d) (section 13.1; Chapter 4, section 4.5). Stomach upset is usually a side effect rather than an allergy, but the nurse does not give a drug against a recorded allergy without that review (a), and does not remove a label alone (b). Waiting for an allergist would delay treatment that the team can usually arrange safely (c).

7. [CORE] Which nursing actions help prevent hospital-acquired pneumonia in a patient on a medical unit who is not on a ventilator? Select all that apply.

a. Brushing the patient's teeth and gums on a regular schedule

b. Keeping the patient lying flat in bed to conserve energy

c. Screening swallowing before the first oral intake after a stroke

d. Helping the patient sit up and walk as soon as it is safe

e. Using a chlorhexidine mouth rinse for every patient on the unit

f. Keeping the head of the bed raised during tube feeding

Answer: a, c, d, f — Oral care (a), swallowing screens (c), early mobility (d) and an upright position during tube feeding (f) are prevention measures supported by studies (section 13.2). Lying flat (b) increases the risk of aspiration and deconditioning. Routine chlorhexidine oral care is not recommended even for ventilated patients; toothbrushing is the recommended practice (e).

8. [CORE] Which patient's pneumonia is classified as hospital-acquired?

a. A patient admitted for a hip fracture who develops pneumonia on day 4 of the stay

b. A long-term care resident admitted with pneumonia that began 2 days before transfer

c. A patient admitted with fever and cough that started at home the day before

d. A patient who develops pneumonia on day 3 of mechanical ventilation in critical care

Answer: a — HAP was not incubating at admission and appears 48 hours or more after admission (a) (section 13.2). Pneumonia that starts in long-term care is managed as community-acquired (b). Symptoms that began at home before admission point to CAP (c). Pneumonia that starts more than 48 hours after intubation is ventilator-associated pneumonia (d).

9. [CORE] A drowsy patient vomits while lying flat after receiving a sedative. Within 2 hours, the patient's SpO2 falls and crackles are heard. Which statement about this problem is accurate?

a. It is caused by bacteria from the mouth and always needs antibiotics that cover anaerobic organisms.

b. It occurs only in patients with dysphagia from a stroke.

c. It is most likely a chemical injury from stomach contents, which may settle within about 48 hours.

d. It can be ruled out because the event was witnessed.

Answer: c — A witnessed episode of vomiting in a person with reduced consciousness, followed by rapid hypoxemia, suggests aspiration pneumonitis. This is a chemical injury that may settle within about 48 hours with supportive care (c) (section 13.2). The cause is chemical, not bacterial, and the ATS/IDSA guideline suggests not adding routine anaerobic coverage unless abscess or empyema is suspected (a). Reduced consciousness, not only stroke, is a risk factor (b). Pneumonitis is often witnessed (d).

10. [CORE] A patient admitted to an Ontario hospital with a cough and fever is suspected of having influenza. Which precautions should the nurse use while the test result is pending?

a. Airborne precautions in a negative-pressure room, with an N95 respirator only

b. Droplet and contact precautions in a single room, with gown, gloves, mask and eye protection

c. Routine practices only, until a positive laboratory test result confirms that the patient has influenza

d. Contact precautions only, with gown and gloves

Answer: b — Ontario guidance lists influenza, RSV and COVID-19 under droplet and contact precautions, which start when infection is suspected (b) (section 13.3; Chapter 4, section 4.3). Airborne precautions (a) are for infections such as tuberculosis and measles. Waiting for the test (c) allows spread. Contact precautions alone (d) do not protect against droplets.

11. [CORE] An adult who takes several heart medications is prescribed nirmatrelvir–ritonavir for COVID-19. What is the nurse's most important action before the first dose?

a. Make sure the prescriber or pharmacist has reviewed a full medication list, including natural health products

b. Give the first dose right away, because drug interactions only begin after several days of combined treatment

c. Tell the patient to stop taking all heart medications for the 5 days of antiviral treatment

d. Ask the patient to take the heart medications 2 hours apart from the antiviral to avoid interactions

Answer: a — Ritonavir strongly inhibits CYP3A4, and the monograph warns of serious interactions, including with some antiarrhythmics, statins and anticoagulants. A full medication review comes first (a) (section 13.3). Interactions can occur from the first dose (b). Stopping drugs without an order is unsafe and outside the nurse's authority (c). Spacing doses a few hours apart does not prevent this kind of interaction, which happens in the liver while ritonavir is in the body (d).

12. [CORE] An adult is admitted with severe influenza 4 days after symptoms began, and the test result is pending. Oseltamivir is ordered. Which statement reflects Ontario Health guidance?

a. Oseltamivir offers no benefit once 48 hours have passed since symptoms began, so the nurse should question the order.

b. The dose should wait until the influenza test is positive.

c. Oseltamivir is used only for patients who have no chronic conditions.

d. Oseltamivir is recommended for severe influenza no matter how long symptoms have been present.

Answer: d — For severe or worsening influenza, oseltamivir is first-line regardless of time since symptom onset (d) (section 13.3). The 48-hour window applies to milder illness (a). Treatment does not wait for test results when influenza is circulating (b). Chronic conditions increase, rather than rule out, the need for treatment (c).

13. [CORE] A 78-year-old with no chronic health conditions asks which vaccines are recommended. Which statement is accurate according to NACI?

a. Influenza vaccine is recommended only for people with lung disease.

b. RSV vaccine is recommended only for residents of long-term care homes.

c. One dose of an RSV vaccine is recommended for all adults 75 and older.

d. Pneumococcal vaccine is not recommended after age 75.

Answer: c — NACI recommends that all adults 75 and older receive one dose of an RSV vaccine (c) (section 13.3, Patient Education box). Influenza vaccine is recommended every year for everyone 6 months and older (a). RSV vaccine is not limited to long-term care residents (b). Pneumococcal vaccine is recommended for all adults 65 and older, with no upper age limit (d).

14. [CORE] An RPN is caring for a patient with pneumonia whose condition has been stable. The patient now has a rising oxygen need and new confusion. Which action best reflects scope of practice?

a. Continue caring for the patient without involving others, since the patient was assigned to the RPN

b. Meet immediate safety needs, consult the RN and escalate as hospital policy directs

c. Hand the patient's care over to the RN and leave the bedside to care for other patients

d. Wait for the prescriber's morning rounds before sharing the new findings with anyone

Answer: b — Any nurse who notices deterioration acts at once and escalates. As the patient's needs change, the RPN consults the RN, based on authority, competence and the practice context, including employer policy, which can differ by province or territory (b) (section 13.1; Chapter 1, section 1.3). Continuing alone ignores the change in the patient's needs (a). Stepping away abandons a deteriorating patient (c). Waiting for rounds delays care (d).

15. [CORE] A patient had COVID-19 four months ago and still has fatigue and shortness of breath. Testing has found no other cause. Which statement fits the definition of post-COVID-19 condition?

a. The diagnosis requires a positive COVID-19 test within the past week to confirm active infection.

b. Any symptoms that last up to 4 weeks after infection and then resolve fully fit the definition.

c. The condition affects only people whose COVID-19 was severe enough to need hospital care.

d. Symptoms continue more than 3 months after infection, last 2 months or more and have no other explanation.

Answer: d — The WHO definition requires symptoms more than 3 months after infection, lasting at least 2 months and not explained by another diagnosis (d) (section 13.3). A current positive test is not required (a). Symptoms that resolve within 4 weeks do not fit the definition (b). The condition is not limited to people who were admitted to hospital (c).

16. [RN] A 70-year-old with community-acquired pneumonia is newly confused. Results show urea 8.4 mmol/L, respiratory rate 24 breaths/min and blood pressure 104/66 mm Hg. What is the patient's CURB-65 score, and what does it suggest?

a. 2; a low-risk group, so the patient is suitable for treatment at home without admission

b. 4; a very high-risk group in which death is expected

c. 3; a higher-risk group in which 30-day mortality rose sharply in the original study

d. 1; the patient's age is the only CURB-65 criterion that is met

Answer: c — The patient scores 1 point each for confusion, urea above 7 mmol/L and age 65 or older, for a total of 3. In the derivation study, 30-day mortality rose to 17% at a score of 3 (c) (section 13.1, Going Deeper box). The respiratory rate (under 30) and blood pressure (systolic 90 or higher, diastolic over 60) do not score, so 4 is wrong (b), and the low scores in a and d leave out criteria that are met. No score predicts death for an individual.

17. [RN] Which statement about pneumonia severity scores is accurate?

a. The ATS/IDSA guideline prefers the Pneumonia Severity Index and uses it together with clinical judgment.

b. A CURB-65 score of 0 means the patient can always be safely treated at home, whatever else is found.

c. CURB-65 includes the SpO2, so it fully captures how hypoxemic the patient is.

d. Once a severity score has been calculated, it replaces the nurse's ongoing reassessment of the patient.

Answer: a — The guideline recommends a validated rule alongside clinical judgment and prefers PSI over CURB-65 (a) (section 13.1, Going Deeper box). A patient with a score of 0 may still need admission for hypoxemia, inability to take oral drugs or no safe place to recover (b). CURB-65 does not include oxygenation (c). Scores support decisions but do not replace reassessment (d).

Case: Mr. Teodoro Reyes (Questions 18–23): Mr. Teodoro Reyes, 58, moved to Belleville from the Philippines 3 years ago and works as a cook. He has type 2 diabetes. He comes to the emergency department with a cough for 5 weeks, now producing sputum with streaks of blood, night sweats, and a 6 kg weight loss. His temperature is 38.1 °C, heart rate 98, respiratory rate 22 and SpO2 95% on room air. He lives with his wife, two adult children and a grandchild aged 3. A chest X-ray shows a cavity in the right upper lobe. He is admitted to a medical unit.

18. [CORE] The nurse reviews Mr. Reyes's history and assessment. Which group of findings most strongly suggests active pulmonary TB?

a. Fever of 38.1 °C, heart rate 98 and type 2 diabetes

b. Cough for 5 weeks, blood-streaked sputum, night sweats and weight loss

c. Respiratory rate 22, SpO2 95% and work as a cook

d. Recent arrival in Canada, a large household and work in a busy kitchen

Answer: b — A weeks-long cough with hemoptysis, night sweats and weight loss is the classic pattern of pulmonary TB disease (section 13.4, Recognizing TB). Option a lists a nonspecific fever and tachycardia plus a risk factor, not symptoms of TB. Option c includes mild abnormalities that many lung conditions share, and his job is not a TB risk. Option d lists background and risk information, not symptoms; birth in a country where TB is common raises suspicion, and household size matters for contact tracing, but neither shows that he is ill with TB.

19. [CORE] Which finding suggests that Mr. Reyes is likely to be highly infectious?

a. His type 2 diabetes, which raises his TB risk

b. His temperature of 38.1 °C

c. His SpO2 of 95%

d. The cavity in his right upper lobe

Answer: d — Cavities and upper-lobe disease, along with frequent cough and a positive smear, make a person more infectious (section 13.4, How TB Develops). Diabetes (option a) raises his risk of developing TB disease but does not change how infectious he is. Fever (option b) reflects illness, not the number of bacteria he releases. An SpO2 of 95% (option c) describes his oxygenation, not his infectiousness.

20. [CORE] Mr. Reyes arrives on the unit. What is the nurse's priority?

a. Place him in an airborne infection isolation room with the door closed.

b. Collect a first sputum specimen at the nursing station.

c. Ask his family to wear medical masks while visiting in a shared room.

d. Start droplet precautions in a shared room until the first sputum smear result is known.

Answer: a — TB spreads through droplet nuclei that stay in the air, so a patient with suspected pulmonary TB needs an AIIR under negative pressure at once (section 13.4, Airborne Precautions). Collecting sputum at the station (option b) exposes others. A shared room with masked visitors (option c) does not stop airborne spread. Droplet precautions in a shared room (option d) are the wrong category for TB; the particles are small enough to travel on air currents.

21. [CORE] The physician orders sputum for acid-fast bacilli smear, culture and nucleic acid amplification testing. Which plan best fits the Canadian Tuberculosis Standards?

a. Collect one specimen now; if the smear is negative, TB is ruled out.

b. Collect three specimens, each at least 24 hours apart, from saliva if needed.

c. Collect three or more specimens; same-day collection 1 hour apart is acceptable.

d. Collect one specimen by sputum induction at the bedside, with the room door left open for airflow.

Answer: c — The Standards call for at least three specimens and recommend collecting them on one day, spaced at least 1 hour apart (section 13.4, Testing). A single negative smear (option a) cannot rule out TB, because smear microscopy misses many cases. Saliva (option b) is not a useful specimen; the patient must bring up sputum from the lungs. Sputum induction (option d) creates aerosols and must be done in an AIIR or a booth that meets the same standard, never with the door open.

22. [CORE] Before entering Mr. Reyes's room, which action by the nurse is correct?

a. Put on a medical mask and eye protection.

b. Put on the N95 respirator model for which the nurse was fit-tested and do a seal check.

c. Put on any available N95 respirator; fit testing is needed only for aerosol-generating procedures.

d. Enter without a respirator, because he is wearing a medical mask.

Answer: b — Every health care worker caring for a patient with suspected respiratory TB wears a fit-tested N95 (or equivalent) and performs a user seal check each time it goes on (section 13.4, Clinical Safety box). A medical mask (option a) does not filter droplet nuclei. An unfitted model (option c) may not seal; the rule covers all care, not only procedures. The patient wears a medical mask only when outside the AIIR (option d); inside, staff still need respirators.

23. [CORE] Mr. Reyes is diagnosed with drug-susceptible TB and will finish treatment at home with public health support. Which statement shows that he understands his teaching?

a. "Once I feel better and stop coughing, I can stop the pills."

b. "If my urine turns orange, I should stop the rifampin and call the clinic."

c. "I can take the pills whenever I remember, as long as I take most of them."

d. "I need to take all my pills for at least 6 months, even when I feel well."

Answer: d — Drug-susceptible TB needs about 6 months of treatment, and missed or erratic doses can cause treatment failure and drug resistance (section 13.4, Treatment and Adherence). Stopping when symptoms ease (option a) risks relapse. Orange body fluids (option b) are an expected effect of rifampin, not a reason to stop. Erratic dosing (option c) is a known cause of acquired resistance.

24. [CORE] A patient is starting isoniazid, rifampin, pyrazinamide and ethambutol. Which findings should the nurse teach the patient to report promptly? Select all that apply.

a. Yellowing of the skin or eyes

b. Orange-red urine

c. Blurred vision or trouble telling red from green

d. Numbness or tingling in the hands or feet

e. Mild tiredness in the first week

f. A new skin rash

Answer: a, c, d, f — Jaundice (a) can signal liver injury from isoniazid, pyrazinamide or rifampin. Changes in visual acuity or colour vision (c) can signal optic nerve damage from ethambutol. Numbness or tingling (d) suggests isoniazid neuropathy. Rash (f) can occur with all four drugs (section 13.4, Medications box). Orange-red urine (b) is an expected, harmless effect of rifampin; the patient is warned about it but does not need to report it. Mild tiredness early in treatment (e) is common with TB itself and is not a specific drug warning sign, though the nurse still assesses it at follow-up.

25. [CORE] An adult who received the bacille Calmette-Guérin (BCG) vaccine at age 12 needs testing after contact with a person who has TB. The nurse expects which test?

a. A tuberculin skin test read at 24 hours

b. A chest X-ray alone, because BCG makes all TB tests invalid

c. An interferon-gamma release assay

d. A sputum culture, because it detects TB infection

Answer: c — IGRA is not affected by BCG and is preferred for people who received BCG after infancy (section 13.4, Testing). A TST (option a) is read at 48 to 72 hours, and BCG can cause a false-positive result. BCG does not invalidate the IGRA, and a chest X-ray alone (option b) cannot detect TB infection. Sputum culture (option d) detects TB disease, not TB infection, and a person with TB infection usually has no sputum to test.

26. [CORE] A patient who has never smoked asks how she could have lung cancer. Which response by the nurse is accurate?

a. "Radon gas in homes is the leading cause in people who don't smoke."

b. "Lung cancer in people who never smoked is almost always inherited."

c. "Radon testing takes a few hours, so your family can find out quickly."

d. "Air pollution is the leading cause of lung cancer in Canada."

Answer: a — Health Canada identifies radon as the leading cause of lung cancer in people who don't smoke and the second leading cause overall, after smoking (section 13.5, Lung Cancer in Canada). Family history is one risk factor, but option b overstates it. Health Canada recommends a long-term test of at least 3 months (option c). Smoking, not air pollution (option d), is the leading cause.

27. [CORE] A patient is on the surgical unit the morning after a right lower lobectomy by video-assisted thoracoscopic surgery. Which nursing action best supports recovery?

a. Keep the patient on bed rest until the chest tube is removed to protect the incision.

b. Hold pain medication so the patient can cough more forcefully.

c. Restrict oral fluids until bowel sounds return on day 3.

d. Help the patient walk, with pain controlled enough to allow deep breathing.

Answer: d — The enhanced recovery guideline recommends getting out of bed within 24 hours and multimodal pain control, which allows deep breathing and coughing (section 13.5, Treatment and Nursing Care). Bed rest until tube removal (option a) increases the risk of pneumonia, atelectasis and venous thromboembolism. Uncontrolled pain (option b) makes patients breathe shallowly and avoid coughing. The guideline supports early eating and drinking (option c).

28. [CORE] Thirty minutes after an uncomplicated thoracentesis, which finding should the nurse report immediately?

a. A small dry dressing at the puncture site

b. Sudden dyspnea, sharp chest pain and SpO2 falling from 95% to 88%

c. Mild soreness at the puncture site

d. Breath sounds slightly louder on the treated side than before the procedure

Answer: b — Sudden dyspnea, chest pain and falling SpO2 suggest pneumothorax, the most common complication of thoracentesis, and need urgent escalation (section 13.6, Thoracentesis). A dry dressing (option a) and mild soreness (option c) are expected. Breath sounds often improve after fluid is removed (option d), a sign that the lung has re-expanded.

29. [CORE] In an Ontario hospital, a registered practical nurse (RPN) is caring for a patient after thoracentesis. The patient begins coughing frothy sputum, and the SpO2 is falling. What is the RPN's best action?

a. Document the findings and recheck in 1 hour.

b. Wait for the physician's next rounds, since the RPN did not perform the procedure.

c. Stay with the patient, call for help at once and consult the RN.

d. Transfer the assignment to the RN and leave to care for other patients.

Answer: c — Every nurse who notices deterioration acts at once and escalates, and the RPN consults the RN as the patient's needs change (section 13.6, Scope in Practice box). Waiting an hour (option a) or until rounds (option b) delays care for possible re-expansion pulmonary edema. Handing over and leaving (option d) abandons a deteriorating patient; the RPN stays and works with the RN.

30. [CORE] A patient with suspected pulmonary TB must go to the imaging department. Which action is correct?

a. The patient wears a medical mask, and the transporting staff wear fit-tested N95 respirators.

b. The patient wears an N95 respirator, and staff wear no respiratory protection.

c. The patient goes without a mask, because the corridor is well ventilated and the trip is short.

d. The test is cancelled until the sputum culture result returns in several weeks.

Answer: a — Outside the AIIR, the patient wears a medical mask, and staff who transport or care for the patient wear fit-tested N95s (section 13.4, Airborne Precautions). An N95 on the patient (option b) is not the standard, and staff still need protection. Corridor ventilation (option c) does not protect others. Needed tests are not cancelled (option d); they are planned with precautions, and culture can take 2 to 8 weeks.

31. [CORE] A patient with small cell lung cancer has new confusion and a serum sodium of 121 mmol/L. The nurse recognizes this as most consistent with which condition?

a. Radiation pneumonitis

b. Superior vena cava syndrome

c. Hypercalcemia caused by the cancer's spread to bone tissue

d. Syndrome of inappropriate antidiuretic hormone (SIADH)

Answer: d — SIADH is a paraneoplastic syndrome linked to small cell lung cancer; it causes water retention and low sodium, which can lead to confusion (section 13.5, Recognizing and Diagnosing). Radiation pneumonitis (option a) causes cough, dyspnea and fever, not low sodium. Superior vena cava syndrome (option b) causes swelling of the face and neck. Hypercalcemia (option c) can cause confusion, but the laboratory finding here is low sodium, not high calcium.

32. [CORE] Which assessment finding is most consistent with a large right pleural effusion?

a. Hyperresonance to percussion and loud breath sounds over the right side

b. Dullness to percussion and reduced breath sounds at the right base

c. Coarse crackles that clear with coughing

d. A barking cough with inspiratory stridor

Answer: b — Fluid in the pleural space muffles sound, so percussion is dull and breath sounds are reduced or absent over it (section 13.6, Fluid Around the Lung). Hyperresonance (option a) suggests air, as in pneumothorax. Crackles that clear with coughing (option c) reflect secretions in the airways. Stridor and a barking cough (option d) point to upper airway narrowing.

33. [RN] A patient with metastatic NSCLC finished pembrolizumab 6 weeks ago. He calls the clinic with a new dry cough and breathlessness when climbing stairs. What is the RN's best response?

a. Tell him that immune-related effects stop once treatment ends, so this is likely a cold.

b. Advise him to try an over-the-counter cough suppressant and call back in a week if no better.

c. Arrange same-day assessment, because immune-related pneumonitis can follow the last dose.

d. Tell him to restart his next scheduled infusion early to control the cancer.

Answer: c — Immune-related adverse effects, including pneumonitis, can appear after the last dose of a checkpoint inhibitor; suspected pneumonitis needs prompt imaging and may need corticosteroids (section 13.5, Going Deeper box). Option a is incorrect, because these effects can appear after treatment ends. Option b delays assessment of a potentially serious condition. More immunotherapy (option d) could worsen pneumonitis; moderate pneumonitis means holding the drug.

34. [RN] During ultrasound-guided thoracentesis, about 1.3 L has been removed. The patient develops a persistent cough and says, "My chest feels tight." What should the RN do first?

a. Ask the practitioner to stop the drainage.

b. Encourage the patient to cough, because coughing helps the lung expand.

c. Increase the suction to finish draining the remaining fluid quickly.

d. Give a cough suppressant and continue the procedure.

Answer: a — The British Thoracic Society (BTS) Clinical Statement advises stopping drainage when the patient develops chest tightness, chest pain, a persistent cough or increasing breathlessness, even below 1.5 L, to reduce the risk of re-expansion pulmonary edema (section 13.6, Thoracentesis). Encouraging coughing and continuing (options b and d) ignores warning signs. Suction or vacuum drainage (option c) is not used, and faster drainage raises the risk.

35. [RN] A patient who takes warfarin for atrial fibrillation is starting rifampin for TB infection. What should the RN anticipate?

a. Rifampin will raise the INR, so the warfarin dose will likely be cut in half at once.

b. No change is needed, because rifampin does not interact with warfarin or other anticoagulants.

c. The warfarin should be stopped while rifampin is taken.

d. Rifampin will speed warfarin breakdown, so the INR may fall and needs closer monitoring.

Answer: d — Rifampin strongly induces the liver enzymes that break down warfarin, so the INR tends to fall and the warfarin dose often needs adjustment; the Standards advise monitoring early (within 1 to 2 weeks of starting) and again after rifampin stops (section 13.4, Medications box). Option a reverses the effect. Option b is false; rifampin has many drug interactions. Stopping warfarin (option c) would leave the patient unprotected from stroke and is not the standard approach.

14 Obstructive and Restrictive Lung Disease

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Distinguish obstructive from restrictive lung disease and interpret basic spirometry results.
2. Explain the pathophysiology of asthma, COPD, bronchiectasis, interstitial lung disease and obstructive sleep apnea, and link it to manifestations.
3. Recognize and respond to asthma and COPD exacerbations, including signs of life-threatening deterioration.
4. Give inhaled medications safely and teach inhaler technique for each device type.
5. Support long-term self-management: action plans, pulmonary rehabilitation, vaccination and home oxygen.
6. Provide evidence-based smoking and vaping cessation support in hospital and the community.
7. Address equity in chronic lung disease, including Indigenous, rural and occupational exposures and wildfire smoke.
8. Distinguish RN and RPN roles in respiratory care using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 4	Clinician; Scholar	Foundations of Practice
5, 6, 7	Educator; Advocate; Collaborator	Foundations of Practice; Collaborative Practice; Ethical Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Asthma and chronic obstructive pulmonary disease (COPD) are long-term lung diseases that nurses meet in almost every setting. National surveillance data from the Canadian Chronic Disease Surveillance System (CCDSS) counted about 3.8 million Canadians aged 1 year and older living with diagnosed asthma in 2011–2012, and about 2.0 million Canadians aged 35 and older living with COPD (Public Health Agency of Canada [PHAC], 2018). In hospital, COPD and bronchitis were the second most common reason for a stay in Canada in 2023–2024, after giving birth. They accounted for 76,968 hospitalizations, with an average acute stay of 7.1 days (Canadian Institute for Health Information [CIHI], 2025).

This chapter is the book's home for diseases that block airflow or limit lung expansion. Section 14.1 compares obstructive and restrictive patterns and explains spirometry. Section 14.2 covers asthma, and section 14.3 covers inhaled medications and devices. Section 14.4 covers COPD, section 14.5 smoking and vaping cessation, and section 14.6 bronchiectasis, interstitial lung disease and sleep apnea. Related topics live in other chapters:

- acid–base balance and blood gases (Chapter 3, section 3.7);
- the palliative approach and dyspnea management (Chapter 10);
- respiratory assessment, pulse oximetry and oxygen therapy (Chapter 12);
- pneumonia, respiratory viruses and lung cancer (Chapter 13);
- acute respiratory failure and ventilation (Chapter 15).

14.1 Obstructive and Restrictive Patterns

Two Ways Breathing Gets Harder

Chronic lung diseases usually make breathing harder in one of two ways. In **obstructive lung disease**, the airways are narrowed by inflammation, tightened airway muscle, mucus or loss of the elastic tissue that holds small airways open. Air gets in but has trouble getting out, so breathing out takes longer and some air stays trapped with each breath. The trapped air over-inflates the chest and makes breathing more work. Asthma, COPD and bronchiectasis are obstructive diseases.

In **restrictive lung disease**, the lungs cannot expand fully, so lung volumes are small. The lung tissue itself may be stiff and scarred, as in interstitial lung disease (section 14.6), or the cause may lie outside the lungs, in a stiff chest wall or weak breathing muscles. Breaths tend to be shallow and fast. A person can have both patterns at once. Table 14.1 compares them.

Table 14.1 Obstructive and restrictive patterns compared (Stanojevic et al., 2022; Yang et al., 2021; original wording)

Feature	Obstructive	Restrictive
Main problem	Narrowed airways slow the flow of air out of the lungs; air is trapped	Stiff lungs or a limited chest wall keep the lungs from filling; volumes are small
Examples	Asthma, COPD, bronchiectasis	Interstitial lung disease, including idiopathic pulmonary fibrosis; chest wall or breathing muscle problems
FEV1/FVC ratio	Reduced (below the lower limit of normal)	Normal or high
FVC and lung volumes	FVC normal or reduced; trapped air can raise total lung volume	FVC reduced; total lung capacity below normal confirms restriction
Typical findings	Long, slow breath out; wheeze; over-inflated chest	Rapid, shallow breathing; reduced chest expansion; crackles in some diseases
Main treatments in general	Bronchodilators, inhaled anti-inflammatory medicines, avoiding triggers, smoking cessation, pulmonary rehabilitation	Treating the cause where possible, oxygen when needed, pulmonary rehabilitation (section 14.6)

Spirometry Basics

Spirometry measures how much air a person can blow out after filling the lungs completely, and how quickly (Figure 14.1). The patient takes the deepest possible breath, then blows out as hard and fast as possible and keeps going until no more air comes out. Three results matter most:

- **Forced vital capacity (FVC):** the total volume of air blown out in that forced breath.
- **Forced expiratory volume in 1 second (FEV1):** the volume blown out in the first second.
- **FEV1/FVC ratio:** the share of the FVC that leaves in the first second.

Results are compared with predicted values for the person's age, sex and height, so height is measured accurately (Coates et al., 2013). The international standard discourages fixed race-based adjustments (Stanojevic et al., 2022).

Healthy lungs empty most of their air in the first second. A reduced FEV1/FVC ratio means the air leaves slowly, which is the mark of airflow obstruction. The European Respiratory Society and American Thoracic Society (ERS/ATS) standard defines obstruction as a ratio below the **lower limit of normal (LLN)**, the value below which only 5% of healthy people fall; some COPD guidance uses a fixed cut-off of 0.70 instead (Stanojevic et al., 2022; section 14.4). In restriction, FEV1 and FVC both fall, so the ratio stays normal or rises. A low FVC on its own does not prove restriction, though. Confirming it requires measuring **lung volumes**, especially total lung capacity (Stanojevic et al., 2022).

Spirometry is often repeated after an inhaled bronchodilator. In the Canadian Thoracic Society (CTS) asthma guideline, an increase in FEV1 of at least 12% and at least 200 mL after a bronchodilator, or after a course of controller medication, shows **reversibility** and supports a diagnosis of asthma in people aged 6 and older (Yang et al., 2021; Coates et al., 2013). Section 14.4 explains how

post-bronchodilator results confirm COPD. A **diffusing capacity** test uses a tiny amount of carbon monoxide to estimate how well gas crosses from the alveoli into the blood; it is low in emphysema and interstitial lung disease (Stanojevic et al., 2022).

Results depend on the patient's effort and cooperation. The nurse explains the test, encourages full effort and asks about recent medication use. Bronchodilators are held beforehand only as the laboratory or prescriber instructs; they may be continued when the test is meant to show how well current treatment works (Coates et al., 2013). Canadian guidance advises no smoking for 1 hour, no large meal for 2 hours and no heavy exercise for 30 minutes before testing, and loose clothing. The nurse reports recent eye, chest or abdominal surgery, a recent heart attack, coughing up blood or confusion, which can make testing unsafe or unreliable (Coates et al., 2013).

Figure 14.1 The mouthpiece and flow sensor of a hospital pulmonary function testing system, used for spirometry and related breathing tests. (credit: “Device for Spirometry or Body Plethysmography 02” by Joe Mabel/Wikimedia Commons, CC BY-SA 3.0)

Figure 14.2 A peak flow meter. The patient blows into it in a short, sharp blow, and a marker moves along the scale to show the peak expiratory flow.

Peak expiratory flow (PEF) is the fastest speed of air in a short, sharp blow into a hand-held meter (Figure 14.2). It is less precise than spirometry but useful for tracking asthma at home against the person's own best value, and for judging the severity of an exacerbation (section 14.2). Readings should be compared on the same meter (Yang et al., 2021).

14.2 Asthma

What Happens in Asthma

Asthma is a chronic airway disease, usually driven by ongoing inflammation, in which wheeze, breathlessness, chest tightness and cough come and go and change in intensity over time (Global Initiative for Asthma [GINA], 2026). During a flare, three changes narrow the airways: the smooth muscle around them tightens (**bronchoconstriction**), the inflamed walls swell and thicken, and mucus builds up. The airways are also overly sensitive. **Airway hyperresponsiveness** means they narrow quickly and strongly in response to stimuli that barely affect other people. Because the narrowing rises and falls, airflow limitation is variable, and lung function may be normal between episodes. After many years of asthma, some narrowing can become permanent (GINA, 2026).

Triggers differ from person to person. Common ones include (GINA, 2026; Yang et al., 2021):

- viral respiratory infections;
- allergens, such as house dust mites, animals, pollens and cockroaches;

- tobacco smoke, vaping (including cannabis) and air pollution;
- exercise, cold air, strong emotion and laughter;
- irritants or allergens at work;
- medicines: beta-blockers, and in some people acetylsalicylic acid (ASA) and other nonsteroidal anti-inflammatory drugs (NSAIDs).

Wildfire smoke is a growing seasonal trigger in Canada (Figure 14.3). Its fine particles (PM2.5) are its main health risk, and asthma attacks are among its more serious effects (Health Canada, 2026b). The CTS estimates that about 36% of asthma that starts in adulthood is probably or possibly related to work, so every adult with asthma needs an occupational history (Yang et al., 2021). Smoking and vaping raise the risk of exacerbations; section 14.5 covers cessation.

Who Has Asthma in Canada

In CCDSS data, the age-standardized prevalence of diagnosed asthma among Canadians aged 1 and older rose from 6.5% in 2000–2001 to 10.8% in 2011–2012. Over the same years, the age-standardized rate of new diagnoses fell by 44.8% (PHAC, 2018). In childhood, prevalence was higher in males; from the 25–29 age group onward, it was higher in females (PHAC, 2018).

Risk is not shared equally. People in rural and remote areas, outdoor workers, and people with lower incomes or insecure housing are more exposed to wildfire smoke or less able to limit their exposure (Health Canada, 2026b). Major psychological or socioeconomic problems also raise a person's risk of exacerbations (GINA, 2026). These are structural causes, rooted in housing, work and income, not personal failings (Chapter 2).

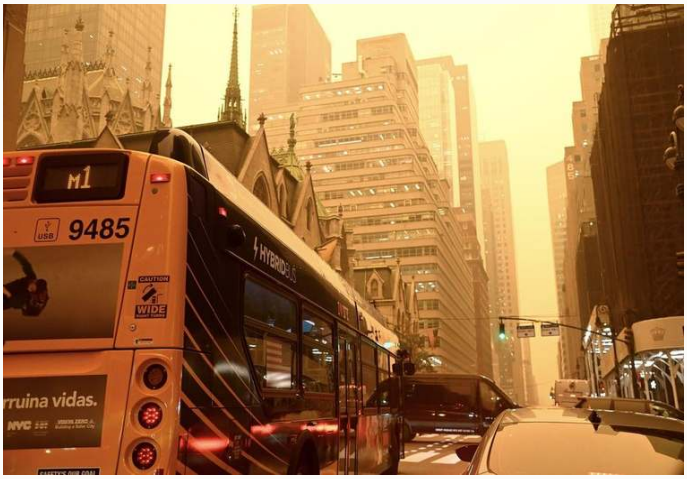

Figure 14.3 Smoke from the June 2023 wildfires in Quebec over New York City. Wildfire smoke can travel far from the fires and trigger asthma attacks. (credit: “Wildfire Smoke” by Marc A. Hermann/Metropolitan Transportation Authority, CC BY 2.0)

Recognizing and Diagnosing Asthma

Typical symptoms are wheeze, cough, chest tightness and breathlessness that vary over time and often follow a trigger. Night-time symptoms on 1 night a week or more mean that asthma is not well controlled (Yang et al., 2021). On examination between flares, the chest may sound normal.

Symptoms alone are not enough for a diagnosis. The CTS requires a compatible history plus objective proof of variable or reversible airflow obstruction (Yang et al., 2021). Spirometry is the preferred test: a reduced FEV1/FVC ratio together with the FEV1 rise described in section 14.1. When spirometry does not settle the question, other tests can (Yang et al., 2021):

- **PEF variability:** a rise in PEF of at least 20% (and at least 60 L/min) after a bronchodilator or controller, or a large difference between readings over the day.
- **Methacholine challenge:** the patient inhales increasing amounts of methacholine, a substance that narrows sensitive airways. Airways that react at a low concentration confirm hyperresponsiveness.
- **Exercise challenge:** a fall in FEV1 after exercise.

Normal spirometry on one day does not rule out asthma (Yang et al., 2021). A confirmed diagnosis matters because treatment is long term.

Asthma Control and Long-Term Treatment

Asthma control describes how well treatment keeps symptoms and flare-ups away. The CTS considers asthma well controlled only when all these are true (Yang et al., 2021):

- symptoms during the day on 2 days a week or fewer, and at night less than once a week and mild;

- normal physical activity, with no time lost from work or school;
- only mild, infrequent exacerbations;
- reliever needed 2 times a week or fewer;
- FEV1 or PEF at 90% or more of the person's best, with little day-to-day PEF variation.

For adolescents and adults, the CTS 2021 guideline builds treatment on inhaled corticosteroids (ICS), the main anti-inflammatory controller (Yang et al., 2021):

- **Mild asthma that is poorly controlled on an as-needed short-acting beta2-agonist (SABA):** start a daily ICS with an as-needed SABA. For people aged 12 and older whose adherence to a daily ICS is poor, as-needed budesonide–formoterol is recommended instead.
- **Mild asthma that is well controlled on an as-needed SABA:** people at higher risk of exacerbations move to a daily ICS or as-needed budesonide–formoterol. People at lower risk may continue the SABA alone, or choose either option for better control.
- **After any severe exacerbation** (one needing systemic corticosteroids, an emergency visit or a hospital stay) in a person using a SABA alone, a controller is started.
- **Asthma not controlled on a low-dose ICS despite good adherence:** a combined ICS and long-acting beta2-agonist (ICS–LABA) inhaler is first choice. A LABA is never used alone in asthma.
- **Poor control on an ICS–LABA:** switching to budesonide–formoterol as **maintenance and reliever therapy (MART)** is an option. The same inhaler is taken daily and also for symptoms.
- **Still not controlled:** adding a leukotriene receptor antagonist (LTRA), such as montelukast, or the long-acting muscarinic antagonist tiotropium is considered. GINA notes that montelukast has been linked to a risk of serious mental health effects (GINA, 2026).

The CTS is clear that a SABA relieves symptoms but does not treat the disease. Using a reliever more than twice a week signals poor control, and using more than two SABA inhalers a year should prompt reassessment (Yang et al., 2021). The GINA 2026 strategy goes further: asthma should not be treated with a SABA alone, because SABA-only treatment is linked to more exacerbations and a higher risk of death (GINA, 2026). In practice, the nurse asks every patient how often they use their reliever and reports rising use.

People whose asthma stays uncontrolled on a medium-dose ICS plus a second controller are referred to a specialist for assessment of **severe asthma** (Yang et al., 2021). In September 2026, the CTS released a guideline on managing severe asthma in children, adolescents and adults (Canadian Thoracic Society [CTS], 2026). Specialist treatment may include **biologics**: injected antibodies that block specific steps in allergic or eosinophilic inflammation, such as immunoglobulin E (IgE) or interleukin-5 (GINA, 2026). Before treatment is stepped up at any level, the clinician confirms adherence and inhaler technique and checks that the inhaler is not empty (Yang et al., 2021; section 14.3).

Every person with asthma should have a **written action plan**, because plans reduce exacerbations. A plan may be based on symptoms or on PEF readings (Yang et al., 2021). It tells the person how to recognize worsening asthma, how to step up treatment, and when to seek urgent care.

MEDICATIONS

Bronchodilators and Inhaled Corticosteroids

- **Short-acting beta2-agonist (SABA):** salbutamol (Ventolin HFA) relaxes airway muscle within minutes. Watch for tremor, fast heart rate and palpitations. Low blood potassium is rare, but during repeated treatments in hospital the nurse follows potassium results as ordered (GlaxoSmithKline, 2025).
- **Long-acting beta2-agonist (LABA):** formoterol, given with budesonide in one inhaler (Symbicort Turbuhaler). In asthma, a LABA is always paired with an ICS (Yang et al., 2021).
- **Inhaled corticosteroid (ICS):** fluticasone propionate (Flovent HFA) and budesonide reduce airway inflammation over days to weeks. They can cause thrush in the mouth and hoarseness. The patient rinses the mouth with water and spits after each use; denture wearers also clean their dentures (AstraZeneca Canada, 2021).
- **Muscarinic antagonists:** short-acting ipratropium and long-acting tiotropium (Spiriva Respimat) block the nerve signals that tighten airway muscle. They can cause dry mouth and trouble passing urine. The mist must be kept out of the eyes, because it

> can worsen narrow-angle glaucoma; eye pain, blurred vision or halos need prompt care (Boehringer Ingelheim, 2019; JAMP Pharma, 2023).
> - Tremor or a racing heart after a reliever is common; chest tightness or wheeze that worsens right after a dose may be paradoxical bronchospasm and needs immediate care (GlaxoSmithKline, 2025).

Asthma Exacerbations in Hospital

An **asthma exacerbation** is a flare in which symptoms and lung function worsen beyond the person's usual day-to-day variation. The CTS has no current guideline on hospital management of adult exacerbations, so this section draws on GINA and the British guideline.

The nurse judges severity from how the patient looks and talks and from objective measures. GINA advises assessing breathlessness, accessory muscle use, pulse, oxygen saturation (SpO2) and PEF while treatment is started (GINA, 2026). The British guideline describes two levels that need urgent action (British Thoracic Society [BTS] & Scottish Intercollegiate Guidelines Network [SIGN], 2019):

- **Acute severe asthma:** any one of these: cannot finish sentences in one breath; respiratory rate 25 breaths/min or more; heart rate 110 beats/min or more; PEF 33% to 50% of best or predicted.
- **Life-threatening asthma:** any one of these: PEF below 33%; SpO2 below 92%; a **silent chest**, in which so little air moves that wheeze can no longer be heard; cyanosis (a blue or grey tinge of the lips, tongue and nail beds that can be harder to see on darker skin; Chapter 12); poor respiratory effort; an abnormal heart rhythm or low blood pressure; exhaustion or a change in level of consciousness.

GINA advises transfer to intensive care if the patient is drowsy, confused or has a silent chest (GINA, 2026). Patients with severe asthma may not look distressed (BTS & SIGN, 2019). Early in an attack, fast breathing blows off carbon dioxide, so the partial pressure of carbon dioxide in arterial blood (PaCO2) is usually low. A "normal" PaCO2 (about 35 to 45 mm Hg) in a breathless patient with asthma is a life-threatening sign, because it means the patient is tiring; a rising PaCO2 signals near-fatal asthma (BTS & SIGN, 2019; Chapter 3, section 3.7). Pulse oximetry may overestimate saturation in people with darker skin (GINA, 2026; Chapter 12).

Nursing care follows the orders and the unit's protocol:

- Sit the patient upright, stay close, and give oxygen to the target range ordered. GINA suggests a target of 92% to 95% in acute asthma (GINA, 2026), while the British guideline uses 94% to 98% (BTS & SIGN, 2019); Chapter 12 explains target ranges.
- Give the inhaled SABA, repeated at short intervals, by metered-dose inhaler with a spacer or by nebulizer. Ipratropium is added for moderate or severe exacerbations, or when the first SABA doses do not help enough (GINA, 2026; BTS & SIGN, 2019).
- Give systemic corticosteroids early, as ordered (GINA, 2026).
- For life-threatening features or asthma that responds poorly, intravenous magnesium sulfate may be ordered (BTS & SIGN, 2019). A single infusion reduced hospital admissions in adults who had not responded well to oxygen, nebulized SABA and corticosteroids (Kew et al., 2014). The nurse watches for flushing and low blood pressure.
- Avoid sedatives of any kind (BTS & SIGN, 2019).

Response is reassessed often: respiratory rate, heart rate, SpO2, accessory muscle use, air entry, ability to speak and PEF. Guidance suggests repeating PEF 15 to 30 minutes after treatment starts and reviewing response within an hour (BTS & SIGN, 2019; GINA, 2026). Worsening or life-threatening features call for an immediate rapid response or critical care call (Chapter 6). Patients who tire, become drowsy or show rising PaCO2 need intensive care; ventilation is covered in Chapter 15.

Before discharge, the patient starts or steps up an ICS-containing controller (GINA, 2026). The nurse checks inhaler technique with the patient's own device and reviews the written action plan. Early follow-up matters: GINA advises a review within 1 week after an exacerbation (GINA, 2026), and the British guideline advises primary care follow-up within 2 working days of discharge (BTS & SIGN, 2019).

CLINICAL JUDGMENT

The Quiet Chest

Daniel Okafor, 24, came to the emergency department with an asthma exacerbation after a cold. He was admitted to a medical unit after several bronchodilator treatments. At 0200, the nurse notes that his loud wheeze has faded and he is lying back with his eyes closed. A family member says, "He's finally settling down."

- **Recognize cues:** Daniel answers in single words and is hard to rouse. His respiratory rate has dropped from 32 to 20 breaths/min, his SpO2 is 89% on the ordered oxygen, and air entry is faint on both sides. He has not received any sedative.
- **Analyze cues:** A quieter chest with faint air entry means less air is moving, not that the airways have opened. A slower rate and drowsiness in a patient who was working hard suggest exhaustion and rising carbon dioxide.
- **Prioritize hypotheses:** Life-threatening asthma with fatigue and impending respiratory failure ranks first. Improvement does not fit falling SpO2 and drowsiness.
- **Generate solutions:** Get help at once, do not leave Daniel alone or lie him flat, keep him upright, keep giving oxygen to target, have bronchodilator treatment continued as ordered, and prepare for blood gases and transfer.
- **Take action:** The nurse stays with Daniel, presses the call bell, calls the rapid response team and gives an SBAR (Situation, Background, Assessment, Recommendation) report (Chapter 6).
- **Evaluate outcomes:** The nurse reassesses responsiveness, respiratory effort and SpO2 every few minutes until the team arrives. A blood gas shows a rising PaCO2, which confirms fatigue. The team transfers Daniel to the intensive care unit, where his breathing can be supported (Chapter 15).

14.3 Inhaled Medications and Devices

Relievers and Controllers

Inhaled medicines go straight to the airways, so they work quickly with small doses and fewer whole-body effects. Patients find it easier to manage their treatment when they understand two plain-language groups. A **reliever** opens narrowed airways within minutes and is used when symptoms appear. A **controller** is used every day to calm airway inflammation or keep airways open for many hours, which prevents symptoms and flare-ups. One medicine can do both jobs: in an **ICS–formoterol reliever**, each dose of budesonide–formoterol both relieves symptoms and treats inflammation (Yang et al., 2021).

The main classes, with Canadian examples, are:

- **Short-acting beta2-agonist (SABA):** salbutamol (Ventolin HFA), the usual reliever.
- **Short-acting muscarinic antagonist (SAMA):** ipratropium, added to a SABA in more severe exacerbations and used in COPD.
- **Long-acting beta2-agonist (LABA):** formoterol and others; in asthma, always combined with an ICS.
- **Long-acting muscarinic antagonist (LAMA):** tiotropium (Spiriva Respimat), mainly used in COPD (section 14.4) and as an add-on in asthma.
- **Inhaled corticosteroid (ICS):** fluticasone propionate (Flovent HFA) and budesonide (Pulmicort Turbuhaler), the main controllers in asthma.
- **Combination inhalers:** an ICS–LABA such as budesonide–formoterol (Symbicort Turbuhaler); LAMA–LABA and triple combinations are used in COPD (section 14.4).

A medicine works only if it reaches the lungs. The CTS reports that up to 70% of patients use their inhaler incorrectly, and that poor technique is linked to poor control (Yang et al., 2021).

Devices and Technique

A **pressurized metered-dose inhaler (pMDI)** releases a measured puff of medicine in a propellant spray. The patient must press the canister just after starting a slow, deep breath, which many people find hard to coordinate. A new pMDI, or one unused for several days, is first primed by spraying into the air as the leaflet directs (GlaxoSmithKline, 2025). A **spacer**, or valved holding chamber, is a tube that attaches to the pMDI and holds the puff so the patient can breathe it in without precise timing; it also cuts down the

medicine left in the mouth and throat. The CTS recommends a valved holding chamber for people of all ages who are prescribed a pMDI (Yang et al., 2021), and a spacer can also increase the amount of medicine delivered (Gupta et al., 2023).

A **dry powder inhaler (DPI)** holds the medicine as a fine powder. There is no propellant: the patient's own fast, deep, forceful breath pulls the powder out, so the patient must never breathe out into the device. The dose is small, so the patient may not taste or feel the powder; this is expected (AstraZeneca Canada, 2021). The Turbuhaler is one example (Figure 14.4). A **soft mist inhaler**, such as the Respimat, releases a slow-moving mist when a button is pressed during a slow, deep breath (Boehringer Ingelheim, 2019). A **nebulizer** turns liquid medicine into a mist that the patient breathes in through a mouthpiece or mask, which helps when a patient is too breathless to use a hand-held device.

Figure 14.4 Three dry powder inhalers: a Turbuhaler, an Accuhaler (sold in Canada as Diskus) and an Ellipta. Each is loaded differently, so the nurse checks technique with the patient's own device. (credit: "Dry powder inhalers" by Brett Montgomery/Wikimedia Commons, CC BY-SA 4.0)

Common errors include not breathing out before the dose, poor timing with a pMDI, breathing in too fast through a pMDI or too gently through a DPI, breathing out into a DPI, and skipping the breath-hold (Table 14.2). Using an empty inhaler is another hidden error. Some pMDIs, including Ventolin HFA, have no dose counter, so the patient must keep count; shaking or floating the canister is not a reliable test (GlaxoSmithKline, 2025). The Respimat has a dose indicator and locks when empty (Boehringer Ingelheim, 2019). A pMDI's plastic casing is rinsed weekly with warm water, never the metal canister, and spacers are cleaned as the manufacturer directs (GlaxoSmithKline, 2025).

The device must fit the person. A DPI needs enough inspiratory flow. The CTS notes that low inspiratory flow is likely a concern for only a small minority (under 5%) of people with chronic lung disease, but breathing-in strength is lower at the extremes of age, and severe disease or an exacerbation can reduce it further; a pMDI with a spacer may then work better (Gupta et al., 2023). Coordination, hand strength, cognition and vision also matter. The CTS recommends choosing inhalers through shared decision-making that weighs technique, preference, cost, side effects and environmental impact. Propellants in pMDIs are potent greenhouse gases, and DPIs and soft mist inhalers have roughly one-tenth of their carbon footprint. However, switching should not be automatic for a patient who prefers a pMDI and uses it well, and used inhalers should be returned to a pharmacy for disposal (Gupta et al., 2023).

Table 14.2 Inhaler devices and key technique points (GlaxoSmithKline, 2025; AstraZeneca Canada, 2021; Boehringer Ingelheim, 2019; Yang et al., 2021; original wording)

Device	How the patient breathes in	Key steps	Common errors
pMDI alone	Slowly and deeply, starting just before pressing the canister	Shake; breathe out away from the mouthpiece; seal lips; press once while breathing in; hold breath; wait about 30 seconds between puffs	Pressing too early or late; breathing in fast; not shaking; no breath-hold; not tracking doses on a device without a counter
pMDI with spacer	Slowly and deeply through the spacer mouthpiece	Shake; attach to spacer; breathe out; seal lips on spacer; one puff into the spacer, then breathe in; hold breath; repeat for each puff	Several puffs into the spacer at once; delay between puff and breath; dirty or cracked spacer
Dry powder inhaler	Fast, deep and forceful from the start	Load the dose as the device directs; breathe out away from the mouthpiece; seal lips; breathe in hard; hold breath; close the device	Breathing out into the device; breathing in too gently; not loading the dose; shaking or tilting some devices after loading

Device	How the patient breathes in	Key steps	Common errors
Soft mist inhaler	Slowly and deeply while pressing the button	Turn the base until it clicks; open the cap; breathe out; seal lips without covering the air vents; press while breathing in; hold the breath for about 10 seconds	Not turning the base fully; covering the air vents; spraying mist into the eyes

Teaching and Checking Technique

Checking technique is part of every encounter, not a one-time lesson. GINA advises asking the patient to show how they use the inhaler, comparing each step with a device-specific checklist, demonstrating the steps that went wrong, and checking again up to 2 or 3 times (GINA, 2026). Technique should be rechecked whenever the device or treatment changes. Faulty technique is linked to more symptoms, more urgent care visits and a greater environmental burden (GINA, 2026). The nurse also checks whether the inhaler is empty, a simple and often missed cause of poor control (Yang et al., 2021). The nurse uses teach-back and an observed demonstration, not just a question such as "Do you know how to use this?"

Admission and discharge are key moments. A patient may use a different device in hospital from the one at home, so the nurse checks technique with the patient's own device before discharge. Written instructions with pictures support verbal teaching. Plain language helps, and a professional interpreter is used when the patient prefers another language (Chapter 2). Cost and coverage affect whether patients fill prescriptions and keep using them. The nurse asks about drug coverage, such as provincial or territorial drug programs and the Non-Insured Health Benefits program for eligible First Nations and Inuit patients, and involves the pharmacist or social worker when cost is a barrier (Chapter 2).

PATIENT EDUCATION

Using Your Inhaler

Using a puffer with a spacer

- Take the cap off, check the mouthpiece, and shake the puffer.
- Put the puffer into the end of the spacer.
- Breathe out gently, away from the spacer.
- Close your lips around the spacer mouthpiece.
- Press the puffer once, then breathe in slowly and deeply.
- Hold your breath as long as is comfortable, then breathe out.
- Wait about 30 seconds before the next puff.

After a steroid inhaler: rinse your mouth with water and spit it out. This helps prevent thrush and a hoarse voice.

Your reliever: use it when you have symptoms, as your action plan says. Carry it with you every day. If you need it more than twice a week, tell your health care provider, because your asthma may not be well controlled.

Get help right away if your reliever does not help, the relief lasts less than 3 hours, or you need it more often than usual. Call 9-1-1 if you cannot speak in full sentences, your lips or nail beds turn grey or blue, or you feel drowsy or confused.

LIFESPAN CONSIDERATIONS

Inhalers and Older Adults

- **Hands:** arthritis or a weak grip can make it hard to press a canister, twist a Turbuhaler or turn the base of a soft mist inhaler. Ask the pharmacist about aids or another device.
- **Coordination and memory:** pressing and breathing at the same time is hard for many older adults. A spacer removes the need for precise timing. Cognitive impairment can make multi-step devices unreliable (Chapter 8).
- **Breath strength:** some older adults cannot breathe in hard enough for a dry powder inhaler, especially during an exacerbation (Gupta et al., 2023).
- **Vision and hearing:** small dose counters and printed steps can be hard to read. Use large print, good light, and teaching that suits the person's hearing.
- **Caregivers:** when a family member or care worker helps, teach that person too and watch them do it.
- **Cost:** ask whether cost leads the person to skip or stretch doses, and involve the pharmacist (Chapter 2).

- **Reassess often:** check technique at every visit, after any decline in health and whenever the device changes.

14.4 Chronic Obstructive Pulmonary Disease

This section follows the person with chronic obstructive pulmonary disease from diagnosis through long-term care to an exacerbation in hospital and the return home. Spirometry is introduced in section 14.1, and inhalers in section 14.3.

What Happens in COPD

Chronic obstructive pulmonary disease (COPD) is a long-term lung condition in which damaged airways, damaged alveoli or both cause airflow obstruction that does not fully reverse and often worsens over time. People with COPD have ongoing breathlessness, cough, sputum and flare-ups (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2025). Two kinds of damage contribute, and most patients have some of each.

- **Chronic bronchitis:** long-standing inflammation of the airways. The airway walls thicken, mucus-producing cells multiply and the small airways narrow and plug with mucus. The person coughs and brings up sputum on most days.
- **Emphysema:** destruction of the walls of the alveoli. Small air sacs merge into larger, floppy spaces with less surface for gas exchange. The lung also loses its elastic recoil, the spring that normally pushes air out and holds small airways open (Figure 14.5).

Both changes trap air. During exhalation, narrowed or unsupported small airways close before the lungs have emptied, so some air stays behind with each breath. This **air trapping** builds up, especially when the person breathes faster during exercise or illness. The result is **hyperinflation**: the lungs sit at a larger volume than normal, the diaphragm is pushed down and flattened, and the breathing muscles work at a mechanical disadvantage (GOLD, 2025). Each breath starts from an already full chest, so people with COPD feel they cannot get a satisfying breath and tire quickly. The mismatch between ventilation and blood flow in damaged lung units lowers oxygen levels and, in some patients, lets carbon dioxide (CO_2) build up (Chapter 12).

Figure 14.5 A cut slice of lung with centrilobular emphysema, the pattern typical of smoking: many small spaces where alveolar walls have been destroyed, lined with black carbon deposits. The specimen number on the ruler is pixelated. (credit: modification of "Centrilobular emphysema 865 lores" by Edwin P. Ewing, Jr./Centers for Disease Control and Prevention, public domain)

People with COPD often live with other conditions that affect their health and prognosis (GOLD, 2025). In Canada, people who have diabetes, high blood pressure, a mood or anxiety disorder or asthma are more likely to have COPD than people without these conditions (PHAC, 2018).

COPD in Canada

COPD mainly affects adults aged 35 and older. In 2011–2012, the most recent year in the national report, surveillance counted about 2.0 million Canadians in this age group living with diagnosed COPD (PHAC, 2018). The burden on hospitals is heavy. In 2023–2024, COPD and bronchitis were the second most common reason for hospital stays in Canada, after giving birth: 76,968 hospitalizations, 2.5% of the total, with an average acute stay of 7.1 days (CIHI, 2025). The CTS notes that, in Canada, COPD exacerbations lead all chronic conditions as a cause of acute hospital stays among adults (Bourbeau et al., 2023).

Smoking tobacco, including exposure to second-hand smoke, is the main cause (PHAC, 2018). Other risk factors include the following (GOLD, 2025):

- **Work exposures:** organic and inorganic dusts, chemicals and fumes.

- **Burning biomass fuels:** wood, crop waste or coal burned for cooking or heat in open fires or poor stoves.
- **Air pollution:** outdoor pollution, which also raises the risk of exacerbations, admissions and death. Health Canada lists people with lung conditions and adults aged 65 and older among those at higher risk from wildfire smoke (Health Canada, 2026b).
- **Genetics: alpha-1 antitrypsin deficiency**, an inherited lack of a protein that protects the lung from damage.
- **Early-life factors:** disadvantages in childhood that limit lung growth.

COPD is often missed. Many people with COPD have symptoms and poor health yet no diagnosis (Bourbeau et al., 2023), and GOLD reports that about 81% of people whose spirometry shows COPD have never been diagnosed (GOLD, 2025).

Risk is shaped by social conditions. In the 2012 Aboriginal Peoples Survey, which did not include people living on reserve, 6.8% of First Nations, Métis and Inuit respondents aged 35 and older self-reported COPD (Métis 7.9%, First Nations 6.6%, Inuit 3.2%); daily smoking, the lowest income level and unmet health care needs were each linked to higher odds (Bird et al., 2017). The diagnoses were self-reported, not confirmed by spirometry, and the authors suggest that the lower figure among Inuit may reflect underdiagnosis or limited access to a regular doctor (Bird et al., 2017). First Nations data belong to First Nations under the principles of OCAP® (First Nations Information Governance Centre, n.d.). Chapter 2 discusses the colonial roots of these gaps.

CANADIAN CONTEXT

COPD in Canada

- **A leading reason for hospital care:** in 2023–2024, COPD and bronchitis accounted for 76,968 hospitalizations, second only to giving birth; patients stayed an average of 7.1 days in acute care (CIHI, 2025).
- **Many Canadians affected:** in 2011–2012, diagnosed COPD was recorded in about 2.0 million people in Canada aged 35 and older (PHAC, 2018).
- **Rehabilitation gaps:** pulmonary rehabilitation eases breathlessness and improves exercise capacity, yet it is underused. Barriers include too few programs, too little capacity, low referral rates and gaps in rural access. The American Thoracic Society (ATS) guideline recommends offering a choice of centre-based or virtual (tele-) rehabilitation, an option for people who live far from a program (Rochester et al., 2023).
- **Wildfire smoke:** Health Canada lists people with lung conditions and adults aged 65 and older among those at higher risk, and advises checking the Air Quality Health Index (Health Canada, 2026b).
- **Indigenous health:** in a national Statistics Canada survey, First Nations, Métis and Inuit adults who could not get care when they needed it had higher odds of COPD (Bird et al., 2017). Community-led tobacco programs that keep tobacco sacred while reducing commercial tobacco use (First Nations Health Authority [FNHA], n.d.) and culturally safe access to diagnosis and rehabilitation build on community strengths (section 14.5; Chapter 2).

Recognizing and Diagnosing COPD

The typical person is an adult aged 35 or older with a history of smoking or other exposure who reports breathlessness, cough, sputum and flare-ups (GOLD, 2025; PHAC, 2018). Because breathlessness creeps up slowly, the nurse asks what the person can no longer do, not only whether they feel short of breath.

Spirometry confirms the diagnosis. A ratio of forced expiratory volume in 1 second to forced vital capacity (FEV1/FVC) below 0.70 after a bronchodilator confirms COPD (Bourbeau et al., 2023; section 14.1). Spirometry alone does not describe how sick a person is (Bourbeau et al., 2023), so the CTS guideline adds two other measures:

- **Symptom burden:** the modified Medical Research Council (mMRC) dyspnea scale (Chapter 12) and the **COPD Assessment Test (CAT)**, a short questionnaire about the effect of COPD on daily life. An mMRC score of 2 or more or a CAT score of 10 or more means moderate to severe symptoms or impaired health (Bourbeau et al., 2023).
- **Exacerbation risk:** a person is at high risk if, in the past year, they had two or more moderate exacerbations (treated with antibiotics, oral corticosteroids or both) or one or more severe exacerbations (needing an emergency department visit or hospital stay) (Bourbeau et al., 2023).

The nurse records the person's usual breathlessness, activity level, SpO2 and sputum when they are well. This baseline makes it easier to see when they are not.

Long-Term Care

The CTS 2023 guideline states that every person with symptoms and spirometry-confirmed COPD should receive maintenance treatment with a long-acting bronchodilator (Bourbeau et al., 2023). Its main recommendations are summarized here:

- **Mild symptoms, low exacerbation risk and only mildly reduced lung function:** start one long-acting bronchodilator, either a LAMA or a LABA.
- **Moderate to high symptoms and low exacerbation risk:** start LAMA/LABA dual therapy.
- **High exacerbation risk with moderate to high symptoms:** use LAMA/LABA/ICS **triple therapy**. For this group, the CTS also recommends triple therapy over dual therapy to lower the risk of death.
- **Ongoing exacerbations despite triple therapy:** consider adding a long-term macrolide antibiotic, after weighing the risks of antimicrobial resistance, hearing loss and prolongation of the QT interval on the electrocardiogram. For people with a chronic bronchitis pattern, the CTS suggests one of two other oral add-on medications.
- **Not recommended:** an ICS on its own, theophylline and maintenance oral corticosteroids such as prednisone.
- **For everyone:** a short-acting bronchodilator as needed (Bourbeau et al., 2023).

ICS-containing therapy raises the risk of pneumonia, especially in severe disease (Bourbeau et al., 2023), so the nurse teaches patients on an ICS to report fever or a change in sputum early. The CTS calls proper inhaler technique one of the most important parts of COPD care (Bourbeau et al., 2023); the nurse checks it at every opportunity (section 14.3).

The CTS also lists smoking cessation counselling, vaccination, self-management education, pulmonary rehabilitation and a written action plan for exacerbations as core treatments (Bourbeau et al., 2023):

- **Smoking cessation:** counselling and medication for everyone who smokes (section 14.5).
- **Vaccination:** influenza, pneumococcal, COVID-19 and respiratory syncytial virus (RSV) vaccines as recommended (Chapter 13).
- **Pulmonary rehabilitation:** a supervised, tailored program of exercise training, education and behaviour change. For people with stable COPD, it improves exercise capacity, breathlessness and quality of life. Started within 3 weeks of discharge after a hospitalized exacerbation, it reduces readmissions (Rochester et al., 2023).
- **Self-management and a written action plan:** the plan tells the person how to recognize a flare-up, which medications to start or increase and when to call for help.
- **Long-term oxygen:** for people with low blood oxygen at rest once their condition is stable and treatment optimized. In Ontario, the criteria are a partial pressure of oxygen in arterial blood (PaO2) of 55 mm Hg or less, or an arterial oxygen saturation (SaO2) of 88% or less, on room air at rest (College of Respiratory Therapists of Ontario [CRTO], 2022). Home oxygen and fire safety are covered in Chapter 12.
- **A palliative approach:** COPD is a life-limiting illness. Managing breathlessness and planning care early belong alongside active treatment (Chapter 10).

Acute Exacerbations in Hospital

The CTS 2023 guideline grades exacerbations by the treatment they need but does not define the acute event in detail, so this book uses the definition in the GOLD 2026 report. An **acute exacerbation of COPD** is a sudden flare-up in which symptoms get worse over a period of days, 14 days at most (GOLD, 2025). The CTS describes a change in at least one major symptom: breathlessness, sputum volume or sputum purulence (Bourbeau et al., 2023). Infections (viral or bacterial) and environmental pollutants are the most frequent triggers (GOLD, 2025). The team also looks for other causes of breathlessness, such as pneumonia (Chapter 13), heart failure (Chapter 18), pneumothorax or pulmonary embolism (Chapter 15).

Recognizing and escalating. The nurse assesses respiratory rate, work of breathing, ability to speak, SpO2, heart rate, temperature, sputum and level of consciousness, and scores them with the hospital's early warning tool (Chapter 6). Table 14.3 links common cues to their meaning and the nurse's response. New drowsiness or confusion, a rising respiratory rate with tiring, or failure to improve with bronchodilators calls for rapid escalation.

Oxygen and blood gases. The nurse gives oxygen to the target range on the order. For people at risk of hypercapnic respiratory failure, including those with COPD, guidelines suggest 88% to 92% (Barnett et al., 2022; O'Driscoll et al., 2017; Chapter 12). Oxygen is never withheld from a hypoxemic patient. **Hypercapnia**, a raised level of CO2 in arterial blood, can develop in some patients when too much oxygen is given (Abdo & Heunks, 2012). An arterial blood gas (ABG) is needed when an at-risk patient is breathless, has a falling SpO2 or becomes drowsy, and blood gases are rechecked 30 to 60 minutes after an oxygen change (O'Driscoll et al., 2017).

Medications. The CTS 2023 guideline covers stable COPD, so for acute treatment this book follows GOLD. Short-acting beta2-agonists, with or without a short-acting muscarinic antagonist, are the first bronchodilators (GOLD, 2025), given by inhaler and spacer or by nebulizer as ordered (section 14.3). For moderate or severe exacerbations, GOLD advises a systemic corticosteroid course of no more than 5 days. It advises a 5-day antibiotic course for patients with purulent sputum or other indications, such as a history of lung infections (GOLD, 2025). The nurse monitors blood glucose in patients on corticosteroids, especially those with diabetes (Chapter 22).

Ventilatory support. If blood gases show rising CO2 with acidemia despite treatment, the team may start non-invasive ventilation (NIV) (Rochwerg et al., 2017). Indications and care are in Chapter 15.

Comfort and function. Many patients find breathing easier sitting upright and leaning forward with the arms supported. The CTS dyspnea guideline supports pursed-lip breathing and walking aids for breathlessness in advanced COPD (Marciniuk et al., 2011). A calm voice and staying with the patient ease the anxiety that feeds breathlessness (Chapter 10). The nurse paces care to save energy, offers small frequent meals, mobilizes the patient early and gives venous thromboembolism (VTE) prophylaxis as ordered (Chapter 7).

Transitions home. GOLD advises starting long-acting maintenance therapy as soon as possible, and recovery can take up to 4 to 6 weeks (GOLD, 2025). Before discharge, the nurse:

- checks inhaler technique with the patient's own devices (section 14.3);
- reviews or writes the action plan with the patient and family;
- confirms a referral to pulmonary rehabilitation (Rochester et al., 2023);
- arranges follow-up with primary care or the respiratory clinic;
- offers cessation support (section 14.5) and reviews vaccines (Chapter 13).

Table 14.3 COPD exacerbation: cues and nursing actions (Barnett et al., 2022; GOLD, 2025; O'Driscoll et al., 2017; original wording)

Cue	What it may mean	Nursing action
More breathlessness than usual; more sputum or a change to yellow or green	An exacerbation, often triggered by infection	Assess vital signs, SpO2 and work of breathing; give ordered short-acting bronchodilators; send sputum if ordered; report
SpO2 below the ordered target (for example below 88%)	Worsening hypoxemia	Raise oxygen within the order to reach the target; reassess after 5 minutes; report if the target is not reached; expect an ABG
SpO2 above the target (for example above 92%) in a patient at risk of hypercapnia	More oxygen than needed; CO2 may rise	Lower oxygen within the order to bring SpO2 into range; never stop it abruptly; watch level of consciousness; report
New drowsiness, confusion or difficulty waking	Rising CO2 or worsening hypoxemia	Check airway, breathing and level of consciousness; call the rapid response team; prepare for an ABG; hold sedating drugs and report
Accessory muscle use, fast breathing, speaks only a few words	Severe exacerbation; breathing muscles tiring	Sit upright; stay with the patient; escalate at once; prepare for an ABG and possible NIV (Chapter 15)
Fever	Infection, possibly pneumonia	Report; obtain cultures and chest X-ray as ordered; give antibiotics as ordered (Chapter 13)

Cue	What it may mean	Nursing action
Little or no relief from bronchodilators	Severe exacerbation or another cause, such as pneumothorax, pulmonary embolism or heart failure	Check that the drug was delivered; escalate for urgent review (Chapters 15 and 18)

GOING DEEPER

Blood Gases in Chronic CO2 Retention

Required for RN students; optional for PN students.

Some people with advanced COPD retain CO2 even when stable. Chapter 3 (section 3.7) explains how to read an ABG; this box applies those steps to chronic CO2 retention. Chapter 12's Going Deeper box covers oxygenation.

Chronic respiratory acidosis. When PaCO2 rises slowly over weeks to months, the kidneys keep more bicarbonate (HCO3−). As a rough guide, HCO3− rises about 4 mmol/L for every 10 mm Hg rise in PaCO2 in chronic respiratory acidosis, compared with only about 1 mmol/L in acute respiratory acidosis (Farley & Licari, 2019). The pH therefore stays near normal. Illustrative values (not from a patient): pH 7.35, PaCO2 60 mm Hg, HCO3− 32 mmol/L. The PaCO2 and HCO3− are both high, and the pH is at the low end of normal: a compensated respiratory acidosis.

Acute-on-chronic. During an exacerbation, PaCO2 can climb faster than the kidneys can respond. Illustrative values: pH 7.25, PaCO2 80 mm Hg, HCO3− 34 mmol/L. The high HCO3− shows the old, chronic retention; the falling pH shows a new, acute rise in CO2 on top of it. This pattern, with drowsiness or tiring, needs urgent escalation, and the team may consider NIV (Chapter 15). The patient's own baseline values, if known from earlier stable blood gases, are the best comparison.

Why the oxygen target is lower. In people at risk, high oxygen concentrations can raise PaCO2, mainly by worsening the match between ventilation and blood flow, not by switching off a "hypoxic drive" (Abdo & Heunks, 2012). A target of 88% to 92% supplies enough oxygen while limiting this effect (O'Driscoll et al., 2017). Withholding oxygen from a hypoxemic patient is never the answer.

14.5 Smoking and Vaping Cessation

No other cause of illness and death in Canada is as preventable as smoking tobacco (Thombs et al., 2025). A hospital stay is a good time to stop: the patient cannot smoke on the unit and is surrounded by people who can help. Chapters 12 and 13 point here for cessation.

Tobacco and Vaping in Canada

In the 2022 Canadian Tobacco and Nicotine Survey, 10.9% of Canadians aged 15 and older, about 3.5 million people, currently smoked cigarettes. Among people who smoked daily, 31.4% had made at least one quit attempt lasting 24 hours in the past year (Health Canada, 2023). Vaping in the past 30 days was reported by 5.8% of people aged 15 and older, 13.6% of youth aged 15 to 19 and 19.7% of young adults aged 20 to 24. Among people who vaped, 18.8% gave quitting smoking as their reason (Health Canada, 2023).

Health Canada states that vaping nicotine can cause dependence, is not harmless, may damage the lungs through harmful chemicals and has long-term risks that are still being studied. It also states that, for a person who smokes, replacing cigarettes completely with vaping carries less harm than smoking (Health Canada, 2026a). The Canadian Task Force on Preventive Health Care suggests against using e-cigarettes to quit except in certain circumstances, citing the lack of long-term safety data (Thombs et al., 2025).

Helping in Hospital

The **Ottawa Model for Smoking Cessation** is a hospital-based program. Staff identify and document every patient's smoking status, trained staff give a standard bedside consultation, cessation medications are ordered through preprinted order forms, and patients who agree are enrolled in automated telephone follow-up after discharge, with calls from cessation nurse specialists for those who relapse or lose confidence (Mullen et al., 2017). In a study at 14 Ontario hospitals, patients who received the program had fewer readmissions than usual-care controls at 30 days (7.1% vs 13.3%), 1 year and 2 years, and lower death rates at 1 and 2 years (Mullen et al., 2017).

The Registered Nurses' Association of Ontario (RNAO) best practice guideline asks nurses to use brief interventions to screen all patients for all forms of tobacco use, build a person-centred plan with them, provide or refer for counselling and medication, and follow up until the person's goals are met (RNAO, 2017). The Task Force likewise advises clinicians to ask patients whether they smoke and to advise those who do to quit (Thombs et al., 2025). In hospital, the nurse can put this into three steps:

- **Ask** every patient, on admission, about smoking, vaping and other tobacco use, and document it.
- **Advise** clearly and kindly to stop, linking the advice to the reason for admission.
- **Offer help** with medication to manage withdrawal now and referral for support after discharge.

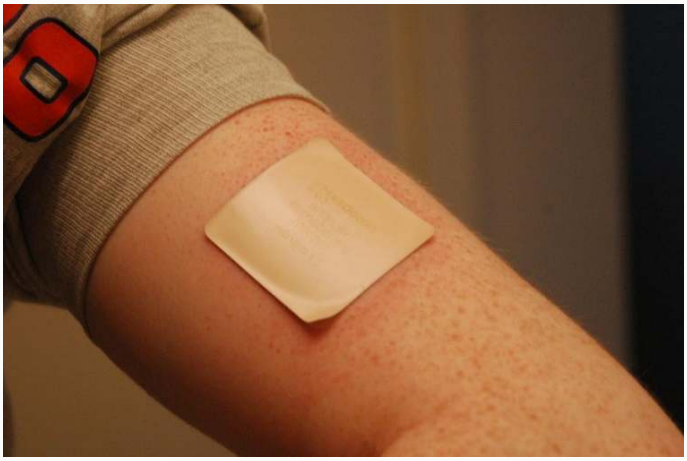

Figure 14.6 A nicotine patch on the upper arm. It gives a steady dose of nicotine through the skin; a short-acting form such as gum or a lozenge can be added for cravings. (credit: “Nicoderm” by RegBarc/Wikimedia Commons, CC BY 2.5)

A patient who cannot smoke in hospital may go into nicotine withdrawal and feel restless, irritable or anxious. Offering **nicotine replacement therapy (NRT)** early, under an order or medical directive, eases withdrawal; in the Ottawa Model, cessation medications are ordered through preprinted order forms (Mullen et al., 2017). Language matters: "a person who smokes," not "a smoker," and no blame (Chapter 11). Many people try to quit several times, and a patient who relapses is invited to plan another attempt (Thombs et al., 2025).

At discharge, the nurse connects the patient to follow-up: the provincial or territorial quit service listed by Health Canada (Health Canada, 2024) or, for First Nations, Inuit, Métis and urban Indigenous people, **Talk Tobacco**, a Canadian Cancer Society service that offers free, confidential, culturally tailored support to quit smoking, vaping or commercial tobacco (1-833-998-8255) (Canadian Cancer Society, n.d.; FNHA, n.d.).

Cessation Medications

Canada's Task Force strongly recommends four medications to help adults stop smoking: NRT, varenicline, bupropion and cytisine. It also recommends combining medication with behavioural support (Thombs et al., 2025). Table 14.4 summarizes them. NRT comes as a long-acting patch (Figure 14.6) and short-acting forms such as gum and lozenges. Alberta's adult inpatient algorithm, for example, pairs a patch with a short-acting form for breakthrough cravings (Alberta Health Services [AHS], 2025). **Varenicline** is a prescription tablet that partly stimulates the brain's nicotine receptors (Auro Pharma, 2025). Bupropion for smoking cessation is sold as Zyban (Bausch Health, 2023). Cytisine is approved in Canada as a natural health product; the Task Force notes that, unlike NRT, it lacks coverage (Thombs et al., 2025).

Table 14.4 Smoking cessation medications in Canada (AHS, 2025; Auro Pharma, 2025; Bausch Health, 2023; Thombs et al., 2025; original wording)

Medication	How it helps	Key cautions	Nursing points
Nicotine patch (NRT)	Gives a steady dose of nicotine through the skin to ease withdrawal	May slightly increase palpitations or chest pain; few other harms	Offer early in the stay under an order or directive; ask about cravings each shift; pair with a short-acting form if ordered
Short-acting NRT (such as gum or lozenge)	Delivers nicotine quickly to relieve sudden cravings	As for the patch	Teach the patient to use it when cravings strike; combined with a patch when ordered

Medication	How it helps	Key cautions	Nursing points
Varenicline	Partly stimulates nicotine receptors, easing craving and withdrawal	Serious neuropsychiatric symptoms reported after marketing; caution with heart disease and with a history of seizures; alcohol may raise the risk of psychiatric effects; lower dose in severe kidney impairment	Nausea is the most common adverse effect; started 1 to 2 weeks before a set quit date, or with a flexible quit date; caution with driving until the person knows how it affects them; use with counselling
Bupropion (Zyban)	Non-nicotine tablet used with behavioural support	Contraindicated with seizures or a seizure history, current or past bulimia or anorexia nervosa, monoamine oxidase (MAO) inhibitors, other bupropion products, or abrupt withdrawal from alcohol or sedatives; seizure risk rises with dose; risk of self-harm and suicidal thinking	Start while the person is still smoking; dry mouth and insomnia are common; ask about seizures, eating disorders and other bupropion products such as Wellbutrin
Cytisine	Recommended cessation aid in Canadian guidance	Approved as a natural health product; check the licensed product information for cautions	Not covered, unlike NRT; the nurse includes it in the list of options the patient can discuss with the prescriber or pharmacist

Commercial and Traditional Tobacco

For many First Nations, tobacco is a sacred medicine. It is burned in ceremony, used in smudging and pipe ceremonies, placed as an offering and given as a gift to Elders and Knowledge Keepers. This **traditional tobacco** is different from **commercial tobacco**: cigarettes, chew and snuff with added chemicals that make them more addictive; commercial tobacco is linked to lung disease, heart disease and several cancers (FNHA, n.d.). The First Nations Health Authority in British Columbia describes its goal as keeping tobacco sacred while reducing commercial tobacco use (FNHA, n.d.).

Practices differ among First Nations, Inuit and Métis communities and individuals, so the nurse asks rather than assumes. Cessation advice addresses commercial tobacco, never ceremony. A patient who wishes to have a smudge or other ceremony in hospital is supported through the hospital's Indigenous health team and policy (Chapter 2).

14.6 Bronchiectasis, Interstitial Lung Disease and Sleep Apnea

The three conditions in this section are less common than COPD, but nurses meet them on every medical unit. Bronchiectasis is an airway disease, interstitial lung disease scars the lung itself, and obstructive sleep apnea is a disorder of breathing during sleep.

Bronchiectasis

Bronchiectasis is permanent widening of the bronchi, seen on chest computed tomography (CT), together with typical symptoms (Chalmers et al., 2025). Damaged airways clear mucus poorly. Mucus pools, bacteria grow, inflammation damages the airways further and the cycle continues. Bronchiectasis has many causes, infectious and immune among them. Daily symptoms and exacerbations, when cough, sputum and breathlessness worsen, matter most to patients (Chalmers et al., 2025).

The European Respiratory Society (ERS) 2025 guideline recommends airway clearance techniques for most patients and pulmonary rehabilitation for those with reduced exercise capacity. It recommends long-term macrolide treatment for people at high risk of exacerbations, and long-term inhaled antibiotics for people with chronic *Pseudomonas aeruginosa* infection who are at high risk. It suggests against routine ICS (Chalmers et al., 2025). The nurse supports daily airway clearance with the physiotherapist or respiratory therapist (Chapter 12), sends sputum cultures as ordered, and teaches the patient to report a change in sputum early. People who cough up sputum every day know their own baseline well, so the nurse asks what is usual for them and reports more sputum, thicker or darker sputum, fever or new breathlessness. The Thoracic Society of Australia and New Zealand (TSANZ) includes bronchiectasis among the conditions for which an oxygen target of 88% to 92% is recommended (Barnett et al., 2022; Chapter 12).

Interstitial Lung Disease

Interstitial lung disease (ILD) is a group of disorders that inflame or scar the lung tissue between the alveoli and blood vessels. Scarring makes the lungs stiff and small and thickens the barrier oxygen must cross: a restrictive pattern (section 14.1). Some ILDs occur with connective tissue diseases such as systemic sclerosis (Boehringer Ingelheim, 2024; Chapter 34); others have other identifiable causes, and some have no known cause.

Idiopathic pulmonary fibrosis (IPF), a scarring ILD of unknown cause, is the most familiar. Patients typically describe slowly worsening breathlessness on exertion and a dry cough. On auscultation, fine crackles that sound like Velcro being pulled apart may be heard at the lung bases (Chapter 12), and some patients have clubbing. Diagnosis rests on high-resolution CT and discussion among specialists (Raghu et al., 2018).

Antifibrotic drugs slow the loss of lung function but do not reverse scarring:

- **Nintedanib** (Ofev) is approved for IPF and for other progressive fibrosing ILDs. Diarrhea is the most common adverse effect. It raises bleeding risk, needs liver tests before and during treatment, is taken with food and must not be used in pregnancy (Boehringer Ingelheim, 2024).
- **Pirfenidone** is approved for IPF. Nausea and rash are common. Patients avoid sun exposure and use a high-protection sunscreen, take it with food and have regular liver tests. Smoking lowers the drug's level, so patients stop smoking before starting it (Sandoz Canada, 2024).

SpO2 can fall during activity even when it is acceptable at rest, so the nurse checks it while the patient walks or receives care, titrates oxygen within the order, paces activity and reports a rising oxygen need, which can signal progression or a new problem such as infection. Care also includes oxygen when needed (Chapter 12) and pulmonary rehabilitation, which improves exercise capacity in ILD (Rochester et al., 2023). Because IPF shortens life, an early palliative approach that addresses breathlessness, cough and planning is part of good care (Chapter 10).

Figure 14.7 A home CPAP machine with its tubing and mask. People who use CPAP at home are encouraged to bring their machine to hospital and use it whenever they sleep. (credit: “ResMed CPAP machine and mask” by Infrogmation/Wikimedia Commons, CC BY-SA 4.0)

Obstructive Sleep Apnea

In **obstructive sleep apnea (OSA)**, the upper airway collapses again and again during sleep. Each collapse stops or reduces airflow until the brain briefly wakes the person to reopen it. Sleep is broken and of poor quality, so people feel sleepy and less alert by day (Ayas et al., 2014). OSA is common: Ayas et al. (2014) report it in about 24% of middle-aged men and 9% of middle-aged women.

The **STOP-Bang** questionnaire is a quick screening tool. It asks about loud snoring, daytime tiredness, observed pauses in breathing and high blood pressure, then adds a body mass index over 35 kg/m², age over 50, a neck circumference over 40 cm and male sex. Each "yes" scores a point: 0 to 2 points suggests low risk, 3 to 4 moderate risk and 5 to 8 high risk (Chung et al., 2016). Screening only flags risk. Diagnosis needs a sleep study, done in a sleep laboratory or at home.

The usual treatment is **continuous positive airway pressure (CPAP)**: a machine blows air through a mask at a set pressure that holds the airway open (Figure 14.7). Many people find the mask hard to get used to. Nurses help with mask fit, dry mouth and claustrophobia and encourage nightly use.

On admission, the nurse asks about snoring, daytime sleepiness and home CPAP, uses STOP-Bang if the hospital does, and reports a high score before surgery or sedation.

People who use CPAP at home are encouraged to bring their machine to hospital, as policy allows, and to use it whenever they sleep, including naps. The nurse records the settings and mask type, follows policy for checking the equipment and involves the respiratory therapist. OSA raises the risk of breathing problems around surgery (Memtsoudis et al., 2018; Chapter 7). Untreated OSA raises the risk of motor vehicle crashes, and people who use CPAP consistently have a crash risk similar to others their age. Each province decides on driving restrictions through its licensing authority, and clinicians use the visit to teach about drowsy driving (Ayas et al., 2014).

CLINICAL SAFETY

Sleep Apnea, Opioids and Sedation

People with OSA may be at greater risk of breathing complications from opioids and from propofol used for procedural sedation, and intravenous benzodiazepine sedation calls for caution (Memtsoudis et al., 2018). Their airway tends to collapse during sleep, and these drugs deepen sedation and blunt the body's response to low oxygen and high CO2. For any patient with known or suspected OSA (a high STOP-Bang score), the nurse:

- monitors sedation level and respiratory rate before each opioid dose and at the peak of its effect, using the hospital's sedation scale (Chapter 5, section 5.4);
- watches for snoring followed by silent pauses, which signal obstruction;
- places CPAP on the patient whenever they sleep, as ordered;
- uses continuous SpO2 or capnography monitoring as ordered or as policy requires;
- reviews every sedating drug on the medication record, including sleeping pills, and asks the prescriber about combinations;
- holds the dose and escalates at once if the patient is hard to rouse or breathing slows.

SCOPE IN PRACTICE

Inhalers, Nebulizers, Oxygen and Cessation Support

- **Authority:** In Ontario, administering a substance by inhalation is a controlled act. RNs and RPNs may perform it, including giving inhalers, nebulized drugs and oxygen, with an order or a medical directive. Nurses cannot initiate controlled acts in public hospitals (College of Nurses of Ontario [CNO], 2025). Titrating oxygen to a target range follows the order or directive (CRTO, 2022). Respiratory therapists are authorized to administer substances by inhalation and may start, titrate and stop oxygen without an order (CRTO, 2024); they often lead this care. In hospital, cessation medications such as NRT are given under an order or directive (Mullen et al., 2017).
- **Competence:** The nurse needs the knowledge, skill and judgment to do the activity safely (CNO, 2025). That means knowing the device, the drug, the oxygen target and what to watch for. Nebulizers generate aerosols, so the nurse follows infection prevention and control (IPAC) precautions (Chapter 4). Brief cessation counselling is part of every nurse's practice (RNAO, 2017).
- **Context:** The setting, resources and patient's needs shape who does what (CNO, 2025). Employer policy may limit, but never expand, scope, and rules differ by province or territory.
- **Deterioration:** Every nurse who sees a patient deteriorate acts at once and escalates (Chapter 6). The RPN consults the RN as the patient's needs change, for example when oxygen needs rise or drowsiness appears.

PRACTICE STORY

Second Time This Month

Names and details are fictional; this is a composite story.

Nurse: Ngozi Eze, RN. Years in practice: 6. Setting: medical unit, community hospital, Ontario.

I recognized Mr. Leblanc the moment I saw his name on the board. He had gone home from our unit 19 days earlier after a COPD flare-up, and now he was back, sitting on the edge of the stretcher, leaning on his elbows, talking in short phrases. His SpO2 was 86% on room air.

I started oxygen by nasal cannula under our directive and titrated to his ordered target of 88% to 92%. Once he settled, I asked him to show me how he used his inhalers. He shook the dry powder inhaler, breathed out into the mouthpiece and then took a slow, gentle breath in. Much of each dose had probably never reached his lungs. No one had watched him use it at discharge; we had only asked whether he knew how.

That evening he was restless and irritable, and he admitted he had been smoking about ten cigarettes a day again. I said nothing about blame. I asked how he was managing the cravings, and he laughed and said, "I'm not." Under our hospital's Ottawa Model directive, I offered a nicotine patch, and the physician added nicotine gum for breakthrough cravings. He agreed to the follow-up calls.

Before discharge, the RPN on my team, Daniel, and I went through his action plan with him and his daughter. Daniel had him demonstrate his inhaler technique twice more. I made sure the physician's referral went to the pulmonary rehabilitation program and called them myself to book his intake for the next week, within the 3-week window after discharge. His daughter asked why no one had mentioned rehabilitation before. I did not have a good answer.

Six weeks later, Mr. Leblanc's daughter left a card at the desk. He had been to eight rehabilitation classes and was walking to the corner store again.

Reflect: Which actions in this story could Daniel, the RPN, carry out on his own, and when should he consult the RN? What changes on your unit would make sure every patient's inhaler technique is watched, not just asked about, before discharge?

Chapter 14 Summary

Introduction

- Asthma and COPD are common long-term lung diseases in Canada; CCDSS data counted about 3.8 million people aged 1 and older with asthma and 2.0 million aged 35 and older with COPD in 2011–2012.
- COPD and bronchitis were the second most common reason for a hospital stay in Canada in 2023–2024.
- This chapter covers obstructive and restrictive disease, asthma, inhalers, COPD, cessation, bronchiectasis, interstitial lung disease and sleep apnea.

14.1 Obstructive and Restrictive Patterns

- Obstruction narrows airways and traps air; restriction keeps the lungs from filling.
- Spirometry measures FVC, FEV1 and their ratio; a reduced FEV1/FVC ratio shows obstruction.
- Restriction is suggested by a low FVC with a normal or high ratio and confirmed by lung volume testing.
- An FEV1 rise of at least 12% and 200 mL after a bronchodilator shows reversibility that supports asthma.
- The nurse prepares the patient, holds bronchodilators only as instructed, and coaches full effort.

14.2 Asthma

- Asthma involves airway inflammation, hyperresponsiveness, variable narrowing and mucus; triggers include viruses, allergens, smoke (including wildfire smoke), work exposures and some medicines.
- Diagnosis needs a compatible history plus objective proof of variable airflow obstruction.
- CTS treatment builds on inhaled corticosteroids; as-needed budesonide–formoterol and MART are key options, and frequent SABA use signals poor control.
- Every person with asthma needs a written action plan.
- In an exacerbation, drowsiness, a silent chest, SpO2 below 92% and a normal or rising PaCO2 are life-threatening signs that need immediate escalation.

14.3 Inhaled Medications and Devices

- Relievers open airways within minutes; controllers prevent symptoms and flare-ups.
- A pMDI needs a slow, deep breath, ideally through a spacer; a dry powder inhaler needs a fast, forceful breath.
- The device must fit the person's inspiratory flow, coordination, hands, cognition and vision.
- The nurse checks technique at every opportunity with observed demonstration and teach-back.

14.4 Chronic Obstructive Pulmonary Disease

- COPD causes airflow obstruction that does not fully reverse; chronic bronchitis and emphysema both lead to air trapping and hyperinflation.
- COPD and bronchitis were the second most common reason for hospital stays in Canada in 2023–2024; smoking is the main cause, and many people are never diagnosed.
- A post-bronchodilator FEV1/FVC below 0.70 confirms COPD; the CTS adds symptom burden (mMRC, CAT) and exacerbation risk to guide treatment.
- The CTS 2023 guideline calls for long-acting bronchodilators for all symptomatic patients, LAMA/LABA for most, and triple therapy for those at high exacerbation risk, with cessation, vaccination, rehabilitation and an action plan.
- In an exacerbation, the nurse gives oxygen to 88% to 92%, short-acting bronchodilators, a short steroid course and antibiotics for purulent sputum as ordered, and escalates new drowsiness at once.
- Discharge includes a technique check, an action plan, pulmonary rehabilitation referral and follow-up.

14.5 Smoking and Vaping Cessation

- In 2022, 10.9% of Canadians aged 15 and older smoked cigarettes, and vaping was most common among young adults.
- The Ottawa Model identifies every patient who smokes, offers counselling and medication in hospital and follows up after discharge; it lowered readmissions and deaths in Ontario hospitals.
- NRT, varenicline, bupropion and cytisine are recommended in Canada, ideally with behavioural support; bupropion is contraindicated with seizures.
- Cessation support addresses commercial tobacco and respects traditional tobacco used in ceremony.

14.6 Bronchiectasis, Interstitial Lung Disease and Sleep Apnea

- Bronchiectasis is permanent widening of the bronchi; daily airway clearance is recommended for most patients.
- IPF causes exertional breathlessness, dry cough and fine basal crackles; nintedanib and pirfenidone slow decline, and an early palliative approach is part of care.
- STOP-Bang screens for OSA, a sleep study confirms it, and CPAP treats it; patients use their CPAP whenever they sleep in hospital.
- People with OSA are more sensitive to opioids and sedatives, so the nurse monitors sedation and breathing closely.
- RNs and RPNs give inhaled drugs and titrate oxygen under orders or directives; every nurse escalates deterioration at once.

Key Terms (57)

acute exacerbation of COPD: A sudden flare-up in which symptoms such as breathlessness, sputum volume or sputum purulence get worse over a period of days, 14 days at most.

air trapping: Air left behind in the lungs at the end of each breath because narrowed or unsupported small airways close early during exhalation.

airway hyperresponsiveness: A tendency of the airways to narrow quickly and strongly in response to stimuli that barely affect other people.

alpha-1 antitrypsin deficiency: An inherited lack of a protein that protects the lungs from damage; a genetic risk factor for COPD.

antifibrotic: A drug, such as nintedanib or pirfenidone, that slows the loss of lung function in pulmonary fibrosis without reversing scarring.

asthma: A chronic, usually inflammatory airway disease with variable symptoms and variable airflow limitation.

asthma control: How well treatment keeps asthma symptoms and exacerbations away, judged against set criteria.

asthma exacerbation: A flare in which asthma symptoms and lung function worsen beyond the person's usual variation.

biologic: An injected antibody medicine that blocks a specific step in airway inflammation, used for some people with severe asthma.

bronchiectasis: Permanent widening of the bronchi, seen on CT, with chronic symptoms and recurrent exacerbations.

bronchoconstriction: Tightening of the smooth muscle around the airways, which narrows them.

chronic bronchitis: Long-standing airway inflammation with thickened airway walls, excess mucus and a cough that brings up sputum on most days.

chronic obstructive pulmonary disease (COPD): A long-term lung condition in which damaged airways, damaged alveoli or both cause airflow obstruction that does not fully reverse and often worsens over time.

commercial tobacco: Manufactured tobacco products, such as cigarettes, chew and snuff, that contain added chemicals and cause addiction and disease.

compensated respiratory acidosis: A high PaCO2 balanced by a rise in bicarbonate retained by the kidneys, so the pH is near normal.

continuous positive airway pressure (CPAP): A machine that delivers air through a mask at a set pressure to hold the upper airway open during sleep.

controller: An inhaled medicine used regularly to reduce airway inflammation or keep airways open, preventing symptoms and flare-ups.

COPD Assessment Test (CAT): A short questionnaire that measures the effect of COPD on daily life; a score of 10 or more shows a moderate to high symptom burden.

diffusing capacity: A test of how well gas crosses from the alveoli into the blood, measured with a small amount of carbon monoxide.

dry powder inhaler (DPI): A device that holds medicine as a powder released by the patient's own fast, forceful breath.

emphysema: Destruction of alveolar walls that reduces the surface for gas exchange and the lung's elastic recoil.

FEV1/FVC ratio: The share of the forced vital capacity blown out in the first second; a reduced ratio shows airflow obstruction.

forced expiratory volume in 1 second (FEV1): The volume of air blown out in the first second of a forced breath.

forced vital capacity (FVC): The total volume of air blown out in one full, forced breath.

hypercapnia: A raised level of carbon dioxide in arterial blood.

hyperinflation: An abnormally large lung volume caused by air trapping, which flattens the diaphragm and makes breathing less efficient.

ICS–formoterol reliever: Budesonide–formoterol used as needed for symptoms, so each reliever dose also treats inflammation.

idiopathic pulmonary fibrosis (IPF): A scarring interstitial lung disease of unknown cause.

inhaled corticosteroid (ICS): An inhaled anti-inflammatory controller, such as fluticasone or budesonide.

interstitial lung disease (ILD): A group of disorders that inflame or scar the lung tissue between the alveoli and blood vessels, causing a restrictive pattern.

long-acting beta2-agonist (LABA): A bronchodilator that keeps airways open for many hours; in asthma it is always combined with an inhaled corticosteroid.

long-acting muscarinic antagonist (LAMA): A long-acting bronchodilator, such as tiotropium, used mainly in COPD and as an add-on in asthma.

lower limit of normal (LLN): The value below which only 5% of healthy people fall; used to judge whether a lung function result is abnormal.

maintenance and reliever therapy (MART): Use of one budesonide–formoterol inhaler both as the daily controller and as the reliever for symptoms.

nebulizer: A device that turns liquid medicine into a mist breathed in through a mouthpiece or mask.

nicotine replacement therapy (NRT): Medication that supplies nicotine without tobacco smoke, as a patch or short-acting forms such as gum and lozenges, to ease withdrawal and cravings.

obstructive lung disease: Lung disease in which narrowed airways slow the flow of air out of the lungs and trap air, as in asthma and COPD.

obstructive sleep apnea (OSA): Repeated collapse of the upper airway during sleep, causing broken sleep and daytime sleepiness.

Ottawa Model for Smoking Cessation: A hospital program that identifies every patient who smokes, provides bedside counselling and medication, and follows patients after discharge.

peak expiratory flow (PEF): The fastest speed of air during a short, sharp blow into a hand-held meter.

pressurized metered-dose inhaler (pMDI): A device that releases a measured puff of medicine in a propellant spray.

pulmonary rehabilitation: A supervised, tailored program of exercise training, education and behaviour change for people with chronic lung disease.

reliever: An inhaled medicine that opens narrowed airways within minutes and is used for symptoms.

restrictive lung disease: Lung disease in which stiff lungs or a limited chest wall keep the lungs from filling, so lung volumes are small.

reversibility: A meaningful improvement in airflow after a bronchodilator or a course of controller treatment; in the CTS asthma guideline, an FEV1 rise of at least 12% and 200 mL.

severe asthma: Asthma that stays uncontrolled despite high-level inhaled treatment, needing specialist assessment.

short-acting beta2-agonist (SABA): A reliever, such as salbutamol, that relaxes airway smooth muscle within minutes.

short-acting muscarinic antagonist (SAMA): A short-acting bronchodilator, such as ipratropium, that blocks the nerve signals that tighten airway muscle.

silent chest: A life-threatening sign in asthma in which so little air moves that wheeze can no longer be heard.

soft mist inhaler: A device that releases a slow-moving mist of liquid medicine during a slow, deep breath.

spacer: A tube, often with a valve (valved holding chamber), that attaches to a pMDI and holds the puff so it can be breathed in without precise timing.

spirometry: A breathing test that measures how much air a person can blow out after a full breath in, and how fast.

STOP-Bang: An eight-item screening questionnaire for obstructive sleep apnea that scores snoring, tiredness, observed apnea, blood pressure, BMI, age, neck circumference and sex.

traditional tobacco: Tobacco used by many First Nations as a sacred medicine in ceremony, offerings and gifts; distinct from commercial tobacco.

triple therapy: Maintenance treatment with a LAMA, a LABA and an ICS, usually in one inhaler, for people with COPD at high risk of exacerbations.

varenicline: A prescription cessation medication that partly stimulates nicotine receptors, easing cravings and withdrawal.

written action plan: A personal written guide that tells a person with asthma how to recognize worsening, step up treatment and seek help.

Licensure Review & Clinical Judgment Questions (35)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

Case: Marisol Vega (Questions 1–4): Marisol Vega, 41, is admitted to a medical unit in Kingston, Ontario, with an asthma exacerbation that began after a cold. She uses a salbutamol inhaler "almost every day" and stopped her steroid inhaler months ago because of the cost. On arrival she is sitting upright, speaking in short phrases and using her neck muscles to breathe. Her respiratory rate is 28 breaths/min, heart rate 112 beats/min and SpO2 92% on room air. An RPN and an RN share her care.

1. [CORE] Which finding in Ms. Vega's admission assessment is a feature of acute severe asthma?

a. Sitting upright to breathe
b. A respiratory rate of 28 breaths/min
c. Daily use of salbutamol before admission
d. The recent cold that preceded the exacerbation

Answer: b — A respiratory rate of 25 breaths/min or more is a feature of acute severe asthma, as are being unable to finish sentences in one breath and a heart rate of 110 beats/min or more, which Ms. Vega also shows (section 14.2). Sitting upright is a common position of comfort and does not grade severity on its own. Daily salbutamol use shows poor control before admission, not the severity of today's flare. A viral infection is a trigger, not a severity finding.

2. [CORE] Salbutamol by metered-dose inhaler with a spacer and oxygen to the ordered target are prescribed. What should the nurse do first?

a. Teach her how to use her inhaler correctly
b. Obtain a peak flow reading to confirm the diagnosis
c. Give the salbutamol as ordered while staying with her
d. Ask the pharmacist about coverage for her steroid inhaler

Answer: c — Treating airway narrowing comes first; the nurse gives the ordered bronchodilator and stays to watch her response (section 14.2). Teaching technique matters, but not while she is breathless. Peak flow helps judge severity and response, but it should not delay treatment, and her asthma diagnosis is not in question. Coverage is an important barrier to address before discharge, not a first action.

3. [CORE] One hour after treatment, which finding shows that Ms. Vega is responding?

a. She speaks in full sentences and her respiratory rate is 20 breaths/min
b. Her wheeze is quieter and she is more drowsy than before
c. Her heart rate has risen to 120 beats/min with a fine tremor
d. She asks to lie flat and her SpO2 is 89% on oxygen

Answer: a — Full sentences and a slower respiratory rate show improved airflow and less work of breathing (section 14.2). A quieter chest with drowsiness may mean less air is moving and the patient is tiring, which is a life-threatening sign. Faster heart rate and tremor are expected salbutamol effects and do not show improvement. Falling SpO2 on oxygen is a sign of worsening, not response.

4. [CORE] Ms. Vega is ready for discharge with a budesonide–formoterol inhaler. Which statement shows she needs more teaching?

a. "I'll rinse my mouth and spit after I use it."
b. "I'll bring my action plan to my follow-up visit this week."
c. "If I need my reliever more than twice a week, I'll call my provider."
d. "Once I feel better, I can stop it and just use salbutamol."

Answer: d — Stopping her controller and relying on a SABA alone repeats the pattern that led to this admission; a SABA relieves symptoms but does not treat inflammation, the CTS advises a controller after a severe exacerbation in a person using a SABA alone, and GINA links SABA-only treatment to more exacerbations (sections 14.2 and 14.3). Rinsing and spitting after an ICS-containing inhaler prevents thrush. Early follow-up with her action plan is recommended. Needing a reliever more than twice a week signals poor control and should be reported.

5. [CORE] A patient's spirometry report shows a reduced FEV1/FVC ratio. What does this finding mean?

a. Air leaves the lungs slowly because the airways are narrowed
b. The lungs are stiff and cannot fill to a normal volume
c. Gas moves poorly from the alveoli into the blood
d. The patient did not give full effort during the test

Answer: a — A reduced FEV1/FVC ratio means a smaller share of air leaves in the first second, the mark of airflow obstruction (section 14.1). In restriction, FEV1 and FVC fall together, so the ratio is normal or high. Gas transfer is measured by diffusing capacity, not this ratio. Poor effort makes results unreliable but is judged by test quality criteria, not by a low ratio.

6. [CORE] The nurse watches a patient use a pressurized metered-dose inhaler without a spacer. Which actions are errors that the nurse should correct? Select all that apply.

a. Breathing in quickly and forcefully as the canister is pressed
b. Shaking the inhaler before the dose
c. Pressing the canister after the breath in is finished
d. Breathing out away from the mouthpiece before the dose
e. Breathing out right after the puff without holding the breath
f. Waiting about 30 seconds before the second puff

Answer: a, c, e — A pMDI needs a slow, deep breath started just before the canister is pressed, followed by a breath-hold (section 14.3, Table 14.2). Breathing in fast, pressing after the breath is over and skipping the breath-hold all reduce the dose reaching the lungs. Shaking the inhaler, breathing out first and waiting about 30 seconds between puffs are correct steps.

7. [CORE] A patient starting fluticasone propionate by inhaler asks why the nurse recommends rinsing after each dose. Which response is accurate?

a. "Rinsing makes the medicine work faster in your lungs."
b. "Rinsing prevents the shakiness this medicine can cause."
c. "Rinsing removes the propellant that can harm your teeth."
d. "Rinsing and spitting helps prevent thrush and a hoarse voice."

Answer: d — Inhaled corticosteroid left in the mouth and throat can cause thrush and hoarseness; rinsing with water and spitting reduces this (section 14.2, Medications box). Rinsing does not change how fast the medicine acts in the lungs. Tremor is a beta2-agonist effect, not an ICS effect. Protecting teeth from propellant is not the reason for rinsing.

8. [CORE] A patient with asthma says, "I only use my blue puffer, and I go through about four of them a year." What is the nurse's best interpretation?

a. Her asthma is well controlled because she avoids daily medicine
b. Her reliever use suggests poor control and a higher risk of exacerbations
c. She needs a stronger short-acting reliever to reduce the number of inhalers
d. Her use is normal for someone with mild asthma

Answer: b — Using more than two SABA inhalers a year should prompt reassessment, and treating asthma with a SABA alone is linked to more exacerbations and a higher risk of death (section 14.2). Avoiding a controller is not a sign of good control. A stronger short-acting reliever does not treat airway inflammation. This level of use is not normal for well-controlled mild asthma.

9. [CORE] Why does the nurse encourage a patient who uses an inhaled corticosteroid by metered-dose inhaler to use a valved holding chamber (spacer)?

a. It allows two puffs to be sprayed into the chamber at once
b. It removes the need to shake the inhaler before each puff
c. It holds the puff so precise timing with the breath matters less
d. It lets the patient breathe in quickly and forcefully through it

Answer: c — A spacer holds the puff so the patient can breathe it in without precise timing, and it reduces medicine left in the mouth; the CTS recommends one for all ages prescribed a pMDI (section 14.3). Puffs go into the spacer one at a time. The inhaler still needs shaking. A slow, deep breath is needed with a spacer; a fast, forceful breath is for dry powder inhalers.

10. [CORE] During a summer of wildfires in northern Ontario, a patient with asthma asks how the smoke affects her. Which response is accurate?

a. "Fine particles in the smoke can trigger asthma attacks, even when you can't see smoke."
b. "Smoke affects only people who work outdoors near the fire."
c. "If you can't smell smoke, the air is safe for your lungs."
d. "Wildfire smoke irritates the eyes but does not affect asthma."

Answer: a — Fine particles (PM2.5) are the main health risk in wildfire smoke, they cannot be seen, and asthma attacks are among the more serious effects (section 14.2). Outdoor workers face more exposure, but anyone breathing the smoke can be affected, especially people with lung conditions. Air quality can be poor without any visible or smelled smoke. The smoke affects the airways as well as the eyes.

11. [CORE] An RPN on a medical unit is caring for a patient admitted with asthma. The patient becomes drowsy, the wheeze becomes faint and SpO2 falls despite oxygen. What should the RPN do?

a. Document the findings and reassess in 1 hour
b. Give an extra dose of salbutamol without an order
c. Ask the patient's family to keep the patient awake
d. Stay with the patient, call for immediate help and notify the RN

Answer: d — Drowsiness, a quiet chest and falling SpO2 are life-threatening signs; every nurse who recognizes deterioration acts at once and escalates, through the rapid response team where the employer has one, and the RPN consults the RN as the patient's needs change (section 14.2; Chapter 1, section 1.3). Waiting an hour delays urgent care. Giving medication without an order or directive is outside the nurse's authority. Family cannot replace urgent clinical assessment.

12. [CORE] A patient is booked for spirometry to help diagnose asthma. Which instruction should the nurse give?

a. "Take an extra puff of your reliever just before the test so you can blow harder."
b. "Follow the lab's instructions about holding your inhalers, and don't smoke for an hour before."
c. "Eat a large meal shortly before the test so you have enough energy to blow."
d. "Wear a snug belt to support your abdomen while you blow out during the test."

Answer: b — For diagnostic testing, bronchodilators are held only as the laboratory or prescriber instructs, and smoking is avoided for 1 hour beforehand (section 14.1). A dose just before the test could hide reversible obstruction. Large meals within 2 hours and tight clothing interfere with full breaths.

13. [CORE] Which spirometry pattern suggests a restrictive lung disease such as pulmonary fibrosis?

a. Reduced FEV1/FVC ratio with a large rise in FEV1 after a bronchodilator
b. Reduced FEV1/FVC ratio with no change after a bronchodilator
c. Reduced FVC with a normal or high FEV1/FVC ratio
d. Normal FVC with a reduced FEV1

Answer: c — In restriction, the lungs cannot fill fully, so FVC and FEV1 fall together and the ratio stays normal or high; lung volume testing confirms it (section 14.1). A reduced ratio with a large bronchodilator response suggests asthma. A reduced ratio without reversibility suggests fixed obstruction such as COPD. A normal FVC with a low FEV1 lowers the ratio, which is an obstructive pattern.

14. [CORE] A patient with a dry powder inhaler asks how to breathe in. Which instruction is correct?

a. "Breathe in fast, deep and hard from the start."
b. "Breathe in slowly over 5 seconds, as with your puffer."
c. "Breathe out into the mouthpiece first to warm it."
d. "Take several small breaths through the device."

Answer: a — A dry powder inhaler has no propellant, so the patient's own fast, forceful, deep breath releases the powder (section 14.3). A slow breath suits a pMDI or soft mist inhaler. Breathing out into a DPI can blow the powder out and dampen it. Small breaths may not draw out the full dose.

15. [CORE] Which finding is consistent with the CTS criteria for well-controlled asthma?

a. Waking at night with cough two nights a week
b. Missing one day of work a month because of asthma
c. Using the reliever five times a week
d. Using the reliever once a week, with normal activity

Answer: d — The CTS criteria include reliever use 2 times a week or fewer and normal physical activity (section 14.2). Night symptoms should occur less than once a week. Any time lost from work because of asthma means it is not well controlled. Reliever use five times a week exceeds the limit.

16. [RN] A patient with severe asthma has been breathing at 34 breaths/min for several hours. An arterial blood gas now shows a PaCO2 of 42 mm Hg. How should the RN interpret this result?

a. Reassuring, because the value lies within the normal range
b. A warning sign that the patient is tiring and may be developing respiratory failure
c. Evidence that the bronchodilator treatment has been effective
d. Expected in asthma, because carbon dioxide is retained in all exacerbations

Answer: b — Early in an attack, fast breathing lowers PaCO2; a "normal" value in a patient who has been breathing fast for hours suggests fatigue and is a life-threatening sign, and a rising value signals near-fatal asthma (section 14.2; Chapter 3, section 3.7). A normal number is not reassuring in this context. It reflects ventilation, not proof of bronchodilator effect. Carbon dioxide is usually low, not retained, in early exacerbations.

17. [RN] An 82-year-old patient with asthma is being discharged after a severe exacerbation. She is weak and short of breath, and her prescriber is choosing a new ICS-containing inhaler. Which device is the best fit for now?

a. A dry powder inhaler, because it has no propellant
b. A soft mist inhaler without teaching, because it needs no coordination
c. A pressurized metered-dose inhaler with a valved holding chamber
d. A dry powder inhaler with instructions to breathe in more forcefully

Answer: c — Older age and a recent exacerbation make low inspiratory flow more likely; a pMDI with a valved holding chamber needs only a slow breath and no precise timing (section 14.3). A DPI depends on a forceful breath she may not manage, and telling her to try harder does not fix weak inspiratory flow. Every device needs teaching and observed practice; a soft mist inhaler still requires pressing the button during a slow breath.

Case: Mrs. Agnes Kowalczyk (Questions 18–23): Mrs. Agnes Kowalczyk, 76, lives alone in Belleville, Ontario, and has COPD treated with a LAMA/LABA inhaler and a salbutamol inhaler as needed. She smokes about 10 cigarettes a day. She comes to the emergency department after 3 days of worsening breathlessness and a cough now producing thick yellow-green sputum. Her respiratory rate is 30 breaths/min, heart rate 108 beats/min, blood pressure 148/86 mm Hg, temperature 37.9 °C and SpO2 85% on room air. She is sitting forward with her hands on her knees, using her neck muscles to breathe, and speaks in short phrases. She is admitted to a medical unit.

18. [CORE] The nurse reviews Mrs. Kowalczyk's assessment. Which findings need the nurse's immediate attention?

a. Temperature 37.9 °C and blood pressure 148/86 mm Hg
b. Daily smoking and living alone
c. SpO2 85%, respiratory rate 30 breaths/min and use of neck muscles to breathe
d. Thick yellow-green sputum and a 3-day history of symptoms

Answer: c — Low oxygen saturation, fast breathing and accessory muscle use show hypoxemia and increased work of breathing, which threaten her now (section 14.4, Acute Exacerbations in Hospital; Table 14.3). A mild fever and a modest rise in blood pressure (a) need follow-up but are not immediately dangerous. Smoking and living alone (b) matter for discharge planning and cessation support, not for immediate safety. Sputum change and the time course (d) help explain the cause but are not the most urgent cues.

19. [CORE] Which explanation best fits the change in Mrs. Kowalczyk's sputum together with her worsening breathlessness?

a. An acute exacerbation of COPD, probably triggered by a respiratory infection
b. Expected day-to-day variation in stable COPD
c. A side effect of her LAMA/LABA inhaler
d. Heart failure causing pink, frothy sputum

Answer: a — An exacerbation is an acute worsening of breathlessness, cough and sputum over a few days, and infections are among the most frequent triggers (section 14.4; GOLD, 2025); purulent sputum supports infection. Her change is outside her usual pattern, so it is not normal variation (b). Long-acting bronchodilators do not cause purulent sputum (c). Heart failure can cause breathlessness, but its classic sputum is pink and frothy, not yellow-green (d), although the team still considers it.

20. [CORE] Mrs. Kowalczyk is placed on oxygen at 4 L/min by nasal cannula. Two hours later her SpO2 is 97%, and she is hard to rouse and mumbling. Which problem is the nurse's highest priority?

a. Anxiety related to breathlessness

b. Rising carbon dioxide from more oxygen than her target allows

c. Dehydration from fast breathing

d. Pain from coughing

Answer: b — In a patient at risk of hypercapnia, SpO2 above the 88% to 92% target with new drowsiness points to rising CO2, a life-threatening problem (section 14.4, Going Deeper; Table 14.3). Anxiety (a) does not cause someone to become hard to rouse. Dehydration (c) and pain (d) may need attention but do not explain sudden drowsiness and are less urgent.

21. [CORE] Which set of orders would the nurse expect for Mrs. Kowalczyk's exacerbation, based on current guidance?

a. An inhaled corticosteroid on its own, oral theophylline, and oxygen titrated to SpO2 94% to 98%

b. Oral prednisone for 14 days, no antibiotic until an X-ray confirms pneumonia, and oxygen titrated to SpO2 100%

c. An antibiotic only, with all bronchodilators held until the sputum culture and sensitivity results return

d. Short-acting bronchodilators, up to 5 days of a systemic corticosteroid, an antibiotic, and oxygen to SpO2 88% to 92%

Answer: d — GOLD advises short-acting bronchodilators first, a systemic corticosteroid course of no more than 5 days and, for patients with purulent sputum such as hers, a 5-day antibiotic course; guidelines suggest 88% to 92% for patients at risk of hypercapnia (section 14.4). An ICS alone and theophylline (a) are not recommended in COPD, and 94% to 98% is too high a target for her. A 14-day steroid course and a target of 100% (b) exceed guidance and risk harm. Bronchodilators are never held while awaiting cultures (c).

22. [CORE] The nurse finds Mrs. Kowalczyk drowsy with SpO2 97% on 4 L/min. Her order is for oxygen titrated to SpO2 88% to 92%. What should the nurse do first?

a. Remove the oxygen completely and wait for her to wake up before reassessing her breathing.

b. Increase the oxygen flow, because new drowsiness in COPD usually means worsening hypoxemia.

c. Lower the oxygen within the order to reach the target range, assess her, and call for urgent help.

d. Document the finding, notify her family and recheck her level of consciousness in 1 hour.

Answer: c — The nurse lowers oxygen within the order to the target range, assesses her and escalates at once, expecting an ABG (section 14.4; Table 14.3; Chapter 6). Stopping oxygen abruptly (a) can cause dangerous rebound hypoxemia. Her SpO2 is already above target, so more oxygen (b) would worsen CO2 retention. Documenting and waiting an hour (d) delays care for a deteriorating patient.

23. [CORE] On day 4, Mrs. Kowalczyk is preparing for discharge. Which finding best shows that the plan is working?

a. She correctly demonstrates her inhaler technique and describes when to use her action plan.

b. She asks for her oxygen to be turned up "to be safe."

c. She says she will start pulmonary rehabilitation "if things get worse again."

d. She plans to cut down to five cigarettes a day and decline follow-up calls.

Answer: a — Correct technique and understanding of the action plan are key outcomes before going home (section 14.4, Transitions home; section 14.3). Wanting more oxygen (b) suggests a misunderstanding of her target. Pulmonary rehabilitation (c) is recommended soon after a hospitalized exacerbation, not only if she worsens. Cutting down without support (d) shows the cessation plan is not yet working; the nurse continues to offer support.

24. [CORE] A nurse is supporting a hospitalized patient who smokes. Which actions reflect evidence-based cessation support? Select all that apply.

a. Asking about smoking, vaping and other tobacco use on admission and documenting the answer

b. Offering nicotine replacement therapy under an order or medical directive to manage withdrawal

c. Telling the patient that repeated relapse shows they are not ready to quit

d. Arranging follow-up support after discharge, such as a quit service or follow-up calls

e. Referring to the patient as "a smoker" in the chart to make the risk clear

f. Including the patient's preferences when choosing among medications

Answer: a, b, d, f — Screening and documenting all tobacco use (a), treating withdrawal with NRT (b), linking to follow-up (d) and shared decision-making (f) are part of the Ottawa Model, the RNAO guideline and the Task Force recommendations (section 14.5). Relapse is common and many people need several attempts, so blaming the patient (c) is wrong. Stigma-free, person-first language such as "a person who smokes" is used instead of "a smoker" (e) (Chapter 11).

25. [CORE] A patient with COPD and no oxygen target written is admitted with an exacerbation. The nurse calls the prescriber for an order. Which target range does the nurse expect?

a. 94% to 98%

b. 88% to 92%

c. 92% to 96%

d. 80% to 85%

Answer: b — For patients at risk of hypercapnic respiratory failure, including those with COPD, guidelines suggest 88% to 92% (section 14.4; Chapter 12). The ranges of 94% to 98% (a, British guideline) and 92% to 96% (c, Australian and New Zealand position statement) are for most other acutely ill adults. A range of 80% to 85% (d) is too low and risks hypoxemia.

26. [CORE] A patient with COPD is being discharged after a hospital stay for an exacerbation. Which statement about pulmonary rehabilitation should the nurse include in teaching?

a. "Rehabilitation programs are meant only for people who already need oxygen at home."

b. "It is safest to wait at least 3 months after this flare-up before you start a program."

c. "Starting a program soon after you leave hospital can lower your chance of coming back."

d. "Rehabilitation works mainly by adjusting the doses of your inhalers to suit your activity."

Answer: c — Pulmonary rehabilitation started within 3 weeks of discharge reduces readmissions, and it is strongly recommended after a hospitalized exacerbation (section 14.4; Rochester et al., 2023). It is not limited to people on oxygen (a). Waiting months (b) misses the recommended window. Rehabilitation is exercise training, education and behaviour change, not inhaler dose changes (d).

27. [CORE] A patient wearing a nicotine patch ordered under a medical directive tells the nurse, "I still get strong cravings every couple of hours." What is the nurse's best response?

a. Remove the patch, because ongoing cravings show that nicotine replacement is not working for this patient.

b. Suggest switching to vaping, because e-cigarettes relieve cravings faster than any form of NRT.

c. Advise the patient to step outside for one cigarette whenever a strong craving occurs.

d. Check the directive or ask the prescriber about adding a short-acting NRT form for cravings.

Answer: d — Inpatient algorithms, such as Alberta's, pair a patch with a short-acting form of NRT to relieve sudden cravings (section 14.5; Table 14.4). Removing the patch (a) would worsen withdrawal. The Task Force suggests against e-cigarettes for cessation except in certain circumstances, and the guidance cited in this chapter does not compare how fast vaping and NRT relieve cravings (b). Smoking (c) undermines the quit attempt.

28. [CORE] A patient with known obstructive sleep apnea is on the surgical unit after a hip replacement and is receiving an opioid for pain. Which action is most important?

a. Use CPAP whenever the patient sleeps, and monitor sedation and breathing around each opioid dose.

b. Store the CPAP machine until discharge so that it does not interfere with postoperative care.

c. Give opioid doses while the patient is asleep so that rest is not interrupted by pain assessments.

d. Rely on continuous SpO2 alone, because a normal reading rules out slow or shallow breathing.

Answer: a — People with OSA are at greater risk of breathing complications from opioids, so they use CPAP during sleep and are monitored for sedation and slow breathing (section 14.6, Clinical Safety box; Chapter 5, section 5.4). Storing the CPAP (b) raises the risk of obstruction during sleep. Giving opioids to a sleeping patient (c) bypasses sedation assessment. A patient on oxygen can have a normal SpO2 while CO2 rises, so SpO2 alone is not enough (d).

29. [CORE] A patient with idiopathic pulmonary fibrosis starts pirfenidone. Which teaching point should the nurse include?

a. Take it on an empty stomach for better absorption.

b. Avoid sun exposure and use a high-protection sunscreen.

c. The drug will reverse the scarring in the lungs within months.

d. Smoking will not affect the drug.

Answer: b — Pirfenidone commonly causes rash and photosensitivity, so patients avoid the sun and use sunscreen (section 14.6). It is taken with food to reduce nausea and dizziness (a). Antifibrotics slow the decline in lung function; they do not reverse scarring (c). Smoking lowers pirfenidone levels, and patients are asked to stop before starting it (d).

30. [CORE] An RPN on a medical unit cares for a patient with COPD who has an order for oxygen titrated to SpO2 88% to 92%. The patient's oxygen needs have risen from 1 L/min to 4 L/min over the shift, and the patient now seems more confused. What should the RPN do?

a. Keep increasing the oxygen within the order as needed and reassess the patient at the end of the shift.

b. Note the trend and wait for the respiratory therapist's next scheduled visit to review the oxygen.

c. Act at once to assess and escalate, and consult the RN about the patient's changing needs.

d. Stop the oxygen for a short trial to see whether the patient's confusion improves on room air.

Answer: c — Every nurse who notices deterioration acts at once and escalates, and the RPN consults the RN as the patient's needs change (section 14.6, Scope in Practice box; Chapter 6). Continuing to titrate without escalating (a) ignores a deteriorating trend. Waiting for a scheduled visit (b) delays care. Stopping oxygen, even briefly (d), can cause dangerous rebound hypoxemia.

31. [CORE] A patient with bronchiectasis asks why the physiotherapist wants her to do airway clearance every day, even when she feels well. Which response by the nurse is most accurate?

a. "Airway clearance is needed only during a chest infection, when there is extra mucus to remove."

b. "Doing it every day means you will not need antibiotics if you have a flare-up later."

c. "Airway clearance is mainly a way to measure how well your lungs are working at home."

d. "Damaged airways clear mucus poorly; daily clearance helps break the cycle of infection and damage."

Answer: d — In bronchiectasis, damaged airways clear mucus poorly, which leads to infection, inflammation and further damage; airway clearance is recommended for most patients (section 14.6; Chalmers et al., 2025). It is routine, not only during infection (a). It does not replace antibiotics during exacerbations (b). It is a treatment, not a measurement (c).

32. [CORE] A First Nations patient with COPD is offered cessation support and says, "I use tobacco in ceremony. I don't want to give that up." What is the nurse's best response?

a. "All tobacco harms the lungs, so ceremonial use will need to stop as well."

b. "If you want to keep using tobacco, you may not be ready for cessation support yet."

c. "You will need to decide between your ceremonies and your lung health."

d. "This support is about cigarettes and other commercial tobacco. Tell me about your smoking."

Answer: d — Traditional tobacco used in ceremony is different from commercial tobacco, and cessation support addresses commercial tobacco while respecting ceremony (section 14.5). Options a and c dismiss a sacred practice and are not culturally safe. Option b wrongly closes the door on support the patient may want.

33. [RN] A patient with severe COPD who is known to retain CO2 has these ABG results during an exacerbation: pH 7.25, PaCO2 82 mm Hg, HCO3− 35 mmol/L. How should the nurse interpret them?

a. Compensated respiratory acidosis at the patient's usual baseline

b. Metabolic alkalosis with respiratory compensation

c. Acute respiratory acidosis on top of chronic CO2 retention

d. Metabolic acidosis

Answer: c — The high HCO3− reflects long-standing kidney compensation for chronic CO2 retention, while the low pH shows a new, acute rise in CO2 that the kidneys have not matched: acute-on-chronic respiratory acidosis needing urgent escalation (section 14.4, Going Deeper). A compensated state (a) would have a near-normal pH. Metabolic alkalosis (b) needs a high pH. Metabolic acidosis (d) would show a low HCO3−.

34. [RN] A patient asks about bupropion (Zyban) to help quit smoking. Which history should the nurse report to the prescriber before it is started?

a. A history of seizures

b. Mild seasonal allergies

c. Use of a salbutamol inhaler as needed

d. A previous attempt to quit with NRT

Answer: a — The Canadian monograph lists seizures, whether current or in the past, as a contraindication, and the seizure risk rises with dose (section 14.5; Table 14.4). Seasonal allergies (b) and as-needed salbutamol (c) are not contraindications. A previous NRT attempt (d) is common and does not prevent use of bupropion.

35. [RN] According to the CTS 2023 guideline, which patient with stable COPD is the best candidate for LAMA/LABA/ICS triple therapy?

a. A patient with a CAT score of 6 and no exacerbations in the past year

b. A patient with a CAT score of 18, an FEV1 of 55% predicted and one hospital admission for an exacerbation in the past year

c. A patient with mild symptoms who wants an ICS on its own

d. A patient with a CAT score of 12 and one exacerbation treated at home with oral prednisone in the past year

Answer: b — The CTS recommends triple therapy for people at high exacerbation risk (two or more moderate or at least one severe exacerbation in the past year) with moderate to high symptoms and impaired lung function; one hospitalization counts as severe (section 14.4). A patient with low symptoms and no exacerbations (a) is at low risk and would usually start one long-acting bronchodilator. ICS on its own (c) is not recommended. One moderate exacerbation (d) is low risk, so LAMA/LABA dual therapy is the starting choice.

15 Acute Respiratory Failure and Pulmonary Embolism

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Distinguish hypoxemic from hypercapnic respiratory failure, link causes to findings, and recognize impending failure early.
2. Explain acute respiratory distress syndrome (ARDS) and the nursing care that supports lung-protective treatment, including prone positioning.
3. Care safely for patients on non-invasive ventilation and invasive mechanical ventilation, including preventing ventilator-associated complications.
4. Recognize pneumothorax, including tension pneumothorax, and respond as an emergency.
5. Assess and maintain chest drainage systems and respond to problems.
6. Recognize, help diagnose and care for patients with pulmonary embolism.
7. Teach patients and families during recovery from critical respiratory illness and after a pulmonary embolism.
8. Distinguish RN and RPN roles in these settings using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 4, 6	Clinician; Scholar	Foundations of Practice
3, 5	Clinician; Collaborator; Coordinator	Foundations of Practice; Collaborative Practice
7, 8	Educator; Professional	Collaborative Practice; Legal Practice

Introduction

Acute respiratory failure happens when the lungs can no longer keep the oxygen and carbon dioxide in the blood within safe limits. It can follow almost any serious illness, from pneumonia or a flare of chronic obstructive pulmonary disease (COPD) to an opioid overdose or major surgery. Nurses on medical-surgical units are often the first to see it develop, and many of these patients need critical care. In 2013–2014, time in an intensive care unit (ICU) was part of 11% of hospital stays by adults in Canada (excluding Quebec), and invasive ventilation was used for 33% of ICU patients (Canadian Institute for Health Information [CIHI], 2016). A pulmonary embolism (PE), a clot blocking blood flow in the lungs, can strike a patient who seemed to be recovering.

Sections 15.1 to 15.6 cover acute respiratory failure, acute respiratory distress syndrome, non-invasive and mechanical ventilation, pneumothorax and chest injury, chest tubes and chest drainage, and PE. Related topics live elsewhere:

- acid–base balance and blood gases (Chapter 3, section 3.7);
- sepsis and infection prevention and control (IPAC) (Chapter 4);
- early warning scores, rapid response and shock (Chapter 6);
- preventing venous thromboembolism (VTE) after surgery (Chapter 7);
- respiratory assessment and oxygen therapy (Chapter 12);
- pneumonia (Chapter 13), and asthma and COPD (Chapter 14);
- deep vein thrombosis and anticoagulation (Chapter 19).

15.1 Acute Respiratory Failure

Two Kinds of Failure

The lungs have two jobs: to move oxygen into the blood and to move carbon dioxide (CO_2) out. Respiratory failure is classed by which job fails. Many patients have elements of both.

In **hypoxemic respiratory failure (type 1)**, oxygenation fails. The British Thoracic Society (BTS) defines it as an arterial partial pressure of oxygen (PaO_2) below 60 mm Hg (8 kPa), roughly equal to an arterial oxygen saturation of 90%, with a normal or low arterial partial pressure of carbon dioxide ($PaCO_2$) (O'Driscoll et al., 2017). Breathing still clears CO_2, but blood leaves the lungs short of oxygen. Chapter 12 (section 12.1) explains the mechanisms:

- **Ventilation–perfusion (V/Q) mismatch:** some areas of lung get blood but too little air. It is the most common cause of low blood oxygen, and extra oxygen usually corrects it (Sarkar et al., 2017).
- **Shunt:** blood flows past alveoli that are collapsed or filled with fluid or pus, so it picks up no oxygen at all. Because the extra oxygen never reaches that blood, hypoxemia from shunt responds poorly to oxygen therapy (Sarkar et al., 2017).
- **Diffusion limitation:** a thickened or damaged alveolar membrane slows the passage of oxygen.

Pneumonia (Chapter 13), acute respiratory distress syndrome (ARDS; section 15.2), pulmonary edema (Chapter 18) and PE (section 15.6) are common causes.

In **hypercapnic respiratory failure (type 2)**, ventilation fails: not enough air moves in and out to clear CO_2, and $PaCO_2$ rises (O'Driscoll et al., 2017). The BTS counts a $PaCO_2$ above the normal range as hypercapnia (its guideline gives about 34–46 mm Hg; Chapter 3 uses 35–45 mm Hg, and ranges vary by laboratory), and a patient with a high $PaCO_2$ has type 2 failure even when the oxygen saturation measured by pulse oximetry (SpO_2) is normal (O'Driscoll et al., 2017). CO_2 forms acid in the blood, so a sudden rise lowers the pH. Oxygen often falls as well. Causes fall into four groups:

- **Reduced drive to breathe:** opioids, sedatives and other central nervous system depressants (Chapter 5, section 5.4; Chapter 11).
- **Weak breathing muscles or nerves:** neuromuscular diseases such as Guillain–Barré syndrome and myasthenia gravis (Chapter 32).
- **Chest wall problems:** chest wall deformity and severe obesity (O'Driscoll et al., 2017; Davidson et al., 2016).
- **Airway disease:** COPD and severe asthma, where narrowed airways trap air and the breathing muscles tire (Chapter 14).

Timing matters as much as type. **Acute** failure develops over minutes to days, so the body has no time to adapt. **Chronic** respiratory failure develops over months or years, as in some people with advanced COPD; the kidneys keep extra bicarbonate, which brings the pH close to normal despite a high $PaCO_2$. **Acute-on-chronic** failure is a sudden worsening on top of a chronic problem, so the pH falls even though bicarbonate is high (Rochwerg et al., 2017). Chapter 14 shows these patterns on arterial blood gases (ABGs). Table 15.1 compares the two types.

Table 15.1 Hypoxemic and hypercapnic respiratory failure compared (Davidson et al., 2016; O'Driscoll et al., 2017; Rochwerg et al., 2017; Sarkar et al., 2017; original wording)

Feature	Hypoxemic (type 1)	Hypercapnic (type 2)
Main problem	Oxygen does not get into the blood well enough	Too little air moves in and out, so CO_2 builds up
ABG pattern	PaO_2 below about 60 mm Hg; $PaCO_2$ normal or low	$PaCO_2$ above the normal range; pH low if the rise is acute or acute-on-chronic; PaO_2 often low too
Common causes	Pneumonia, ARDS, pulmonary edema, PE, collapsed lung tissue	Opioids and sedatives, neuromuscular disease, chest wall disease, severe obesity, COPD or asthma exacerbation
Key early cues	Fast breathing, fast heart rate, restlessness, rising oxygen needs	Fast shallow breathing and hard work, or slow breathing after opioids; drowsiness, confusion

Feature	Hypoxemic (type 1)	Hypercapnic (type 2)
Main supports	Oxygen to the target range; high-flow nasal cannula; positive pressure; treating the cause	Controlled oxygen to the target range; treating the cause; bilevel non-invasive ventilation; reversing drug effects as ordered
Cautions	Shunt responds poorly to more oxygen; a rising oxygen need is a warning sign	A normal SpO2 does not rule it out; too much oxygen can raise PaCO2 in at-risk patients

Recognizing Failure Early

Respiratory failure rarely arrives without warning. The early cues show a body working hard to compensate:

- a rising respiratory rate and heart rate, which are more common in hypoxemia than cyanosis (O'Driscoll et al., 2017);
- more work of breathing: use of neck and shoulder muscles, flaring nostrils, speaking in short phrases, sitting forward to breathe;
- restlessness, anxiety or new confusion, which can be the first sign of low oxygen or high CO2 (O'Driscoll et al., 2017);
- needing more oxygen to stay in the target range (Chapter 12, section 12.4).

Late cues show that compensation is failing. The patient tires: breathing slows or becomes irregular, and the patient becomes drowsy, confused or hard to rouse. A rising CO2 causes drowsiness and, when severe, coma (O'Driscoll et al., 2017). The SpO2 falls even as oxygen is increased. In a patient with severe asthma, a quiet chest with faint air entry means that little air is moving (Chapter 14). **Central cyanosis**, a bluish or greyish colour of the tongue, lips and lining of the mouth, is a late and unreliable sign. On darker skin it may look grey or whitish rather than blue, so the nurse checks the tongue and oral mucosa in good light and never waits for colour change to act (Chapter 12, section 12.2).

Two traps deserve attention. First, pulse oximetry measures oxygen, not CO2. A patient on supplemental oxygen can show a normal SpO2 while the PaCO2 climbs (O'Driscoll et al., 2017). This is why a sleepy patient on opioids with a slow respiratory rate needs a full assessment, not just a glance at the oximeter (Chapter 5, section 5.4). Second, a patient who stops struggling is not necessarily improving.

Early warning scores combine these vital signs and help the nurse decide when to call for help; escalation and the rapid response team are covered in Chapter 6 (section 6.2). An ABG confirms the type of failure: a low PaO2 with a normal or low PaCO2 points to type 1, and a high PaCO2 with a low pH points to acute type 2. Chapter 3 (section 3.7) explains how to read a blood gas.

Nursing Care

The nurse uses the Clinical Judgment Measurement Model (CJMM) (Chapter 1, section 1.4).

Recognize and analyze cues. The nurse counts the respiratory rate for a full minute and looks at the patient's work of breathing, colour, level of consciousness and SpO2, then compares the findings with earlier ones. Trends matter more than a single value.

Prioritize hypotheses. The nurse asks three questions. Is this mainly a problem of oxygen, of CO2, or both? What is the likely cause, such as pneumonia, fluid overload, an opioid or a COPD flare? How fast is the patient getting worse?

Generate solutions and take action. Actions depend on the cause, the orders, and the nurse's role and setting:

- **Stay with the patient and call for help** when cues are worsening; use the escalation process in Chapter 6.
- **Position the patient upright,** if tolerated, to help the lungs expand (Chapter 12).
- **Give oxygen to the ordered target range.** Patients at risk of hypercapnic failure, such as those with COPD, usually have a target of 88–92% until blood gases are known (O'Driscoll et al., 2017). Oxygen is never withheld from a patient who is hypoxemic; it is adjusted to the target (Abdo & Heunks, 2012).
- **Report a rising oxygen need at once.** It may lead to high-flow nasal cannula (Chapter 12), non-invasive ventilation (section 15.3) or intubation.
- **Support airway clearance:** coughing, deep breathing and suctioning when needed (Chapter 12, section 12.5).
- **Treat the cause as ordered,** for example bronchodilators for a COPD flare (Chapter 14), antimicrobials for pneumonia (Chapter 13) or diuretics for heart failure (Chapter 18).

- **Reverse drug effects when ordered.** For opioid-induced respiratory depression, the nurse stops the opioid, stimulates the patient, supports breathing and gives naloxone according to the order, medical directive and policy (Chapter 5, section 5.4; Chapter 11).
- **Monitor closely:** continuous pulse oximetry, frequent respiratory rate and level of consciousness, and blood gases as ordered.
- **Communicate clearly.** The nurse reports findings to the most responsible provider or rapid response team using SBAR (Situation, Background, Assessment, Recommendation) (Chapter 6, section 6.2).

Goals of care. Before a crisis, the team needs to know what the patient wants. Would the patient want intubation and ICU care, or a trial of non-invasive ventilation only? The BTS advises agreeing on and documenting what will happen if non-invasive ventilation fails before it is started, involving the patient wherever possible (Davidson et al., 2016). The nurse prompts this conversation early and supports the patient and family through it (Chapter 10, section 10.2).

Evaluate outcomes. The nurse reassesses after every intervention. A falling respiratory rate with better alertness and a steady SpO2 suggests improvement. A falling respiratory rate with drowsiness suggests exhaustion or rising CO2.

CLINICAL JUDGMENT

Tiring on Non-invasive Ventilation

Names and details are fictional; this is a composite story.

Mr. Albert Nakamura, 70, has COPD and was admitted to a step-down unit with an exacerbation. Bilevel non-invasive ventilation (NIV), often called BiPAP, was started 2 hours ago. His first blood gas showed pH 7.30 and PaCO2 68 mm Hg. His written plan says he wants a trial of intubation if needed.

- **Recognize cues:** He is harder to rouse than an hour ago and is not following commands. His respiratory rate is 34 breaths/min, his SpO2 is 90% and air is leaking around the mask. The repeat ABG shows pH 7.24 and PaCO2 82 mm Hg.
- **Analyze cues:** His acidosis is worsening and his CO2 is rising despite NIV. A rising PaCO2 explains the drowsiness. Worsening pH and respiratory rate signal that NIV is failing (Davidson et al., 2016).
- **Prioritize hypotheses:** The main concern is hypercapnic failure that NIV is not reversing. A poor mask seal may add to it. A drowsy patient also risks aspiration.
- **Generate solutions:** call the physician and respiratory therapist now; check the mask fit; prepare for intubation and ICU transfer, in line with his stated wishes.
- **Take action:** The nurse stays with Mr. Nakamura, raises the head of the bed, refits the mask with the respiratory therapist and gives an SBAR report: "Mr. Nakamura is on BiPAP with a worsening ABG, rising respiratory rate and drowsiness. I recommend urgent bedside review for intubation." The nurse brings suction and the bag-valve mask to the bedside and updates his daughter.
- **Evaluate outcomes:** The physician confirms Mr. Nakamura's wishes with his daughter, and he is intubated and moved to the ICU within the hour.

15.2 Acute Respiratory Distress Syndrome

What ARDS Is

Acute respiratory distress syndrome (ARDS) is a sudden, widespread injury to both lungs that causes hypoxemic respiratory failure. It is not caused mainly by heart failure. In 2024, an international group of experts published a new global definition that builds on the earlier Berlin definition from 2012 (Matthay et al., 2024). The 2024 definition has four parts:

- **Risk factor and cause:** ARDS follows an acute trigger, such as pneumonia, infection outside the lungs, trauma, transfusion, aspiration or shock. The lung swelling is not mainly due to heart failure or fluid overload.
- **Timing:** hypoxemic respiratory failure begins or worsens within 1 week of the trigger or of new or worsening breathing symptoms.
- **Imaging:** opacities in both lungs on chest X-ray or computed tomography (CT), or matching findings on ultrasound, not fully explained by fluid around the lungs, collapse or masses.

- **Hypoxemia:** a ratio of PaO2 to the fraction of inspired oxygen (FiO2) of 300 mm Hg or less. Alternatively, a ratio of SpO2 to FiO2 of 315 or less can be used, but only when the SpO2 is 97% or lower.

The 2024 definition differs from Berlin in important ways (Matthay et al., 2024). It includes patients who are not intubated but are receiving high-flow nasal oxygen at 30 L/min or more, or non-invasive ventilation or continuous positive airway pressure (CPAP) of at least 5 cm H2O. It also allows pulse oximetry and ultrasound, so that ARDS can be recognized where blood gases and X-rays are not available. ARDS in intubated patients is graded mild, moderate or severe by the oxygen ratio (see the Going Deeper box in section 15.3), and patients may move between categories as the illness changes (Matthay et al., 2024).

In ARDS, inflammation damages the thin barrier between the alveoli and the capillaries. Fluid leaks into the air spaces even though the heart is working normally; this is **noncardiogenic pulmonary edema**. Flooded and collapsed alveoli receive blood but no air, creating a large shunt. That is why patients with ARDS stay hypoxemic despite high levels of oxygen (Sarkar et al., 2017). The injured lungs also become stiff and small, so each breath takes more pressure to deliver.

Causes include pneumonia (Chapter 13), sepsis (Chapter 4, section 4.6), aspiration of stomach contents (Chapter 13), major trauma, transfusion (Chapter 20) and shock (Chapter 6) (Matthay et al., 2024).

Supporting the Lungs

No drug cures ARDS. Care treats the cause and supports the lungs while they heal, without causing further injury.

Lung-protective ventilation means using small breaths and limited pressures to avoid overstretching the injured lung. A 2017 guideline from the American Thoracic Society (ATS), the European Society of Intensive Care Medicine and the Society of Critical Care Medicine strongly recommends small tidal volumes and limits on inspiratory pressure for all patients with ARDS (Fan et al., 2017). The 2024 ATS update suggests higher positive end-expiratory pressure (PEEP), without lung recruitment manoeuvres, for moderate to severe ARDS. It recommends against prolonged lung recruitment manoeuvres. It also makes conditional recommendations for corticosteroids, for neuromuscular blockers in early severe ARDS, and for extracorporeal membrane oxygenation (ECMO) for some carefully chosen patients whose ARDS is severe (Qadir et al., 2024). The Going Deeper box in section 15.3 gives the numbers.

Prone positioning means turning the ventilated patient onto the abdomen for long periods. In the prone position, more of the lung takes part in gas exchange. In the PROSEVA trial of 466 patients with severe ARDS, prone sessions of at least 16 hours a day lowered death at 28 days from 32.8% to 16.0% (Guérin et al., 2013). The 2017 guideline strongly recommends prone positioning for more than 12 hours a day in severe ARDS (Fan et al., 2017).

Proning is a planned team procedure:

- Before the turn, the team uses a safety checklist, secures the endotracheal tube, lines and drains, and has suction ready (González-Seguel et al., 2021).
- During the turn, one person at the head of the bed controls the airway and directs the move (González-Seguel et al., 2021).
- After the turn, the nurse confirms tube position and ventilation, and watches for drops in SpO2, low blood pressure and dysrhythmias, which are common adverse events (González-Seguel et al., 2021).
- While the patient is prone, the nurse protects the face, eyes, chest, knees and other pressure points. Pressure injuries and facial swelling are among the most frequent complications. Rotating the head and arms and repositioning about every 2 hours are commonly used strategies (González-Seguel et al., 2021). Chapter 35 covers pressure injury prevention.

Fluid management. In a large trial in acute lung injury, a conservative fluid strategy did not significantly change the death rate at 60 days. It did increase the number of days alive and off the ventilator, without causing more shock or failure of other organs (National Heart, Lung, and Blood Institute ARDS Clinical Trials Network, 2006). The nurse supports it with accurate intake and output and daily weights.

Recovery

Post-intensive care syndrome (PICS) is new or worse problems with physical, cognitive or mental health that begin after critical illness and last beyond the hospital stay (Needham et al., 2012). Survivors may face weakness, trouble with memory and

concentration, anxiety or low mood for months or years.

Families are affected too. In **post-intensive care syndrome–family (PICS-F)**, family members experience anxiety, acute stress, posttraumatic stress, depression or complicated grief, sometimes for more than four years (Davidson et al., 2012). How the team communicates with families and includes them in care and decisions may shape these outcomes (Davidson et al., 2012).

Nurses help prevent PICS from the first ICU day. They aim for light sedation, regular delirium screening and early mobility (Devlin et al., 2018), and they keep the family informed and involved. At discharge, the nurse explains that slow recovery is common and links the patient and family with follow-up visits, support groups or ICU follow-up clinics where they exist (Davidson et al., 2012).

15.3 Non-invasive and Mechanical Ventilation

Non-invasive Ventilation

Non-invasive ventilation (NIV) delivers breathing support through a tight-fitting mask rather than a tube in the airway (Figure 15.1). There are two main forms:

- **Continuous positive airway pressure (CPAP)** gives one steady pressure throughout the breath. It holds small airways and alveoli open and improves oxygenation.
- **Bilevel positive airway pressure** gives a higher pressure when the patient breathes in and a lower pressure when the patient breathes out. The extra push rests tired muscles and helps clear CO2; it is often called BiPAP, a brand name.

The evidence is strongest for two groups (Rochwerg et al., 2017):

- **COPD exacerbation with respiratory acidosis.** The European Respiratory Society (ERS) and ATS strongly recommend bilevel NIV when an exacerbation causes respiratory acidosis (pH 7.35 or lower), whether acute or acute-on-chronic. They suggest not using NIV for patients whose CO2 is high but whose pH is normal. The BTS advises starting NIV when a pH below 7.35 and a PaCO2 above 6.5 kPa (about 49 mm Hg) persist despite optimal medical treatment (Davidson et al., 2016).
- **Cardiogenic pulmonary edema.** The ERS and ATS strongly recommend either bilevel NIV or CPAP (Rochwerg et al., 2017; Chapter 18).

Figure 15.1 Non-invasive ventilation through a full face mask that covers the nose and mouth, connected to a ventilator. This is a posed demonstration; the person's eyes are pixelated. (credit: modification of "BIPAP" by James Heilman, MD/Wikimedia Commons, CC BY-SA 4.0)

NIV is safest when the patient can cooperate and keep the airway protected (Rochwerg et al., 2017). Caution is needed when the patient has a reduced level of consciousness, severe hypoxemia or severe acidemia (Klompas et al., 2022). NIV must never delay intubation when intubation is the better choice; delay is a main risk of NIV (Davidson et al., 2016; Rochwerg et al., 2017).

Nursing care of the patient on NIV. NIV belongs where enhanced nursing care and monitoring are available (Davidson et al., 2016). The nurse:

- **fits the mask** with the respiratory therapist (RT). A full face mask is usually tried first, and overtightening is avoided (Davidson et al., 2016);
- **protects the skin.** Ulcers over the bridge of the nose are the most common problem, affecting 5–10% of patients (Davidson et al., 2016). The nurse checks the skin often, uses protective dressings per policy and offers mask breaks when safe (Chapter 35);

- **reduces aspiration risk.** The nurse keeps the head of the bed raised, watches for nausea and drowsiness, and reports a patient who cannot protect the airway;
- **supports communication:** keeps the call bell in reach and agrees on simple signals;
- **monitors closely:** continuous SpO2 (usually 88–92% in hypercapnic failure), respiratory rate, heart rate, level of consciousness, comfort and mask leak (Davidson et al., 2016). Blood gases are checked before and after NIV starts, then as ordered (Davidson et al., 2016).

Is NIV working? A falling respiratory rate and an improving pH within the first hours predict success (Rochwerg et al., 2017; Davidson et al., 2016). A worsening pH and respiratory rate mean the plan must change (Davidson et al., 2016). Rising drowsiness, exhaustion or no improvement within the first hours are warning signs to escalate at once.

Infection control. NIV can spread respiratory particles, so the nurse follows local IPAC policy (Chapter 4, section 4.3). For pandemic viral illness, the ERS/ATS guideline made no recommendation; it noted that NIV in a protected environment, such as a negative-pressure room, may be reasonable (Rochwerg et al., 2017).

Intubation

Intubation means placing an endotracheal tube through the mouth into the trachea for ventilation (Figure 15.2). Common reasons include a patient who cannot protect the airway, failing NIV and severe or worsening hypoxemia or acidosis. Repeated intubation attempts can cause hypoxemia (Law et al., 2021a), so the team prepares carefully.

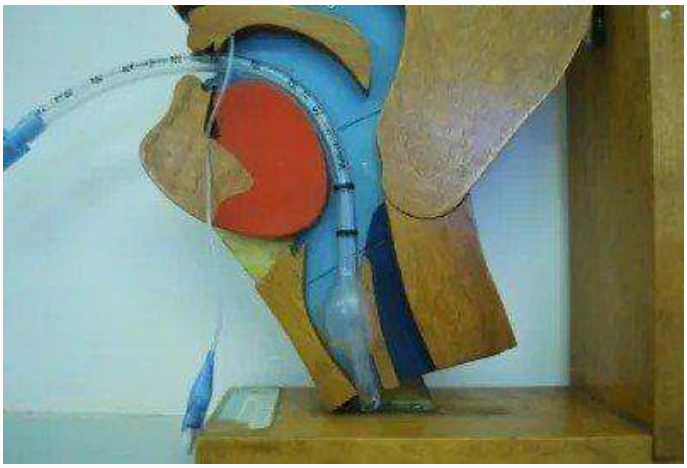

Figure 15.2 An endotracheal tube in a teaching model of the airway. The tube passes through the mouth into the trachea, and its inflated cuff seals the trachea around it. (credit: “Endotracheal tube” by John Campbell/Flickr, public domain)

Following policy and the team leader, the nurse helps prepare by:

- checking that suction, oxygen, a bag-valve mask, monitoring and intravenous (IV) access are ready and working;
- preparing the medications ordered, such as sedatives and neuromuscular blockers, as the team directs;
- taking part in the team briefing, in which the airway leader explains the plan (Law et al., 2021b);
- explaining what is happening to the patient and family.

After the tube is placed, **end-tidal carbon dioxide (ETCO2)** monitoring by waveform capnography is the main way to confirm it. With the tube in the trachea, CO2 shows in every exhaled breath; with the tube in the esophagus, the trace is flat or fades. When sustained exhaled CO2 cannot be detected, the default response is to remove the tube (Chrimes et al., 2022). Team members say aloud what the capnography shows, and the nurse speaks up if the trace is absent. A chest X-ray is often ordered afterward to help check the tube's position; it does not replace capnography. The nurse records the tube size and centimetre mark at the lips or teeth, and helps secure the tube per policy.

Caring for the Ventilated Patient

Mechanical ventilation uses a machine to move air into the lungs through an endotracheal or tracheostomy tube.

Safety checks. Each shift and after any transfer, the nurse checks:

- a bag-valve mask connected to oxygen and suction set up and working at the bedside (Chapter 12, section 12.5);
- the tube's centimetre mark and how it is secured;
- that alarms are on and audible.

Alarms. A high-pressure alarm usually means the ventilator meets resistance, as with secretions, coughing, biting on the tube or a kinked circuit. A low-pressure or low-volume alarm usually means air is escaping, as with a disconnection or a leak. The nurse looks at the patient first, then traces the circuit to the ventilator, and never silences an alarm and walks away. If the patient is in distress and the cause is not obvious at once, the nurse calls for help and, following policy, ventilates by bag-valve mask until the RT or physician arrives.

Preventing ventilator-associated pneumonia. Ventilator-associated pneumonia (VAP) is a pneumonia that develops in a patient on a ventilator (Chapter 13). Up to 1 in 10 patients on invasive ventilation develops hospital-acquired pneumonia (Klompas et al., 2022). Table 15.2 lists prevention practices. Endotracheal tubes that drain secretions from above the cuff are an added option for patients expected to need ventilation for more than 48–72 hours. Oral care with chlorhexidine is no longer recommended (Klompas et al., 2022).

Table 15.2 Practices that help prevent ventilator-associated pneumonia (Klompas et al., 2022; original wording)

Practice	What the nurse does	Why it helps
Avoid intubation when safe	Supports high-flow oxygen or NIV for suitable patients, and escalates if they fail	No tube means no tube-related pneumonia
Minimize sedation	Uses the lightest sedation that keeps the patient safe; takes part in daily sedation interruptions	Linked to shorter ICU stays
Daily spontaneous breathing trial	Checks readiness with the team each day and monitors the patient during the trial	Patients come off the ventilator about a day sooner on average
Raise the head of the bed	Keeps the head of the bed at 30–45 degrees unless contraindicated	Linked to lower VAP rates; simple, cheap and low risk
Oral care with toothbrushing	Brushes teeth, gums and tongue regularly, without chlorhexidine	Linked to lower VAP rates and shorter ventilation and ICU stays
Early mobility	Works with physiotherapy to sit, stand and walk the patient when safe	May shorten ventilation and ICU stays

Sedation and delirium. The Society of Critical Care Medicine suggests light rather than deep sedation for ventilated adults. It also suggests non-benzodiazepine sedatives over benzodiazepines (Devlin et al., 2018). The 10-level **Richmond Agitation–Sedation Scale (RASS)** runs from +4 (combative) through 0 (alert and calm) to −5 (unarousable) (Sessler et al., 2002). The same guideline advises that critically ill adults be assessed for delirium regularly with a valid tool (Devlin et al., 2018). The **Confusion Assessment Method for the ICU (CAM-ICU)** looks at four features: an acute change or fluctuation in mental status, inattention, an altered level of consciousness and disorganized thinking. Delirium is present when the first two features are present along with either of the last two (Island Health, 2018; Chapter 8, section 8.2).

Communication. A patient with an endotracheal tube cannot speak. The nurse asks yes-or-no questions, offers letter boards or writing materials, and makes sure the patient has glasses and hearing aids, which also helps prevent delirium (Devlin et al., 2018).

Weaning. Weaning is the process of reducing ventilator support, and the team checks readiness every day. In a **spontaneous awakening trial**, sedation is paused so the patient becomes alert. In a **spontaneous breathing trial**, the patient breathes with little or no ventilator help (Klompas et al., 2022). The nurse monitors the patient closely during the trial and after extubation, and reports distress, a rising respiratory rate or a falling SpO2.

GOING DEEPER

Ventilator Modes and Settings in Plain Terms

Required for RN students; optional for PN students.

A ventilator gives each breath in one of two basic ways. In **volume-controlled** modes, the clinician sets the size of each breath, and the pressure needed to deliver it varies with how stiff the lungs are. In **pressure-controlled** modes, the clinician sets the pressure, and the size of each breath varies. The RT and physician choose and adjust the mode.

- **Tidal volume:** the volume of each breath. In ARDS, guidelines strongly recommend 4–8 mL per kg of **predicted body weight** (Fan et al., 2017). Predicted body weight is calculated from height and sex, not from actual weight.
- **Respiratory rate:** the number of breaths the ventilator guarantees each minute. Changing it changes how much CO2 is cleared.
- **FiO2:** the fraction of inspired oxygen, from 0.21 (room air) to 1.0.
- **Positive end-expiratory pressure (PEEP):** pressure kept in the lungs at the end of each breath to stop alveoli from collapsing. Higher PEEP is suggested for moderate to severe ARDS (Qadir et al., 2024).
- **Plateau pressure:** the pressure in the alveoli when air is held briefly at the end of a breath in. In ARDS, it is kept below 30 cm H2O (Fan et al., 2017).

The **PaO2/FiO2 (P/F) ratio** shows how well the lungs oxygenate for the oxygen given. For example, a PaO2 of 75 mm Hg on an FiO2 of 0.5 gives a ratio of 150. In intubated patients receiving a PEEP of at least 5 cm H2O, the 2024 definition grades ARDS as mild (P/F more than 200 and up to 300), moderate (more than 100 and up to 200) or severe (100 or less) (Matthay et al., 2024).

The nurse watches for:

- rising airway pressures;
- a falling tidal volume in pressure modes;
- falling SpO2 or ETCO2 changes;
- patient–ventilator distress, such as the patient breathing against the machine.

The nurse reports these at once. Any FiO2 or PEEP change is followed by reassessment.

LIFESPAN CONSIDERATIONS

Older Adults and Critical Respiratory Illness

Many patients with respiratory failure are older adults, and CIHI expects the aging population to place more demands on Canadian ICUs in the coming decades (CIHI, 2016). Frailty, meaning low reserve across body systems, raises the risk of complications and slow recovery (Chapter 8, section 8.1). Older adults are at high risk of delirium, which often shows as quiet withdrawal rather than agitation. Regular screening, light sedation, glasses and hearing aids, sleep and early mobility all help (Devlin et al., 2018; Chapter 8, section 8.2). Bed rest quickly weakens muscles, so the nurse supports mobility as soon as it is safe. Many older survivors live with the physical, cognitive or mental effects of PICS (Needham et al., 2012). Before a crisis, the nurse helps make sure the team knows the patient's values and wishes about intubation, NIV and ICU care, and involves the substitute decision-maker when needed (Chapter 10, section 10.2). At discharge, the nurse prepares the patient and family for a slow recovery and links them with follow-up supports (Davidson et al., 2012).

CANADIAN CONTEXT

Critical Care Far From the City

Many people in rural, remote and northern Canada live hours from an ICU. A patient in respiratory failure may need stabilization in a small hospital or nursing station, then transfer by air or land (Figure 15.3). In Ontario, Ornge provides air ambulance and critical care land transport from 14 bases. It carries out about 20,000 patient-related transports a year across more than one million square kilometres (Ornge, n.d.). Other provinces and territories run their own transport services.

For First Nations people and Inuit who are eligible, the Non-Insured Health Benefits (NIHB) program helps pay for medical travel that provincial and territorial programs do not cover. A physician or registered nurse escort may be approved when the patient needs monitoring or stabilization during travel. A non-medical escort may be approved when the patient cannot travel alone, for example because of language or decision-making needs (Indigenous Services Canada [ISC], 2022). Critical illness can still mean long separation from family, community and language. The nurse asks early about escorts, interpreters and the patient's supports, and helps the family stay in contact (Chapter 2).

15.4 Pneumothorax and Chest Injury

Air in the Pleural Space

A **pneumothorax** is air in the pleural space, the thin gap between the pleura covering the lung and the pleura lining the chest wall. Normally this space holds only a film of fluid at a pressure below atmospheric pressure, which keeps the elastic lung stretched against the chest wall. Once air enters, that pull is lost and the lung recoils and collapses. The BTS guideline groups pneumothorax by cause (M. E. Roberts et al., 2023):

- **Primary spontaneous pneumothorax:** occurs with no known lung disease, although CT often shows small emphysema-like changes.
- **Secondary spontaneous pneumothorax:** occurs with established lung disease, such as COPD (Chapter 14). The BTS also counts people over 50 with a smoking history in this group. With less reserve, even a small pneumothorax can cause respiratory failure (section 15.1).
- **Traumatic pneumothorax:** follows blunt or penetrating chest injury.
- **Iatrogenic pneumothorax:** results from care, for example thoracentesis, where it is the most common complication (Asciak et al., 2023; Chapter 13), a lung biopsy or pacemaker insertion (M. E. Roberts et al., 2023), or positive-pressure ventilation (section 15.3).

The collapsed lung still receives blood but no air, so that blood returns to the heart without picking up oxygen (section 15.1). Pain adds to the problem by keeping breaths shallow.

Recognizing Pneumothorax

The typical story is sudden, sharp, one-sided chest pain that worsens with breathing (**pleuritic pain**), with shortness of breath. On the affected side, the nurse may find reduced chest movement, reduced or absent breath sounds and a hyperresonant percussion note (Chapter 12). Heart and respiratory rates rise, and SpO2 may fall. Cyanosis is late and harder to see on darker skin, so the nurse checks the lips, oral mucosa and nail beds and does not wait for colour change (Chapter 12). Air escaping into the tissues causes **subcutaneous emphysema**, felt as crackling under the fingers. It is common and usually minor after chest drain insertion, but a spreading area can mean a blocked drain or a large air leak (Asciak et al., 2023).

A chest X-ray is commonly used to confirm the diagnosis (Figure 15.4), and the BTS advises a follow-up X-ray 2 to 4 weeks later for patients managed by observation or needle aspiration (M. E. Roberts et al., 2023). Bedside ultrasound is more sensitive in injured patients: in a Cochrane review, among 100 patients of whom 30 had a pneumothorax, ultrasound would miss about 3 and a chest X-ray taken lying flat about 16 (Chan et al., 2020). CT, the reference test in that review, gives the most definitive answer (Chan et al., 2020).

The BTS states that size alone is no longer a reason for invasive treatment, although it affects which procedures are safe (M. E. Roberts et al., 2023). Options, chosen with the patient, include observation for a primary pneumothorax with few symptoms, needle aspiration, a chest drain (section 15.5) and an ambulatory device: a small drain with a one-way valve that lets suitable patients go home with close follow-up. Surgery or pleurodesis (sealing the pleural layers together) is considered to prevent recurrence. Before discharge, patients learn to return at once if breathless and to stop smoking. The BTS advises no commercial flights until an X-ray shows full resolution (then waiting 7 days) and discourages scuba diving for life unless definitive surgery has been done (M. E. Roberts et al., 2023).

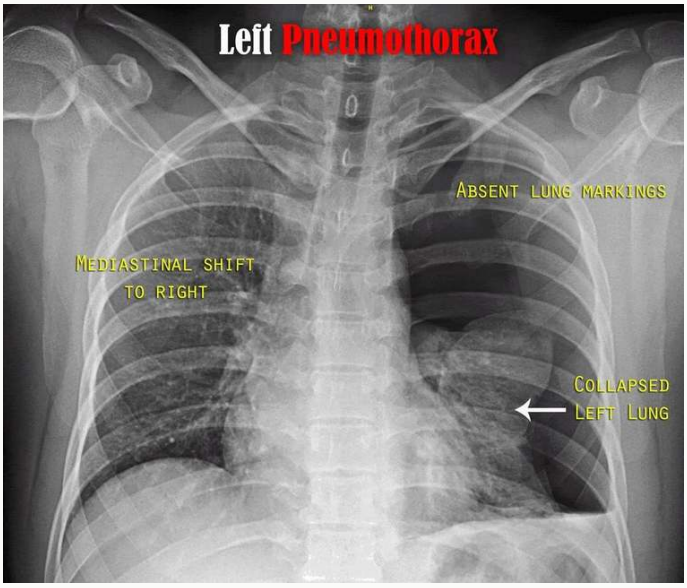

Figure 15.4 Chest X-ray of a large left pneumothorax, labelled: no lung markings in the air-filled space, the collapsed left lung, and the mediastinum shifted to the right. A shift like this, with signs of shock, points to tension pneumothorax, which is treated at once without waiting for an X-ray. (credit: "X-ray of pneumothorax signs" by Karthik Easvur/Wikimedia Commons, CC BY-SA 3.0)

Tension Pneumothorax

In a **tension pneumothorax**, air enters the pleural space with each breath but cannot leave. Pressure climbs, the lung collapses fully and the heart and great vessels are pushed aside. Venous return and cardiac output fall, causing obstructive shock (Chapter 6). Death can follow within minutes.

Early signs are chest pain, respiratory distress, tachycardia, low SpO2 and reduced air entry on one side. A Canadian emergency guideline notes that low blood pressure appears in fewer than a quarter of cases and that tracheal deviation and distended neck veins are uncommon or hard to detect (Shared Health, 2025). Patients on a ventilator are more likely to have hypoxemia, hypotension and cardiac arrest, and these often appear within minutes (D. J. Roberts et al., 2015).

Decompression must be done the moment the condition is suspected, to prevent collapse of breathing and circulation (Shared Health, 2025). The nurse stays with the patient, calls the rapid response team or a code as policy directs (Chapter 6), gives high-flow oxygen, attaches a monitor and checks any existing chest drain for clamps, kinks or blockage. The nurse brings equipment for immediate decompression by a provider authorized and trained to do it: a long catheter-over-needle through the chest wall, or a **finger thoracostomy**, in which the provider opens the pleura through a small incision. Needle decompression fails in about 40% of cases, and finger thoracostomy succeeds more often (Shared Health, 2025).

Other Chest Injuries in Brief

A **hemothorax** is blood in the pleural space from injured chest wall vessels, lung or great vessels, or after surgery. Signs resemble pneumothorax, but percussion is dull and the patient may show hypovolemic shock (Chapter 6). A hemothorax in an unstable patient may need a large-bore drain (Asciak et al., 2023).

Rib fractures hurt, so patients breathe shallowly and avoid coughing, which can lead to pneumonia and respiratory failure. One trauma review reports a death rate of at least 20% in older adults with rib fractures (Brasel et al., 2017). A **flail chest** is three or more ribs each broken in two or more places; the loose segment may move inward on inspiration, but bruised lung and pain cause most of the breathing problem. Pain control comes first: acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) and, for severe pain, early epidural or paravertebral analgesia (Brasel et al., 2017; Chapter 5). The nurse coaches deep breathing, coughing and walking, and watches for a pneumothorax or hemothorax that can appear later (Brasel et al., 2017). Major trauma is covered in Chapter 33.

15.5 Chest Tubes and Chest Drainage

A chest tube lets air, blood or fluid leave the pleural space while stopping air from being drawn back in. The principles are the same across products, but designs differ, so the nurse follows the manufacturer's instructions and hospital policy for the system in use.

Why and How Chest Tubes Are Placed

A **chest tube** (intercostal chest drain) is a flexible tube placed between the ribs into the pleural space. Common reasons include pneumothorax that has not settled with simpler treatment, hemothorax, pleural infection or empyema, large effusions, pleurodesis and recovery from thoracic surgery such as lobectomy (Chapter 13) (Asciak et al., 2023).

Tube size is measured in French (Fr) units. Small-bore drains (14 Fr or smaller), usually inserted over a guidewire, suit most purposes, including pleural infection. Large-bore drains (often larger than 20 Fr, mostly inserted by blunt dissection) may be needed after thoracic surgery, for hemothorax in an unstable patient or for a pneumothorax with a large air leak (Asciak et al., 2023).

At insertion, the nurse:

- confirms that the provider has obtained informed consent (Chapter 1, section 1.5); complications follow 8% to 20% of insertions (Asciak et al., 2023);
- checks for anticoagulant use and bleeding risk as policy directs, gives prescribed analgesia and sets up the drainage unit;
- positions and supports the patient as the operator directs;
- monitors SpO2, heart rate, blood pressure, pain and signs of a vasovagal reaction;
- keeps the field sterile as policy directs.

The drain is sutured in place and dressed, and a chest X-ray within a few hours confirms its position (Asciak et al., 2023).

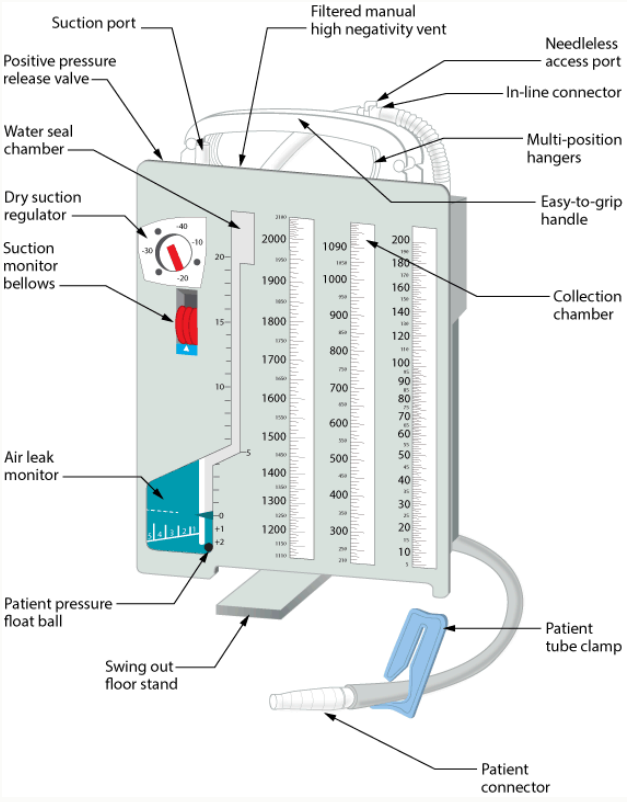

Figure 15.5 A chest drainage unit with its parts labelled. (credit: "Chest tube drainage system with labelled parts" by Glynda Rees Doyle and Jodie Anita McCutcheon/BCcampus, CC BY 4.0)

How Drainage Systems Work

Most chest drainage units combine up to three functions in one plastic box (Figure 15.5).

- **Collection chamber:** drainage collects here in a marked chamber so it can be measured.
- **Water seal:** air from the patient bubbles out through a short column of water, but the water stops air from flowing back toward the chest. The **water seal** therefore acts as a one-way valve, and the tube end must stay under the right depth of water (Asciak et al., 2023).
- **Suction control:** routine suction is not recommended, because its benefit is unproven; it is avoided right after insertion, and when used the pressure is prescribed (Asciak et al., 2023). In **wet suction** units, the height of a water column limits suction, and gentle continuous bubbling in that chamber is expected. In **dry suction** units, an adjustable control on the unit, rather than a water column, sets the suction level (Getinge, n.d.).

A one-way **flutter valve** (sometimes called a Heimlich valve) lets air out without a water seal, so the patient can walk around or go home with a drain (M. E. Roberts et al., 2023). **Digital chest drainage** systems provide suction electronically and measure air leak continuously, which can help guide removal (Asciak et al., 2023; Figure 15.6).

Figure 15.6 A portable digital chest drainage unit at the bedside. It applies suction electronically and measures air leak continuously. (credit: "P4053296 logo" by TKiefer/Wikimedia Commons, CC BY-SA 4.0)

Two rules apply to every system. The unit stays upright and below the chest, so fluid cannot flow back into the pleural space (Asciak et al., 2023; da Silva et al., 2024). The tubing lies without kinks or dependent loops, because fluid trapped in a loop resists drainage (da Silva et al., 2024).

Assessing the Patient and the System

The nurse assesses the patient first: respiratory rate and effort, SpO2, breath sounds on both sides, chest movement, heart rate, blood pressure, pain, the insertion site and any subcutaneous emphysema. Pain control matters, because a patient in pain will not breathe deeply or cough. Walking, deep breathing and coughing are encouraged (da Silva et al., 2024).

The nurse then traces the system from the chest to the unit, checking:

- secure connections and tubing free of kinks and loops;
- the water seal level;
- **tidalling**, the rise and fall of fluid in the water seal or tubing with breathing, which shows the drain is open to the pleural space;
- bubbling in the water seal, which shows an **air leak** from the lung or a loose connection;
- drainage amount, colour and consistency, marked and timed as policy directs;
- the suction source and setting, if ordered.

After surgery, one review recommends recording drainage every 30 to 60 minutes for the first 3 to 4 hours (da Silva et al., 2024). Bubbling when the patient coughs or breathes out is expected while a pneumothorax resolves or after lung surgery. Tidalling can stop when the lung has fully re-expanded, but it usually means the tube is blocked (Asciak et al., 2023). The nurse reports at once a sudden rise in bloody drainage (one review cites more than 100 mL in an hour after the first 3 postoperative hours; units set their own limits), new continuous bubbling, tidalling that stops while the patient becomes more breathless, spreading subcutaneous emphysema or any sign of tension pneumothorax (da Silva et al., 2024; Asciak et al., 2023). When a large effusion is draining, coughing, chest tightness or pain can signal **re-expansion pulmonary edema**, a rare but life-threatening complication; drainage is stopped as ordered and the patient assessed (Asciak et al., 2023). Table 15.3 brings these checks together.

Table 15.3 Chest drainage: what to check and what to do (Asciak et al., 2023; da Silva et al., 2024; original wording)

Finding	What it may mean	Nursing action

Finding	What it may mean	Nursing action
Fluid in the water seal rises and falls with breathing	The drain is open to the pleural space	Record it; keep checking as policy directs
Tidalling stops and the patient is comfortable, with clear breath sounds	The lung may have re-expanded	Check tubing for kinks or loops; report and expect a chest X-ray
Tidalling stops and the patient is more breathless	The tube may be blocked or kinked; air or fluid may be building up	Check the whole system, stay with the patient and get help at once
Bubbling in the water seal when the patient coughs or breathes out	Expected air leak from the lung	Record it and watch for change
New continuous bubbling in the water seal	Large air leak from the lung or a leak in the system	Check connections from the chest to the unit; report at once
Sudden increase in bright red drainage	Possible bleeding	Assess vital signs and the patient; report at once
Crackling under the skin that is spreading	Air escaping into tissues; possible blocked drain or large leak	Assess breathing, check the drain and report

Troubleshooting

Disconnection or a broken unit. Air can enter the chest through an open tube, so the nurse acts at once as policy directs to restore the closed system: usually by reconnecting the tubing, or by attaching a new unit with aseptic technique if the ends are contaminated (Asciak et al., 2023). One review allows clamping by hand for less than a minute while this is done (da Silva et al., 2024). The nurse then assesses breathing and SpO2 and reports the event. If the unit tips over, the nurse sets it upright, checks the water seal and replaces the unit if the chambers have mixed, following the manufacturer's instructions.

Accidental removal. A dislodged drain is never pushed back in, because of infection risk; a new drain may be needed at a new site (Asciak et al., 2023). The nurse covers the site at once with a dressing and pressure as policy directs, calls for help and watches for a growing or tension pneumothorax (da Silva et al., 2024).

Clamping. Clamping a bubbling drain can trap air and cause a tension pneumothorax (Asciak et al., 2023). Drains are not clamped for transport; the unit is kept below the chest instead. Brief clamping, for example while changing a unit, happens only as policy allows and for the shortest possible time (da Silva et al., 2024). Clamping as part of a prescribed plan, such as controlled drainage of a large effusion, follows the written order (Asciak et al., 2023).

Milking and stripping. Squeezing or stripping the tubing to move clots is not routine care: the evidence is weak, and correct positioning may be enough to keep the drain open (da Silva et al., 2024). Clots are cleared only as ordered or as policy allows, and small-bore drains may have prescribed saline flushes (Asciak et al., 2023).

Transport and mobility. The unit travels upright, below the chest and unclamped. The nurse asks whether ordered suction may be paused or must continue on a portable device.

Removal

A drain comes out when it has done its job: typically, the air leak has stopped, drainage is low and the X-ray shows a re-expanded lung. A physician, a nurse practitioner (NP) or another suitably trained person removes it, according to policy (Asciak et al., 2023).

The nurse gives prescribed analgesia beforehand, often at least 30 minutes ahead (da Silva et al., 2024), explains each step and positions the patient as directed. The patient takes a breath and bears down (the Valsalva manoeuvre) as the tube is pulled; the BTS reports that timing removal to the end of a breath in or out does not seem to change the risk of a large pneumothorax remaining, as long as the Valsalva manoeuvre is done (Asciak et al., 2023). The tube comes out in one steady pull and the site is covered quickly (Asciak et al., 2023), and an occlusive dressing is applied (da Silva et al., 2024). Afterward, the nurse monitors breathing, SpO2, breath sounds, pain, the dressing and any subcutaneous emphysema, and a chest X-ray is done as ordered (Asciak et al., 2023).

CLINICAL SAFETY

Chest Tube Safety

- Keep the drainage unit upright and below chest level at all times, including during transport and walks.
- Do not clamp a drain that is bubbling. Clamping can cause a tension pneumothorax. Clamp only briefly when policy allows, or when a written order sets out a plan.
- Keep tubing free of kinks and dependent loops, and keep connections secure.
- Assess the patient before the equipment. New breathlessness, falling SpO2, reduced breath sounds or a dropping blood pressure need action now, not after the next check.
- If the tubing disconnects or the drain falls out, act at once as policy directs: reconnect, or cover the site, then stay, assess and call for help.
- Never push a dislodged drain back in.
- Keep the bedside supplies that hospital policy requires, and check them at the start of each shift.
- Follow the manufacturer's instructions for the specific system.

(Asciak et al., 2023; da Silva et al., 2024)

15.6 Pulmonary Embolism

Pulmonary embolism ranges from a small clot found by chance to sudden cardiac arrest. It can develop in patients already in hospital, where nurses are often the first to notice it. This section builds on venous thromboembolism prevention (Chapter 7, section 7.6); deep vein thrombosis and anticoagulants are taught in full in Chapter 19.

How PE Develops

A **pulmonary embolism (PE)** is a blockage of the pulmonary artery or one of its branches, usually by a clot that has broken off from a **deep vein thrombosis (DVT)** in the leg or pelvis and travelled through the right heart into the lungs. Together, DVT and PE are called **venous thromboembolism (VTE)**. Clots form when parts of **Virchow's triad** are present: slow or still blood flow (stasis), injury to the vessel wall and blood that clots more readily than normal (hypercoagulability). Surgery combines all three.

Lung units beyond the clot still receive air but no blood, so ventilation and perfusion no longer match and blood oxygen falls. The blocked arteries also raise the pressure the right ventricle must pump against. The right ventricle can dilate and fail, starving the left ventricle of blood and lowering cardiac output; in a large PE this causes obstructive shock (Chapter 6).

The European Society of Cardiology (ESC) guideline groups risk factors by strength (Konstantinides et al., 2020):

- **Strong:** hip or knee replacement, lower-limb fracture, major trauma, spinal cord injury, a previous VTE, a recent heart attack and recent hospital care for heart failure or atrial fibrillation.
- **Moderate:** cancer and chemotherapy (Chapter 9), estrogen-containing contraceptives and hormone replacement therapy, the postpartum period, infection, inflammatory bowel disease and inherited or acquired clotting disorders (**thrombophilia**).
- **Weaker:** bed rest for more than 3 days, obesity, pregnancy, older age and long periods of sitting during travel.

About 40% of people with PE have no identifiable risk factor (Konstantinides et al., 2020).

Recognizing PE

The signs of PE are nonspecific. It is usually suspected in a patient with shortness of breath (often sudden), chest pain (often pleuritic), fainting or near-fainting, or coughing up blood (**hemoptysis**) (Konstantinides et al., 2020). Other cues include a fast heart rate and breathing rate, low SpO2, anxiety and signs of DVT, such as one swollen, painful or warm leg. Redness is harder to see on darker skin, so the nurse compares leg size, warmth and tenderness with the other side. Some patients have few signs, and some PEs are found by chance on CT (Konstantinides et al., 2020). A large PE presents with shock: low blood pressure, cool skin, confusion and, at worst, cardiac arrest.

Older adults may have vague symptoms: breathlessness may be blamed on heart or lung disease, and a faint on a fall (Chapter 8). The nurse keeps PE in mind whenever an older patient's breathing or heart rate changes without a clear reason.

Diagnosis

Testing is stepwise, so that low-risk people are not exposed to radiation and contrast dye. The details below follow the ESC guideline (Konstantinides et al., 2020) and the 2026 American Heart Association and American College of Cardiology (AHA/ACC) guideline (Creager et al., 2026), whose stepwise approach matches Choosing Wisely Canada's advice for Canadian emergency departments (Choosing Wisely Canada, 2024).

Step 1: Pretest probability. The provider judges how likely PE is, often with a structured rule. The **Wells rule** gives points for features such as signs of DVT, a fast heart rate, recent surgery or immobility, a past VTE, hemoptysis, cancer and whether PE is more likely than another diagnosis (Creager et al., 2026). The **YEARS** approach uses three items: signs of DVT, hemoptysis and PE as the most likely diagnosis (Konstantinides et al., 2020). For patients already judged low risk, the **pulmonary embolism rule-out criteria (PERC)** are eight simple clinical checks; a patient who meets all eight needs no testing. PERC is not used where PE is common (Konstantinides et al., 2020). The rules are not validated in some groups, such as pregnant patients and people with clotting disorders, so clinical judgment guides care (Choosing Wisely Canada, 2024).

Step 2: D-dimer. D-dimer is a fragment released when fibrin breaks down. A normal result makes PE unlikely when pretest probability is not high. The test gives more false-positive results with age, so for patients over 50 an **age-adjusted D-dimer cut-off** of age × 10 mcg/L reduces false positives. Under YEARS, PE is excluded when no item is present and the D-dimer is below 1,000 mcg/L, or when items are present and it is below 500 mcg/L (Konstantinides et al., 2020). Units and cut-offs vary by laboratory. Choosing Wisely Canada advises against ordering a CT pulmonary angiogram or a lung scan until a decision rule has been used and, where needed, a D-dimer result is back (Choosing Wisely Canada, 2024).

Step 3: Imaging. CT pulmonary angiography (CTPA) uses IV contrast to show clots in the pulmonary arteries. It is the test of choice, and a negative result rules out PE in patients with low or intermediate probability. A **ventilation–perfusion (V/Q) scan** compares where air and blood reach the lungs. It may be preferred in pregnancy, in young patients (especially women), after a severe reaction to contrast and in severe kidney failure (Konstantinides et al., 2020; Chapter 27). A DVT close to the trunk on leg ultrasound justifies treatment without further imaging (Konstantinides et al., 2020).

Step 4: Severity. Once PE is confirmed, the team looks for right ventricular strain: a dilated right ventricle on echocardiography or CT, a raised **troponin** (a marker of heart muscle injury) or natriuretic peptide (a marker of heart strain), and a clinical score, the simplified Pulmonary Embolism Severity Index (sPESI) (Konstantinides et al., 2020).

In rural and remote communities, CTPA may not be available locally, and transfer for imaging can mean time away from family and community (Chapter 2).

Risk Levels and Treatment

The ESC sorts PE into high, intermediate and low risk (Konstantinides et al., 2020), and Canadian protocols, such as Manitoba's provincial guideline, use the same levels (Shared Health, 2024) (Table 15.4). The 2026 AHA/ACC guideline introduced a five-category system (A to E) that readers may meet in practice (Creager et al., 2026).

High-risk PE, often called **massive pulmonary embolism**, means the circulation is unstable, with persistent hypotension (systolic pressure below 90 mm Hg, or a drop of 40 mm Hg or more lasting over 15 minutes with no other cause), obstructive shock or cardiac arrest (Konstantinides et al., 2020). For PE with hemodynamic compromise, the American Society of Hematology (ASH) recommends **thrombolysis**, treatment with a drug that dissolves the clot, followed by anticoagulation (Ortel et al., 2020). Canadian protocols, such as Manitoba's, use **alteplase**, and Manitoba's guideline tells clinicians not to delay it while awaiting specialist advice if there are no contraindications (Shared Health, 2024). Contraindications centre on bleeding risk: active internal bleeding, a past stroke, recent brain or spinal surgery or head injury, a brain tumour or vascular malformation, a bleeding disorder and severe uncontrolled hypertension (Hoffmann-La Roche, 2024; Southern Health–Santé Sud, 2024). Other options are catheter-directed treatment, mechanical clot removal and surgical **embolectomy**, often chosen by a **PE response team (PERT)** (Creager et al., 2026; Shared Health, 2024).

Intermediate-risk PE means stable blood pressure with a higher clinical score, right ventricular strain or a raised troponin. ASH suggests anticoagulation alone rather than routine thrombolysis (Ortel et al., 2020). The patient is monitored closely, and reperfusion is considered if early circulatory failure appears (Creager et al., 2026).

Low-risk PE means a stable patient with no heart strain and a low clinical score. ASH suggests home treatment when the patient has support, can get the medication and has no other reason to stay (Ortel et al., 2020).

Anticoagulation is the treatment at every level, and the ESC recommends starting it when clinical probability is high or intermediate, while tests are under way (Konstantinides et al., 2020). Anticoagulants do not dissolve the clot; they stop it from growing while the body breaks it down. When an injected drug is needed first, low-molecular-weight heparin (LMWH) is recommended over unfractionated heparin (Creager et al., 2026). In high- and intermediate-risk PE, one provincial guideline advises avoiding direct oral anticoagulants (DOACs) until the patient is stable, and any heparin infusion is stopped before alteplase (Shared Health, 2024). For ongoing treatment, a DOAC is suggested over warfarin for most patients (Ortel et al., 2020). Treatment lasts at least 3 to 6 months, and longer for some (Creager et al., 2026; Chapter 19).

Table 15.4 Pulmonary embolism risk levels and usual treatment (Konstantinides et al., 2020; Ortel et al., 2020; Creager et al., 2026; original wording)

Risk level	Typical findings	Usual treatment	Nursing focus
High (massive)	Shock, persistent low blood pressure or cardiac arrest	Thrombolysis followed by anticoagulation; catheter or surgical clot removal if thrombolysis is unsafe or fails; specialist team	Call for help at once; oxygen, monitoring and IV access; watch for bleeding and neurologic change during and after thrombolysis
Intermediate	Stable blood pressure, but a higher clinical score, right ventricular strain on imaging or a raised troponin	Anticoagulation in hospital with close monitoring; reperfusion considered if the patient worsens	Frequent vital signs and SpO2; recognize early shock and escalate; bleeding precautions
Low	Stable, no heart strain, low clinical score	Anticoagulation, often at home or with early discharge	Teaching about the anticoagulant, bleeding signs and when to seek help; arrange follow-up

Nursing Care

Using the CJMM (Chapter 1, section 1.4), the nurse treats sudden breathlessness, tachycardia, low SpO2 or chest pain after surgery as cues to analyze at once; hypoxemia and early shock are the priority problems.

- **Oxygen and monitoring:** Give oxygen to the target range (Chapter 12), monitor vital signs and SpO2 (with cardiac monitoring as ordered), sit the patient up if blood pressure allows and secure IV access.
- **Recognizing deterioration:** Rising heart rate, falling blood pressure, new confusion, cool skin or falling urine output signal shock; escalate through the rapid response system using SBAR (Chapter 6).
- **Bleeding precautions:** During and after thrombolysis, the patient needs continuous cardiac and SpO2 monitoring, frequent blood pressure and neurologic checks, close watch for bleeding and as few needle punctures and intramuscular injections as possible (Southern Health–Santé Sud, 2024). A severe headache, new confusion or weakness can mean bleeding in the brain: stop the infusion as the protocol directs and report at once. Swelling of the lips or tongue can signal angioedema (Hoffmann-La Roche, 2024). Patients over 75 bleed more easily (Southern Health–Santé Sud, 2024), and falls add to the risk for older adults on anticoagulants (Chapter 8).
- **Mobility:** Once anticoagulation is under way and the patient is stable, walking is encouraged as ordered; in a meta-analysis of patients with DVT, early walking on anticoagulants did not raise the rate of new PE (Liu et al., 2015).
- **Anxiety:** Stay with the patient, explain each step and involve the family.
- **Teaching and transition:** Teach about the anticoagulant, bleeding and follow-up. The care team should ask about breathlessness and exercise tolerance at every visit for at least a year to detect chronic thromboembolic pulmonary disease (Creager et al., 2026).

MEDICATIONS

Thrombolytics and Anticoagulants for PE

Alteplase, heparin, enoxaparin, apixaban, rivaroxaban and warfarin are marketed in Canada (Drug Shortages Canada, n.d.; Health Canada, 2026). Doses and full teaching are in Chapter 19.

- **Alteplase:** a thrombolytic that activates the body's clot-dissolving system. Bleeding is the main risk. Monitor all puncture sites, avoid intramuscular injections and do neurologic checks. Stop the infusion and report at once if signs of serious bleeding appear. Its Canadian product monograph lists heart attack and stroke; use for PE follows guidelines and hospital protocols (Hoffmann-La Roche, 2024).
- **Heparin (unfractionated):** an IV anticoagulant that boosts antithrombin. It acts and wears off quickly. An infusion is stopped before thrombolysis (Shared Health, 2024), and its effect can be reversed with protamine (Hoffmann-La Roche, 2024).
- **Low-molecular-weight heparins (such as enoxaparin):** injected under the skin; often the first anticoagulant.
- **Direct oral anticoagulants (such as apixaban and rivaroxaban):** block a single clotting factor; suggested over warfarin for most patients (Ortel et al., 2020).
- **Warfarin:** blocks vitamin K–dependent clotting factors and needs international normalized ratio (INR) monitoring.

For every anticoagulant, the nurse watches for bleeding, checks kidney function and platelet counts as ordered, and confirms the reversal plan with the pharmacist.

PATIENT EDUCATION

After a Pulmonary Embolism

- Take your anticoagulant exactly as prescribed. Do not skip doses or stop it unless your prescriber tells you to. Tell every health care provider, dentist and pharmacist that you take it.
- Check with your pharmacist before starting any new medicine, herbal product or supplement.
- Watch for bleeding: nosebleeds or bleeding gums that will not stop, blood in urine, black or bloody stools, unusual bruising, or coughing or vomiting blood. Call your prescriber about minor bleeding.
- Call 9-1-1 for sudden shortness of breath, chest pain, fainting, coughing up blood, a severe headache, weakness on one side or bleeding that will not stop.
- Report a new swollen, painful leg.
- Keep follow-up appointments. Tell your care team if your breathing or exercise tolerance has not returned to normal; lasting symptoms need checking.
- Stay active as you are able, and build up slowly.
- Ask your care team before long trips. Walk and stretch your legs during long periods of sitting.

SCOPE IN PRACTICE

Non-invasive Ventilation, Ventilated Patients and Chest Drains

Who cares for a patient on NIV, a ventilated patient or a patient with a chest drain depends on authority, competence and context, as the College of Nurses of Ontario (CNO) sets out in its Scope of Practice standard (CNO, 2025; Chapter 1, section 1.3). Employer policy and the province or territory also matter. Some employers assign ventilated patients only to registered nurses (RNs), while others employ registered practical nurses (RPNs) in critical care roles. These are employer decisions, not CNO rules. An employer can limit a nurse's practice but cannot expand it beyond what the law and the standards allow (CNO, 2025).

Respiratory therapists (RTs) manage ventilators and airways. In Ontario they are authorized to intubate, suction beyond the larynx and give substances by inhalation, and they work from orders and medical directives (College of Respiratory Therapists of Ontario [CRTO], 2024).

Chest drains are inserted by physicians and, where they are competent and employer policy allows, by NPs, who are authorized to perform procedures below the dermis and must be competent to do so (CNO, 2026). On surgical units, both RNs and RPNs assess and maintain chest drains, as policy directs and when they are competent.

Every nurse who notices deterioration acts at once. Examples include signs of tension pneumothorax, a disconnected drain or a patient struggling on NIV. The nurse stays with the patient, calls for help and escalates (Chapter 6). The RPN consults the RN as the patient's needs change.

PRACTICE STORY

The Bubbles That Would Not Stop

Names and details are fictional; this is a composite story.

Nurse: Nadia Benali, RPN. Years in practice: 4. Setting: thoracic surgery unit, community hospital, Ontario.

Mr. Ivan Petrenko was 71 and one day out from a right upper lobectomy. At my 0800 check his chest drain was tidalling nicely, and the water seal bubbled only when he coughed, which the surgeon had told us to expect. He was sitting up, SpO2 94% on 2 L by nasal cannula, and pleased he had walked to the door.

At 1015 his call bell went. He said his chest felt "tight, like a belt." His breathing rate was 28, and his SpO2 had dropped to 89%. In the water seal, the bubbling no longer came and went; it was steady and fast. I started from his chest and worked toward the unit. The dressing was dry. Then I found it: the connector between the drain and the tubing had separated by about a centimetre where the tape had peeled when he turned.

I reconnected it right away and taped it as our policy shows. The continuous bubbling slowed to the old pattern within a minute. I raised the head of his bed, increased his oxygen as ordered and stayed with him. I pressed the bell for my RN partner, Daniel. I gave him SBAR: what I had found, what I had done and his current numbers. Daniel assessed him with me and paged the surgical resident, who ordered a chest X-ray. By 1100 Mr. Petrenko's SpO2 was back to 93%, and the film showed only a small pocket of air.

Afterward, Daniel thanked me for checking the system from the patient outward instead of assuming that more bubbling just meant more leak from the lung. I filed an incident report, and our educator added "check connections at every turn" to our mobility teaching.

Reflect: Mr. Petrenko's condition changed from stable to uncertain. Which actions belonged to Grace, and at what point did she need to consult the RN? What might have happened if the connector had been clamped instead of reconnected?

Chapter 15 Summary

Introduction

- Acute respiratory failure and pulmonary embolism are common emergencies that nurses on medical-surgical units are often the first to recognize.
- In 2013–2014, ICU time was part of 11% of hospital stays by adults in Canada (excluding Quebec), and invasive ventilation was used for 33% of ICU patients.

15.1 Acute Respiratory Failure

- Hypoxemic (type 1) failure is a failure of oxygenation (PaO2 below about 60 mm Hg). Hypercapnic (type 2) failure is a failure of ventilation, with a high PaCO2.
- Causes of type 2 failure include opioids and sedatives, neuromuscular disease, chest wall disease and severe obesity, and COPD or asthma.
- Early cues include a rising respiratory and heart rate, more work of breathing, restlessness and a rising oxygen need. Late cues include slowing breathing, drowsiness and a falling SpO2 despite oxygen.
- A normal SpO2 on oxygen does not rule out rising CO2.
- The nurse positions the patient upright, gives oxygen to target, treats the cause as ordered, escalates with SBAR and makes sure goals of care are known.

15.2 Acute Respiratory Distress Syndrome

- The 2024 global definition requires a trigger, onset within 1 week, bilateral opacities not mainly from heart failure, and a PaO2/FiO2 ratio of 300 or less (or SpO2/FiO2 of 315 or less when the SpO2 is 97% or lower). It includes patients on high-flow nasal oxygen or NIV.
- Leaky capillaries flood and collapse alveoli, causing a shunt that responds poorly to oxygen.
- Care relies on lung-protective ventilation, prone positioning for severe ARDS and a conservative fluid strategy.

- Nurses coordinate safe prone turns and prevent pressure injuries.
- Survivors and families are at risk of post-intensive care syndrome.

15.3 Non-invasive and Mechanical Ventilation

- Bilevel NIV is strongly recommended for COPD exacerbations with respiratory acidosis, and bilevel NIV or CPAP for cardiogenic pulmonary edema.
- NIV must not delay intubation. A worsening pH and respiratory rate signal failure.
- A capnography waveform showing CO2 in every exhaled breath is the mainstay for confirming that an endotracheal tube is in the trachea.
- Safety checks, assessing the patient first when an alarm sounds, and VAP prevention practices are core nursing care.
- Light sedation, RASS and CAM-ICU screening, communication supports and daily breathing trials help patients leave the ventilator sooner.

15.4 Pneumothorax and Chest Injury

- A pneumothorax is air in the pleural space. It may be primary spontaneous (no known lung disease), secondary spontaneous (established lung disease or, under BTS guidance, age over 50 with a smoking history), traumatic or iatrogenic.
- Typical cues are sudden pleuritic chest pain, dyspnea, reduced breath sounds and hyperresonance on one side, tachycardia and falling SpO2. Chest X-ray, bedside ultrasound or CT confirm it.
- Under the BTS 2023 guideline, treatment depends on symptoms, safety and patient choice rather than size alone. Options range from observation to aspiration, chest drains and ambulatory devices.
- Tension pneumothorax causes obstructive shock and can kill within minutes. Hypotension, tracheal deviation and distended neck veins are late or unreliable signs. The nurse calls for help, gives oxygen and prepares for immediate decompression by a qualified provider.
- Hemothorax, rib fractures and flail chest impair breathing; pain control and pulmonary care prevent pneumonia and respiratory failure, especially in older adults.

15.5 Chest Tubes and Chest Drainage

- Chest tubes drain air, blood or fluid. Small-bore drains suit most uses; large-bore drains may be needed after thoracic surgery, for hemothorax in an unstable patient or for a large air leak.
- The water seal acts as a one-way valve. Suction, wet or dry, is used only when prescribed. Flutter valves and digital systems are alternatives to a standard water-seal unit.
- The nurse assesses the patient first, then the system: tidalling, bubbling, drainage, connections and suction setting. A sudden rise in bloody drainage, new continuous bubbling or loss of tidalling with distress must be reported at once.
- Keep the unit upright and below the chest. Do not clamp for transport or clamp a bubbling drain. Avoid dependent loops and do not milk or strip the tubing routinely.
- For removal, the nurse gives analgesia, coaches the Valsalva manoeuvre, applies an occlusive dressing and monitors the patient afterward.

15.6 Pulmonary Embolism

- PE is usually a clot from a DVT that blocks pulmonary arteries. It causes V/Q mismatch, hypoxemia and right ventricular strain, and a massive PE causes obstructive shock.
- Risk factors include surgery, fractures, immobility, prior VTE, cancer, estrogen-containing hormones, pregnancy and thrombophilia. Signs are nonspecific, so the nurse acts on sudden dyspnea, tachycardia and low SpO2.
- Diagnosis follows pretest probability (Wells, YEARS, PERC), then D-dimer (age-adjusted over 50), then CTPA or a V/Q scan. Choosing Wisely Canada advises against imaging before these steps.
- High-risk PE is treated with thrombolysis (alteplase) and anticoagulation. Intermediate-risk PE is treated with anticoagulation and close monitoring, and low-risk PE often at home.

- Nursing care centres on oxygen, monitoring, early escalation, bleeding and neurologic checks during thrombolysis, early mobility once anticoagulated, and teaching.

Key Terms (64)

acute respiratory distress syndrome: A sudden, widespread inflammatory injury to both lungs that causes noncardiogenic pulmonary edema and hypoxemic respiratory failure within 1 week of a trigger.

acute respiratory failure: Failure of the lungs to keep blood oxygen and carbon dioxide within safe limits, developing over minutes to days.

age-adjusted D-dimer cut-off: A D-dimer threshold for patients over 50, calculated as age × 10 mcg/L, that reduces false-positive results in older adults.

air leak: Air entering a chest drainage system from the lung or through a loose connection, seen as bubbling in the water seal chamber.

bilevel positive airway pressure: A form of NIV that gives a higher pressure on inspiration and a lower pressure on expiration, resting the breathing muscles and helping clear CO2.

central cyanosis: A bluish or greyish colour of the tongue, lips and lining of the mouth; a late, unreliable sign of low blood oxygen.

chest tube: A flexible tube placed between the ribs into the pleural space to drain air, blood or fluid and let the lung re-expand; also called an intercostal chest drain.

Confusion Assessment Method for the ICU: A delirium screening tool for critically ill patients, including those who cannot speak, based on four features.

continuous positive airway pressure: A form of NIV that delivers one steady pressure throughout the breath to keep airways and alveoli open.

CT pulmonary angiography (CTPA): A CT scan with IV contrast that shows clots in the pulmonary arteries; the usual imaging test for pulmonary embolism.

D-dimer: A fragment released when fibrin breaks down; a normal level makes pulmonary embolism unlikely when pretest probability is not high.

deep vein thrombosis (DVT): A blood clot in a deep vein, usually of the leg or pelvis, and the usual source of a pulmonary embolism.

digital chest drainage: A chest drainage system that provides suction electronically and measures air leak continuously.

dry suction: A chest drainage design in which an adjustable control on the unit, rather than a column of water, sets the level of suction.

embolectomy: Surgical removal of a clot from the pulmonary arteries.

end-tidal carbon dioxide: The level of CO2 at the end of each exhaled breath; a sustained waveform confirms that an endotracheal tube is in the trachea.

finger thoracostomy: An emergency procedure in which a provider makes a small incision in the chest wall and opens the pleura with a finger to release trapped air.

flail chest: Three or more ribs each broken in two or more places, leaving a loose segment of chest wall that can move inward on inspiration.

flutter valve: A one-way valve attached to a chest drain that lets air out of the pleural space without a water seal; sometimes called a Heimlich valve.

hemoptysis: Coughing up blood.

hemothorax: Blood in the pleural space.

hypercapnic respiratory failure: Type 2 respiratory failure; ventilation fails, so the PaCO2 rises above the normal range, often with a low pH.

hypoxemic respiratory failure: Type 1 respiratory failure; oxygenation fails, with a PaO2 below about 60 mm Hg and a normal or low PaCO2.

intubation: Placement of an endotracheal tube through the mouth into the trachea.

lung-protective ventilation: Ventilation with small tidal volumes and limited pressures to avoid further injury to the lungs.

massive pulmonary embolism: High-risk pulmonary embolism, in which the circulation is unstable (persistent hypotension, obstructive shock or cardiac arrest).

mechanical ventilation: Use of a machine to move air into the lungs through an endotracheal or tracheostomy tube.

non-invasive ventilation: Breathing support delivered through a tight-fitting mask rather than a tube in the airway.

noncardiogenic pulmonary edema: Fluid in the alveoli caused by leaky lung capillaries rather than by heart failure or fluid overload.

P/F ratio: The ratio of arterial oxygen pressure (PaO2) to the fraction of inspired oxygen (FiO2), used to grade the severity of hypoxemia and ARDS.

PE response team (PERT): A group of specialists who advise on treatment choices when pulmonary embolism is intermediate or high risk.

plateau pressure: The pressure in the alveoli measured during a brief pause at the end of inspiration.

pleuritic pain: Sharp chest pain that worsens with breathing in.

pneumothorax: Air in the pleural space, which causes part or all of the lung to collapse.

positive end-expiratory pressure: Pressure kept in the lungs at the end of each breath to stop alveoli from collapsing.

post-intensive care syndrome: New or worse physical, cognitive or mental health problems that begin after critical illness and last beyond the hospital stay.

post-intensive care syndrome–family: Anxiety, acute or posttraumatic stress, depression or complicated grief in family members of a critically ill patient.

predicted body weight: A weight calculated from height and sex and used to set tidal volume.

primary spontaneous pneumothorax: A pneumothorax in a person with no known lung disease.

prone positioning: Placing a ventilated patient face down for long periods to improve gas exchange in severe ARDS.

pulmonary embolism (PE): Blockage of the pulmonary artery or one of its branches, usually by a clot from a deep vein thrombosis.

pulmonary embolism rule-out criteria (PERC): Eight clinical checks used for patients already judged at low risk; a patient who meets all eight needs no further testing for pulmonary embolism.

re-expansion pulmonary edema: Rare, life-threatening fluid in the lung that can follow rapid drainage of air or fluid from the pleural space.

Richmond Agitation–Sedation Scale: A 10-level scale from +4 (combative) to −5 (unarousable), with 0 meaning alert and calm, used to measure sedation and agitation.

secondary spontaneous pneumothorax: A pneumothorax in a person with established lung disease, or, under BTS guidance, a person over 50 with a smoking history.

shunt: Blood flow past alveoli that receive no air, so the blood picks up no oxygen; hypoxemia from shunt responds poorly to extra oxygen.

spontaneous awakening trial: A planned daily pause in sedation to let the patient wake.

spontaneous breathing trial: A daily test in which the ventilated patient breathes with little or no ventilator support to judge readiness for extubation.

subcutaneous emphysema: Air trapped in the tissues under the skin, felt as crackling on palpation.

tension pneumothorax: A pneumothorax in which air enters the pleural space but cannot leave, so pressure rises, compresses the heart and great vessels and causes obstructive shock.

thrombolysis: Treatment with a drug that dissolves a blood clot, such as alteplase.

thrombophilia: An inherited or acquired tendency for blood to clot more readily than normal.

tidal volume: The volume of air delivered with each breath.

tidalling: The rise and fall of fluid in the water seal or tubing with breathing, which shows that a chest drain is open to the pleural space.

troponin: A blood marker of heart muscle injury; a raised level in pulmonary embolism suggests right ventricular strain.

venous thromboembolism (VTE): The combined term for deep vein thrombosis and pulmonary embolism.

ventilation–perfusion (V/Q) scan: A nuclear medicine scan that compares where air and blood reach the lungs; preferred when contrast or radiation is a concern.

ventilator-associated pneumonia: Pneumonia that develops in a patient receiving invasive mechanical ventilation.

Virchow's triad: The three conditions that promote clotting: stasis of blood, injury to the vessel wall and hypercoagulability.

water seal: The chamber of a chest drainage unit in which a column of water lets air leave the chest but stops it from flowing back, acting as a one-way valve.

weaning: The process of reducing ventilator support until the patient breathes without it.

Wells rule: A structured clinical rule that estimates the pretest probability of pulmonary embolism from findings such as signs of DVT, heart rate, recent surgery or immobility, and past VTE.

wet suction: A chest drainage design in which the height of a water column limits the level of suction.

YEARS: A diagnostic approach for suspected pulmonary embolism that combines three clinical items with a D-dimer threshold that depends on whether any item is present.

Licensure Review & Clinical Judgment Questions (35)

Questions tagged **[Core]** apply to all nursing students (NCLEX-RN, REx-PN, and CPNRE). Questions tagged **[RN]** draw on *Going Deeper* content.

1. [CORE] A patient admitted with pneumonia has been on nasal cannula oxygen for 6 hours. Which finding is a late sign that respiratory failure is progressing?

a. Respiratory rate rising from 18 to 26 breaths/min over the past several hours

b. New restlessness and anxiety

c. Respiratory rate slowing from 32 to 14 breaths/min with new drowsiness

d. Needing more oxygen than before to keep the SpO2 within the ordered target range

Answer: c — A slowing rate with drowsiness in a patient who was breathing fast suggests exhaustion and rising CO2, a late and dangerous sign (c) (section 15.1). A rising respiratory rate (a), new restlessness or anxiety (b) and a rising oxygen need (d) are early cues of compensation. They also need prompt reporting, but they show a body that is still compensating.

2. [CORE] A postoperative patient receiving IV opioids is on 2 L/min oxygen by nasal cannula. The SpO2 is 95%, the respiratory rate is 7 breaths/min and the patient is hard to rouse. What is the nurse's priority?

a. Increase the oxygen flow rate and recheck, since the SpO2 is still acceptable

b. Stop the opioid, rouse the patient, call for help and give naloxone as ordered

c. Document the findings and recheck in 30 minutes

d. Obtain a pain score and sedation score before deciding on the next opioid dose

Answer: b — Slow breathing and sedation after opioids suggest hypercapnic respiratory failure from reduced drive. Supplemental oxygen can keep the SpO2 normal while CO2 rises, so the nurse acts on the respiratory rate and level of consciousness (b) (section 15.1; Chapter 5, section 5.4). More oxygen (a) does not treat hypoventilation. Waiting (c) delays urgent care. Scoring pain and sedation before the next dose (d) delays action for a patient who cannot be roused.

3. [CORE] Which ABG result best fits acute hypercapnic (type 2) respiratory failure?

a. pH 7.26, PaCO2 70 mm Hg, PaO2 58 mm Hg

b. pH 7.47, PaCO2 32 mm Hg, PaO2 55 mm Hg

c. pH 7.40, PaCO2 40 mm Hg, PaO2 92 mm Hg

d. pH 7.38, PaCO2 52 mm Hg, HCO3− 31 mmol/L, PaO2 65 mm Hg

Answer: a — A high PaCO2 with a low pH shows an acute rise in CO2 (a) (section 15.1). Option b, with low oxygen and low CO2, fits hypoxemic (type 1) failure in a patient breathing fast. Option c is normal. Option d shows a high PaCO2 with a near-normal pH and raised bicarbonate, the pattern of chronic, compensated CO2 retention (Chapter 14).

4. [CORE] A patient with ARDS remains hypoxemic despite a high FiO2. Which explanation is most accurate?

a. The patient's drive to breathe is suppressed by the oxygen

b. Heart failure is pushing fluid back into the lungs from the left ventricle

c. The oxygen is too dry to cross the alveolar membrane

d. Blood flows past flooded and collapsed alveoli without picking up oxygen

Answer: d — In ARDS, fluid-filled and collapsed alveoli receive blood but no air, creating a shunt that responds poorly to extra oxygen (d) (sections 15.1 and 15.2). Suppressed drive (a) affects CO2 clearance, not shunt. ARDS is noncardiogenic; the edema is not mainly from heart failure (b). Humidity (c) does not explain refractory hypoxemia.

5. [CORE] A patient with pneumonia has bilateral opacities on chest X-ray, developed 3 days after admission, and is receiving high-flow nasal oxygen at 40 L/min. The PaO2/FiO2 ratio is 180 mm Hg, and heart failure has been ruled out. How does the 2024 global definition apply?

a. ARDS cannot be diagnosed until the patient is intubated

b. The patient meets the criteria for ARDS

c. ARDS is ruled out because the onset was after 24 hours

d. ARDS is ruled out because pneumonia explains the opacities

Answer: b — The 2024 definition includes non-intubated patients on high-flow nasal oxygen of at least 30 L/min with a PaO2/FiO2 ratio of 300 mm Hg or less, onset within 1 week of the trigger, and bilateral opacities not explained by heart failure (b) (section 15.2). Intubation is no longer required (a). The time window is 1 week, not 24 hours (c). Pneumonia is a common trigger for ARDS, not an exclusion (d).

6. [CORE] A ventilated patient with severe ARDS has been placed in the prone position. Which nursing action is most important during the prone period?

a. Keep the head turned to the same side throughout to protect the endotracheal tube

b. Stop enteral feeding for the whole prone session

c. Check pressure points often and reposition the head and arms per protocol

d. Return the patient to the supine position as soon as the SpO2 rises above 92%

Answer: c — Pressure injuries and facial swelling are among the most frequent complications of prone positioning. Regular checks and repositioning of the head and arms are common protective strategies (c) (section 15.2). Leaving the head in one position (a) raises the risk of facial pressure injury. Feeding decisions (b) follow the team's protocol, not a fixed rule. Prone sessions are planned for long periods, and an improved SpO2 is not a reason to turn back early (d).

7. [CORE] The daughter of a patient discharged from the ICU after ARDS says, "I can't sleep, and I keep reliving that week." Which response by the nurse is best?

a. "Many families have lasting stress after an ICU stay. Can we talk about supports for you?"

b. "Those feelings are normal, and they will pass on their own once your father is settled at home."

c. "Your father is the patient right now, so his recovery is what we all need to focus on."

d. "You should ask your father's physician to prescribe something for sleep."

Answer: a — Post-intensive care syndrome–family includes anxiety, acute and posttraumatic stress, depression and complicated grief, which can last for years. The nurse acknowledges this and links the family member with support (a) (section 15.2). Promising that it will pass (b) is false reassurance. Dismissing the family member's needs (c) ignores PICS-F. Directing her to her father's physician (d) is not appropriate; she needs her own care and support.

8. [CORE] A patient on bilevel NIV for a COPD exacerbation becomes nauseated and is harder to rouse. What should the nurse do first?

a. Tighten the mask straps to reduce the air leak and improve the delivered pressure

b. Give oral fluids to settle the nausea

c. Lower the head of the bed so the patient can rest more comfortably on the mask

d. Stay, keep the head of the bed raised and call the physician and RT urgently

Answer: d — A drowsy, nauseated patient on a tight mask is at risk of aspiration and may not be able to protect the airway; drowsiness may also mean rising CO2. The nurse stays, keeps the head up and escalates (d) (section 15.3). Tightening the mask (a) adds skin injury risk and does not address the danger. Oral fluids (b) raise aspiration risk. Lowering the head of the bed (c) also raises aspiration risk.

9. [CORE] A patient has been on bilevel NIV for 2 hours for acute hypercapnic respiratory failure. Which finding most strongly suggests NIV is failing?

a. pH fell from 7.29 to 7.23 and respiratory rate rose to 36 breaths/min

b. The respiratory rate has fallen from 30 to 22 breaths/min since NIV was started

c. The patient asks for a short mask break to take a drink of water and rest the face

d. SpO2 is 90% on the ordered oxygen

Answer: a — A worsening pH with a rising respiratory rate means NIV is not reversing hypercapnic failure, and the plan must change (a) (section 15.3). A falling respiratory rate (b) suggests success. A request for a break (c) is common and is managed safely. An SpO2 of 90% (d) is within the usual 88–92% target for hypercapnic failure.

10. [CORE] A patient has just been intubated. Which finding best confirms that the tube is in the trachea?

a. Mist inside the tube during exhalation

b. Breath sounds heard on the right side of the chest

c. A sustained CO2 waveform on capnography with each breath

d. An SpO2 that stays above 92% for the first minute after the tube is placed

Answer: c — A capnography waveform showing CO2 in every exhaled breath is the mainstay for confirming that the tube is in the trachea (c) (section 15.3). Misting (a) and breath sounds (b) can occur even with an esophageal tube and are unreliable. Oxygen saturation (d) may stay high for minutes after an esophageal intubation in a well-oxygenated patient, so it does not confirm placement.

11. [CORE] The high-pressure alarm sounds on a ventilated patient's ventilator. What should the nurse do first?

a. Silence the alarm and call the RT

b. Look at the patient for coughing, biting, secretions or distress

c. Raise the high-pressure alarm limit so that the alarm stops sounding

d. Increase the FiO2

Answer: b — The nurse looks at the patient first; a high-pressure alarm often means coughing, biting, secretions or a kink (b) (section 15.3). Silencing the alarm without assessing (a) is unsafe. Changing alarm limits (c) hides the problem and is outside the nurse's role unless policy allows it. Raising the FiO2 (d) does not address the cause.

12. [CORE] A nurse is planning care for a patient on invasive mechanical ventilation. Which actions help prevent ventilator-associated pneumonia? Select all that apply.

a. Keep the head of the bed at 30–45 degrees unless contraindicated

b. Brush the patient's teeth as part of regular oral care

c. Use chlorhexidine mouth rinse for routine oral care

d. Take part in daily sedation interruption and spontaneous breathing trials

e. Keep the patient sedated deeply to reduce oxygen use

f. Help the patient get out of bed early when safe

Answer: a, b, d, f — Elevating the head of the bed (a), toothbrushing (b), daily sedation interruption and breathing trials (d) and early mobility (f) are essential VAP prevention practices (section 15.3, Table 15.2). Chlorhexidine oral care (c) is no longer recommended because it has no clear effect on VAP rates and may cause harm. Deep sedation (e) prolongs ventilation; light sedation is preferred.

13. [CORE] A ventilated patient has a RASS score of −2. Over the past few hours, the patient's mental status has changed from earlier in the day. On the CAM-ICU letters attention test, the patient makes 5 errors. What does the nurse conclude?

a. Delirium cannot be assessed because the patient is sedated

b. Delirium is absent because the patient follows some commands

c. More testing for disorganized thinking is needed before delirium can be identified

d. The patient screens positive for delirium

Answer: d — The CAM-ICU is positive when an acute change or fluctuation and inattention are both present, plus either an altered level of consciousness or disorganized thinking. A RASS other than 0 means an altered level of consciousness, so all required features are present (d) (section 15.3). The patient responded well enough to complete the letters test, so delirium can be assessed (a). Following some commands does not rule out delirium (b). Disorganized thinking need not be tested because feature 3 is present (c).

14. [CORE] A registered practical nurse (RPN) on a step-down unit in Ontario is asked to care for a patient on bilevel NIV. How should the RPN decide whether to accept the assignment?

a. Weigh authority, competence and context, including employer policy and support

b. Accept, because CNO allows RPNs to care for any patient admitted to a step-down unit

c. Decline, because CNO limits RPNs to caring for stable patients with predictable outcomes

d. Accept, because the RT is solely responsible for patients on NIV

Answer: a — The College of Nurses of Ontario (CNO) Scope of Practice standard asks nurses to consider authority, competence and context (CNO, 2025). Context includes employer policy, the setting and available resources, such as an RN and an RT to consult (a) (section 15.3; Chapter 1, section 1.3). No blanket rule allows every assignment (b). "Stable and predictable" is a common employer practice, not a CNO rule (c). The nurse remains accountable for nursing assessment and care even when an RT manages the device (d).

15. [CORE] Which patient is the best candidate for a trial of bilevel NIV, according to current guidelines?

a. A patient with a COPD exacerbation whose PaCO2 is 52 mm Hg and whose pH is 7.40

b. A patient who is vomiting repeatedly and cannot protect the airway on their own

c. A patient with a COPD flare, pH 7.28 and PaCO2 72 mm Hg despite treatment

d. A patient in respiratory arrest

Answer: c — Bilevel NIV is strongly recommended for COPD exacerbations with respiratory acidosis, and the BTS advises starting it when acidosis persists despite treatment (c) (section 15.3). During an exacerbation, NIV is not suggested for high CO2 without acidosis (a). A patient who cannot protect the airway (b) or who has stopped breathing (d) needs intubation, not NIV.

16. [RN] An intubated patient with ARDS on a PEEP of 10 cm H2O has a PaO2 of 72 mm Hg on an FiO2 of 0.6. How is this patient's ARDS classified under the 2024 global definition?

a. Mild
b. Moderate
c. Severe
d. Not ARDS, because the PaO2 is above 60 mm Hg

Answer: b — The P/F ratio is 72 ÷ 0.6 = 120, which falls in the moderate range (more than 100 and up to 200) for intubated patients on a PEEP of at least 5 cm H2O (b) (Going Deeper box, section 15.3). Mild (a) is more than 200 and up to 300. Severe (c) is 100 or less. The definition uses the ratio, not the PaO2 alone (d).

17. [RN] A ventilated patient with ARDS is 175 cm tall and weighs 110 kg. The ordered tidal volume is based on actual body weight. Which action by the nurse is best?

a. Accept the order, since a larger patient needs larger breaths to meet oxygen demand
b. Increase the respiratory rate to make up for the larger breaths
c. Check the plateau pressure only if the patient's SpO2 begins to fall below target
d. Question the order, because lung-protective ventilation uses predicted body weight

Answer: d — Lung-protective ventilation for ARDS uses 4–8 mL/kg of predicted body weight, which is based on height and sex. Basing it on actual weight in a patient with obesity would overstretch the lungs, so the nurse questions the order with the physician and RT (d) (Going Deeper box, section 15.3). Lung size does not grow with body weight (a). A higher rate (b) does not correct oversized breaths. Plateau pressure is monitored routinely, not only when the SpO2 falls (c).

Case: Harjit Sandhu (Questions 18–27): Harjit Sandhu, 58, is on a surgical unit on day 1 after a right lower lobectomy. He has a right chest drain connected to a drainage unit with wet suction as ordered. His vital signs are stable, and he rates his pain 3 out of 10.

18. [CORE] Which finding shows the nurse that Mr. Sandhu's chest drain is open to the pleural space?

a. Continuous, vigorous bubbling in the water seal chamber during every breath
b. Fluid in the water seal rising and falling with each breath
c. No fluid in the collection chamber over the past 2 hours
d. Absence of bubbling in the wet suction control chamber

Answer: b — Tidalling (b) shows that pressure changes in the pleural space are reaching the water seal, so the drain is open (section 15.5). Continuous bubbling in the water seal (a) means a large air leak or a system leak and must be investigated. No drainage (c) may mean the drain is blocked or that drainage has stopped; it does not show that the drain is open. Gentle continuous bubbling in a wet suction chamber is expected, so its absence (d) suggests the suction is not working as set.

19. [CORE] At 1500, the nurse finds 250 mL of bright red drainage in the collection chamber over the past hour. In the previous hours, drainage was 30 to 50 mL per hour of pink fluid. What should the nurse do first?

a. Milk the tubing firmly from the chest toward the unit to keep clots from blocking the drain
b. Lower the drainage unit further below the chest
c. Assess him and his vital signs, then report to the surgeon at once
d. Record the amount and recheck the drainage in 4 hours

Answer: c — A sudden rise in bright red drainage suggests bleeding, which needs prompt assessment and reporting (c) (section 15.5; Table 15.3). Milking (a) is not routine care and does nothing for bleeding. The unit is already below the chest; moving it lower (b) does not address the problem. Waiting 4 hours (d) delays care for possible hemorrhage.

20. [CORE] Mr. Sandhu is going to the imaging department for a chest X-ray. Which action by the nurse is correct?

a. Keep the unit upright, below his chest and unclamped
b. Clamp the chest tube near the insertion site until he returns to the unit
c. Place the drainage unit on the stretcher beside his pillow so it stays in view
d. Empty the collection chamber into a graduated container before transport so the drainage does not spill

Answer: a — Drains are not clamped for transport; the unit stays upright and below the chest (a) (section 15.5). Clamping (b) can trap air and cause a tension pneumothorax. A unit placed at pillow level (c) is above the chest, so fluid could flow back into the pleural space. The collection chamber of a closed system is not emptied (d); drainage is measured and marked, and the unit is changed only as policy directs.

21. [CORE] While Mr. Sandhu is walking, his chest tube is pulled out of his chest. What is the nurse's priority action?

a. Reinsert the tube gently along the same track, then secure it with tape and notify the surgeon
b. Clamp the tubing and return Mr. Sandhu to bed
c. Ask him to cough forcefully to expel any trapped air
d. Cover the site at once as policy directs and call for help

Answer: d — The nurse covers the site at once with a dressing as policy directs, gets help and watches for a growing or tension pneumothorax (d) (section 15.5). A dislodged drain is never pushed back in (a); a new drain may be needed at a new site. Clamping the tubing (b) does nothing once the tube is out of the chest. Coughing (c) does not remove air from the pleural space and delays care.

22. [CORE] Recognize cues: Which group of findings is most significant?

a. Temperature 37.1 °C, her recent knee surgery, her anxiety and her statement that something is wrong

b. Blood pressure 128/76 mm Hg and alertness

c. Pain in her operated knee and difficulty sleeping

d. Sudden dyspnea, heart rate 118, SpO2 88% and a swollen, tender calf

Answer: d — Sudden breathlessness, tachycardia, hypoxemia and signs of DVT together are the key cues (d) (section 15.6). A normal temperature (a) is not a concerning cue, although recent surgery is a risk factor. Her stable blood pressure and alertness (b) are reassuring, not concerning. Knee pain and poor sleep (c) are expected after surgery and do not explain her sudden symptoms.

23. [CORE] Analyze cues: Which condition best explains Ms. Beaulieu's findings?

a. Opioid-induced respiratory depression

b. Pulmonary embolism

c. Postoperative pneumonia

d. Anxiety attack

Answer: b — Sudden dyspnea, pleuritic chest pain, tachycardia, hypoxemia and a swollen calf after joint replacement point to PE (b) (section 15.6). Opioid-induced respiratory depression (a) causes slow, shallow breathing and drowsiness, not tachypnea (Chapter 5). Pneumonia (c) usually develops over hours to days with fever and cough. An anxiety attack (d) does not cause hypoxemia or a swollen calf, and assuming anxiety could miss a life-threatening condition.

24. [CORE] Prioritize hypotheses: Which problem is the nurse's priority?

a. Impaired gas exchange

b. Fear related to sudden illness

c. Acute pain in the operated knee

d. Risk for falls related to anticoagulant therapy and reduced mobility after knee surgery

Answer: a — Hypoxemia from PE threatens life and comes first (a) (section 15.6). Fear (b) is real and is addressed while care proceeds, but it is not the most urgent problem. Knee pain (c) is not the immediate threat. Fall risk with anticoagulant therapy (d) matters, but it is not an immediate threat to life.

25. [CORE] Generate solutions and take action: What should the nurse do first?

a. Give the prescribed as-needed analgesic for her chest pain, document the findings and reassess her in 30 minutes

b. Encourage her to walk to help her breathing

c. Give oxygen, stay with her and call the rapid response team

d. Massage her calf to relieve the swelling

Answer: c — The nurse treats hypoxemia, stays with the patient and escalates at once (c) (section 15.6; Chapter 6). An analgesic (a) may ease pain but delays escalation for a possible PE. Walking (b) increases oxygen demand in an unstable patient. Massaging a calf with a suspected DVT (d) is avoided and does not treat the problem.

26. [CORE] Take action: The physician orders LMWH to start now and a CT pulmonary angiogram. Ms. Beaulieu asks why she is getting a "blood thinner" before the scan confirms anything. Which response by the nurse is best?

a. "The medication dissolves the clot, so it helps the scan show the problem more clearly."

b. "When a clot is likely, starting treatment during testing keeps it from getting worse."

c. "It is a routine order for everyone after knee surgery, so it is not related to your symptoms."

d. "The scan is risky, and the medication protects your kidneys from the contrast dye."

Answer: b — Guidelines recommend starting anticoagulation when PE is likely, while testing continues (b) (section 15.6). Anticoagulants stop clots from growing; they do not dissolve them, and they do not change how the scan looks (a). Prophylaxis is routine after joint replacement, but this order is for suspected PE, so (c) is misleading. LMWH does not protect the kidneys from contrast (d).

27. [CORE] Evaluate outcomes: CTPA confirmed a PE. Which finding 24 hours later best shows that Ms. Beaulieu is improving?

a. Heart rate 124, new confusion and restlessness

b. Blood pressure 88/50 mm Hg with cool hands

c. Several small bruises at her LMWH injection sites on the abdomen

d. SpO2 94% on 2 L, heart rate 92, less dyspnea

Answer: d — Better oxygen saturation, a slower heart rate and less dyspnea show improvement (d) (section 15.6). A rising heart rate with confusion (a) and low blood pressure with cool hands (b) suggest worsening and possible shock, which need urgent escalation. Small bruises at injection sites (c) are common with LMWH and do not show whether the PE is improving.

28. [CORE] Which findings should the nurse recognize as possible signs of a tension pneumothorax? Select all that apply.

a. Severe, worsening shortness of breath

b. Heart rate 132

c. Falling blood pressure

d. Bradycardia that improves with oxygen

e. Reduced breath sounds on one side

f. Productive cough with fever developing over 3 days

g. Falling SpO2

Answer: a, b, c, e, g — Respiratory distress (a), tachycardia (b), reduced air entry on one side (e) and hypoxemia (g) are early signs. Falling blood pressure (c) is a later sign of obstructive shock (section 15.4). Tension pneumothorax causes a fast heart rate, not bradycardia that improves with oxygen (d). A productive cough with fever over several days (f) suggests infection, not tension pneumothorax.

29. [CORE] A patient's chest drain tubing separates from the drainage unit while the patient is turning in bed. What is the nurse's most appropriate action?

a. Reconnect the tubing at once as policy directs, then assess the patient

b. Leave the tubing open to air until the surgeon arrives to check it

c. Clamp the chest tube close to the dressing and leave it clamped until the next chest X-ray confirms that the lung is expanded

d. Remove the chest tube and cover the site with gauze

Answer: a — The nurse restores the closed system right away as policy directs, using a new sterile unit if the ends are contaminated, and then assesses the patient (a) (section 15.5). An open tube (b) lets air into the chest. Leaving a drain clamped (c) can cause a tension pneumothorax. Removing the drain (d) is outside routine nursing action and is not indicated.

30. [CORE] Which patient has the strongest risk factor for pulmonary embolism?

a. A 30-year-old who sat through a 3-hour bus ride

b. A 45-year-old with mild obesity who walks daily and takes no medications

c. A 70-year-old admitted 2 days ago with a hip fracture who is on bed rest

d. A 25-year-old who is 10 weeks pregnant

Answer: c — Lower-limb fracture is a strong risk factor, and this patient is also older and less mobile (c) (section 15.6). A short bus ride (a) carries little risk; prolonged sitting during long travel is only a weak factor. Obesity (b) is a weak factor, and daily walking lowers stasis. Pregnancy (d) raises risk, but less than a fracture of the leg.

31. [CORE] A patient is receiving alteplase for a high-risk pulmonary embolism. Which finding requires the nurse to stop the infusion as the protocol directs and report at once?

a. Mild oozing at the IV site that stops with light pressure

b. A new severe headache and confusion

c. Heart rate decreasing from 118 to 100

d. SpO2 rising from 88% to 93%

Answer: b — A new severe headache with confusion may signal bleeding in the brain, a critical bleed that calls for stopping the infusion and reporting at once (b) (section 15.6). Minor oozing that stops with pressure (a) is watched and reported, but it is not a critical bleed. A slowing heart rate (c) and rising SpO2 (d) suggest improvement.

32. [CORE] An RPN on a surgical unit is caring for a patient with a chest drain. The patient was stable this morning but is now very short of breath, with SpO2 86% and absent breath sounds on the drain side. What should the RPN do?

a. Stay, call the rapid response team, give oxygen and inform the RN

b. Finish giving medications to her other patients, then report the change to the RN at the next scheduled huddle

c. Ask the RN to take over the patient and return to other assignments

d. Clamp the chest drain to stop air from leaking out

Answer: a — Every nurse who notices deterioration acts at once and escalates, and the RPN consults the RN as the patient's needs change (a) (Scope in Practice box; section 15.4). Delaying (b) risks death from a possible tension pneumothorax. Handing over and leaving (c) abandons an unstable patient. Clamping a drain (d) can make a tension pneumothorax worse.

33. [RN] A 72-year-old patient in the emergency department has suspected PE, and the provider has judged her clinical probability to be low. Her D-dimer result is 620 mcg/L, and the laboratory's standard cut-off is 500 mcg/L. Using an age-adjusted cut-off, how should the nurse interpret this result?

a. The result is above the laboratory's standard cut-off, so CTPA is required to rule out PE

b. The result cannot be used because she is over 50

c. It is below her age-adjusted cut-off of 720 mcg/L, so PE can be excluded without imaging

d. The result means a V/Q scan should replace CTPA

Answer: c — For patients over 50, the age-adjusted cut-off is age × 10 mcg/L, which is 720 mcg/L for this patient. Her result of 620 mcg/L is negative, and with low probability PE is excluded (c) (section 15.6). Against the age-adjusted cut-off the result is not positive (a). Age-adjusted D-dimer was designed for patients over 50, so (b) is wrong. A D-dimer result does not decide between CTPA and V/Q scanning (d).

34. [RN] For which patient with suspected PE would the nurse expect a V/Q scan rather than CTPA?

a. A patient with a past anaphylactic reaction to iodinated contrast

b. A patient with mild asthma and a normal chest X-ray who is not pregnant

c. A patient with a history of hip replacement

d. A patient who is hypotensive and too unstable to leave the emergency department

Answer: a — A V/Q scan is preferred when contrast is a concern, such as after a previous anaphylactic reaction to contrast (a) (section 15.6). Mild asthma with a normal X-ray (b) and a past hip replacement (c) are not reasons to avoid CTPA. An unstable patient (d) needs immediate bedside assessment and treatment, and a V/Q scan is not a bedside test.

35. [RN] A patient with confirmed PE has a blood pressure of 124/78 mm Hg, a raised troponin and a dilated right ventricle on CT. Which plan does the nurse anticipate?

a. Immediate systemic thrombolysis, because a raised troponin shows the right ventricle is failing

b. Discharge home today with an oral anticoagulant

c. No anticoagulation until an echocardiogram is repeated

d. Anticoagulation in hospital with close monitoring

Answer: d — A stable blood pressure with right ventricular strain and a raised troponin means intermediate-risk PE. Treatment is anticoagulation with close monitoring, and reperfusion is considered if the patient worsens (d) (section 15.6; Table 15.4). Routine thrombolysis (a) is not suggested for patients without hemodynamic compromise. Signs of heart strain make home treatment (b) unsuitable. Anticoagulation should not be delayed (c).

IV Cardiovascular & Vascular Nursing Care

UNIT CLINICAL SCOPE & INTEGRATION

Integrates Canadian Cardiovascular Society (CCS) and Hypertension Canada guidelines across cardiac assessment, 12-lead ECG and bedside dysrhythmia interpretation, pacemaker and ICD care, coronary artery disease, acute coronary syndromes (STEMI/NSTEMI), heart failure, valvular and inflammatory heart disease, hypertension, aortic aneurysms, peripheral arterial disease, and venous thromboembolism.

Contents of UNIT IV

Chapter	Chapter Title	Visual Assets	Page
Chapter 16	Cardiac Assessment and Dysrhythmias	22 Figs • 4 Tbls	p. 439
Chapter 17	Coronary Artery Disease and Acute Coronary Syndromes	5 Figs • 4 Tbls	p. 476
Chapter 18	Heart Failure, Valvular and Inflammatory Heart Disease	10 Figs • 4 Tbls	p. 504
Chapter 19	Hypertension and Vascular Disorders	8 Figs • 4 Tbls	p. 538

16 Cardiac Assessment and Dysrhythmias

LEARNING OUTCOMES & COMPETENCY MAPPING

By the end of this chapter, you will be able to:

1. Relate the heart's structure, conduction system and cardiac output to assessment findings.
2. Perform a focused cardiovascular assessment, describing findings accurately on a range of skin tones.
3. Interpret common cardiac tests and laboratory values in SI units (troponin, natriuretic peptides, electrolytes) and prepare patients for them.
4. Apply cardiac monitoring safely: lead placement, alarm management and when monitoring is indicated.
5. Analyze a rhythm strip systematically and recognize common dysrhythmias.
6. Respond to dysrhythmias by stability, including the emergency response to pulseless rhythms.
7. Care for patients with atrial fibrillation, heart blocks, pacemakers, implantable cardioverter-defibrillators, cardioversion and defibrillation.
8. Distinguish RN and RPN roles in cardiac monitoring and dysrhythmia response using CNO's authority, competence and context.

How the outcomes map to the CNO entry-to-practice competencies

Outcome	RN competency role (CNO, 2019a)	RPN competency category (CNO, 2019b)
1, 2, 3, 5	Clinician; Scholar	Foundations of Practice
4, 6, 7	Clinician; Collaborator; Educator	Foundations of Practice; Collaborative Practice
8	Professional; Coordinator	Legal Practice; Collaborative Practice

Introduction

Heart disease is one of the main causes of death in Canada. In preliminary data for 2024, diseases of the heart caused 17.7% of all deaths, second only to cancer (Statistics Canada, 2026). Heart problems are not confined to cardiac units. A patient recovering from hip surgery may develop a fast, irregular pulse. A patient admitted with pneumonia may wake at night with pressure in the chest. On any unit, the nurse is often the first person to notice the change, and what the nurse does in the next few minutes matters.

This chapter builds the skills that the later cardiac chapters rely on. Section 16.1 reviews how the heart pumps and how its electrical system works. Section 16.2 covers the focused cardiovascular assessment, and section 16.3 the tests used to find heart disease. Section 16.4 explains cardiac monitoring and a step-by-step way to read a rhythm strip. Sections 16.5 to 16.7 apply that method to common dysrhythmias, to atrial fibrillation and flutter, and to heart blocks, pacemakers and implantable devices.

Chapters 16 to 20 form the book's cardiovascular unit:

- Chapter 17: coronary artery disease and acute coronary syndromes;
- Chapter 18: heart failure and valvular and inflammatory heart disease;
- Chapter 19: hypertension, vascular disorders, venous thromboembolism (VTE) and anticoagulation;
- Chapter 20: blood disorders and transfusion.

16.1 The Heart and Its Rhythm: A Brief Review

Structure and Blood Flow

The heart is a muscular pump with four chambers (Figure 16.1). The upper chambers, the right and left atria, receive blood; the lower chambers, the right and left ventricles, pump it out. Four valves keep blood moving in one direction. The **atrioventricular valves** (tricuspid on the right, mitral on the left) sit between each atrium and its ventricle. The **semilunar valves** (pulmonic and aortic) guard the exits from the ventricles. The closing of these valves makes the normal heart sounds (section 16.2) (Warriner et al., 2019). The heart sits inside a protective sac, the pericardium; inflammation of this sac is covered in Chapter 18.

The heart works as two pumps side by side. The right side sends oxygen-poor blood from the body through the lungs, where it picks up oxygen and gives off carbon dioxide (the pulmonary circuit). The left side pumps oxygen-rich blood from the lungs through the aorta to the body (the systemic circuit).

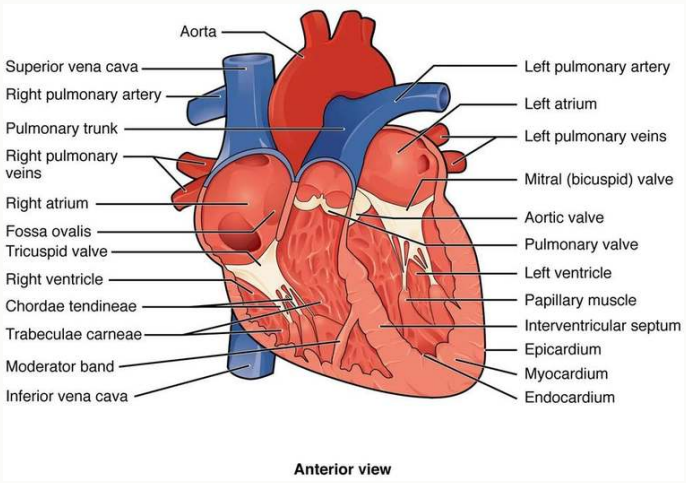

Figure 16.1 The inside of the heart, front view: the four chambers, the four valves and the great vessels. (credit: Figure 19.9, "Internal Structures of the Heart," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

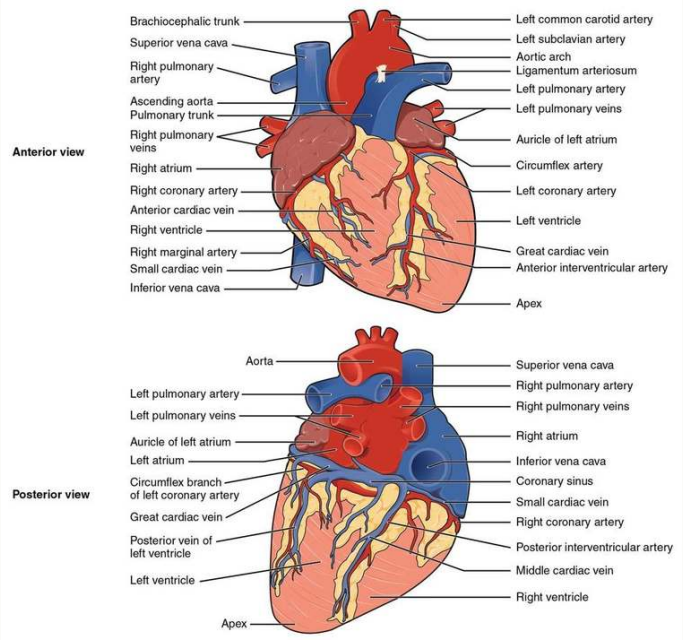

Figure 16.2 The coronary arteries and cardiac veins on the surface of the heart, front view (top) and back view (bottom). (credit: Figure 19.15, "Coronary Circulation," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

The heart muscle gets its own blood supply from the coronary arteries, which branch off the aorta and run over the surface of the heart (Figure 16.2). When the left ventricle contracts in **systole**, the muscle squeezes the vessels inside its own wall. At rest, blood does not move forward through the large surface coronary arteries of the left ventricle while the ventricle contracts (Sniderman et al., 2025). The left ventricle therefore fills its coronary arteries mainly during **diastole**, the relaxation phase between beats. A very fast heart rate shortens diastole, leaving less time for the heart muscle to receive blood just when it needs more (Chapter 17).

The Conduction System

Each heartbeat starts as an electrical impulse (Figure 16.3). The **sinoatrial (SA) node**, a cluster of specialized cells high in the right atrium near the superior vena cava, is the heart's normal pacemaker because its cells fire faster than any others (Sampson & McGrath, 2015). A rhythm that starts in the SA node is called a sinus rhythm.

The impulse spreads across both atria, which contract and push blood into the ventricles. It then reaches the **atrioventricular (AV) node**, low in the right atrium. In a normal heart, the AV node and the bundle of His are the only route from the atria to the ventricles. The AV node conducts about ten times more slowly than the surrounding muscle. This built-in delay lets the atria finish emptying before the ventricles contract. It also limits how many impulses reach the ventricles when the atria fire very fast, as in atrial fibrillation (section 16.6) (Sampson & McGrath, 2015).

From the AV node, the impulse travels down the bundle of His, which divides into the right and left bundle branches. These end in the Purkinje fibres, which spread the impulse through the ventricles almost at once, so the ventricles contract together (Sampson & McGrath, 2015).

Every part of the system can produce impulses, but lower sites fire more slowly. Typical intrinsic rates are 60 to 100 beats per minute (bpm) for the SA node, 40 to 60 bpm for the AV node and 20 to 40 bpm for the His–Purkinje system (Sampson & McGrath, 2015). If the SA node fails, a lower site can take over as a backup. These backup pacemakers are slower, and those below the AV junction are less reliable (Sampson, 2016). Section 16.7 shows why this matters in heart block.

Electrical activation of heart muscle cells is called **depolarization**; it triggers contraction. The return of the cells to their resting electrical state is **repolarization**. On the electrocardiogram (ECG), the **P wave** shows atrial depolarization, the **QRS complex** shows ventricular depolarization, and the **T wave** shows ventricular repolarization (Sampson & McGrath, 2015). The ECG records electrical activity only. It does not show whether the heart is pumping blood, which is why the nurse always checks the patient (section 16.4) (Figure 16.4).

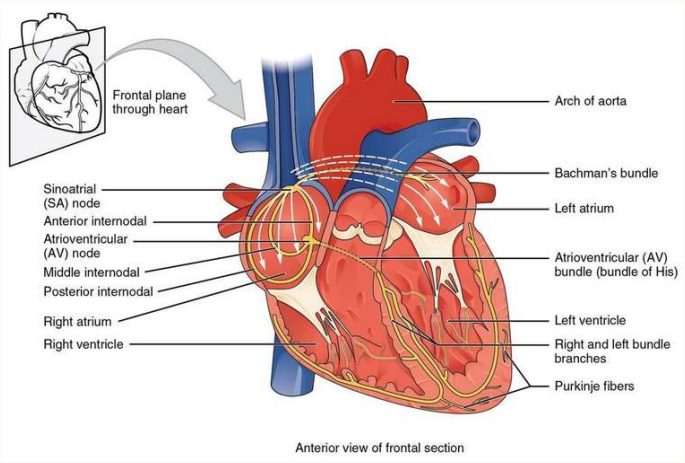

Figure 16.3 The conduction system of the heart, from the sinoatrial (SA) node through the atrioventricular (AV) node and bundle of His to the bundle branches and Purkinje fibres. (credit: Figure 19.18, "Conduction System of the Heart," in Anatomy and Physiology 2e by J. Gordon Betts et al./OpenStax, CC BY-NC-SA 4.0)

Cardiac Output

Cardiac output is the amount of blood the heart pumps each minute. It equals the heart rate multiplied by the **stroke volume**, the amount the left ventricle ejects with each beat (Vincent, 2008). Three factors shape stroke volume:

- **Preload:** how much the ventricle fills, and so how much its muscle is stretched, before it contracts (Vincent, 2008). Bleeding and dehydration lower it; fluid overload raises it.
- **Afterload:** the force the ventricle must work against to eject blood (Vincent, 2008). High blood pressure or a narrowed aortic valve raises it.
- **Contractility:** the strength of the muscle's squeeze, apart from how much it was stretched. Damaged heart muscle contracts less well.

The autonomic nervous system adjusts these factors. Sympathetic nerves act like an accelerator: they speed the heart rate and conduction and strengthen contraction during exercise or stress. Parasympathetic fibres in the vagus nerve act like a brake, slowing the heart at rest (Sampson & McGrath, 2015).

A heart rate that is too slow, as in a severe bradycardia, can lower cardiac output because too few beats occur each minute. A rate that is too fast can also lower it. Acute supraventricular or ventricular tachycardia can lower cardiac output enough to cause cardiogenic shock (Vincent, 2008), partly because a fast rate shortens diastole and leaves the ventricles too little time to fill. The nurse looks for the effects: dizziness, low blood pressure, confusion, chest pain or breathlessness (sections 16.2 and 16.5).

16.2 Focused Cardiovascular Assessment

History

The nurse asks open questions and records the patient's own words. For chest pain or discomfort, the nurse explores:

- **Onset:** when and how it started, and what the patient was doing;
- **Location and radiation:** where it is felt and whether it spreads to the neck, jaw, shoulders, arms or back;
- **Character:** the patient's words, such as pressure, squeezing, fullness, burning or heaviness (Heart and Stroke Foundation of Canada, n.d.-d);
- **Severity and duration:** a pain score (Chapter 5) and how long it lasts;
- **Triggers and relief:** exertion, emotion, meals, breathing, position, rest or medication.

Some patients deny "pain" but describe tightness, pressure or discomfort; such differences in wording are one reason heart attacks in women are missed (Mulvagh et al., 2024).

Associated symptoms matter as much as the pain. The nurse asks about **dyspnea** (shortness of breath), diaphoresis (sweating), nausea, light-headedness, unusual fatigue, palpitations (an awareness of the heartbeat), **syncope** (fainting), swelling of the legs, and **orthopnea**, breathlessness when lying flat (Chapter 18).

Chest pain or discomfort is the most common sign of a heart attack in both women and men (Heart and Stroke Foundation of Canada, n.d.-d; Mehta et al., 2016). Yet many people have none. In a large United States registry of patients with myocardial infarction, 42.0% of women and 30.7% of men presented without chest pain (Canto et al., 2012). Women more often report dyspnea, fatigue or weakness (Mehta et al., 2016). They may also feel pressure in the upper abdomen or upper back, dizziness or extreme fatigue (Heart and Stroke Foundation of Canada, n.d.-d). The nurse never rules out a cardiac cause because the symptoms do not fit the classic picture.

The rest of the history covers:

- **Risk factors:** smoking, high blood pressure, diabetes, high cholesterol, family history and others (Chapter 17);
- **Medications:** prescribed, over-the-counter and natural health products, recent changes, missed doses, and anticoagulants or antiplatelets (section 16.3);
- **Substance use:** tobacco, alcohol, cannabis and stimulants such as cocaine or methamphetamine, asked about without judgment (Chapter 11).

Physical Assessment

Vital signs. The nurse counts an irregular pulse for a full minute. Oxygen saturation (SpO2) is checked with its limits in mind, including reduced accuracy on darker skin (Chapter 12). A **pulse deficit** is the difference between the apical rate, counted with a stethoscope over the apex of the heart, and the radial rate. Two nurses count at the same time for 1 minute, one at the apex and one at the wrist (Abbas et al., 2024). A deficit means some beats heard at the apex are not felt at the wrist; an ECG identifies the rhythm more accurately than the deficit does (Abbas et al., 2024). Orthostatic blood pressure, measured lying and then standing, helps when a patient reports dizziness or fainting (Chapter 8).

Inspection. The **jugular venous pressure (JVP)** estimates the pressure in the right side of the heart. With the patient reclining, the head of the bed is raised to the angle that brings the top of the pulsation in the right internal jugular vein into view, often between 30 and 60 degrees. The vertical height of the top of the pulsation is measured above the sternal angle; a height of more than about 3 cm is above normal. Unlike the carotid pulse, the venous pulse cannot be felt, has two peaks with each beat, and fades with gentle pressure just above the clavicle. A raised JVP most often reflects high filling pressures from heart failure (Chua Chiaco et al., 2013; Chapter 18).

Palpation. The nurse compares the radial, brachial, femoral, popliteal, dorsalis pedis and posterior tibial pulses on both sides. Each carotid pulse is checked one at a time. Each pulse is described as absent, weak, normal or bounding on the agency's scale, and skin temperature and capillary refill are compared with earlier findings.

Edema. Firm pressure over the shin, ankle or top of the foot can leave a pit. A common scale grades pitting from 0 (none) to 4 (a very deep pit of about 8 mm in a grossly swollen limb), but it is subjective, and examiners often disagree. Ankle circumference measured with a tape is more reliable for tracking change (Brodovicz et al., 2009). On darker skin, swelling may show as a larger, shiny area or marked indentation along the sock line (Mukwende et al., 2020).

Auscultation. The first heart sound (**S1**) is the closing of the atrioventricular valves at the start of systole. The second (**S2**) is the closing of the semilunar valves at the start of diastole. The nurse listens with the diaphragm in four areas (Figure 16.5): aortic (second intercostal space, right sternal edge), pulmonic (second intercostal space, left sternal edge), tricuspid (lower left sternal edge) and mitral (fifth intercostal space, midclavicular line). The bell picks up low-pitched sounds (Warriner et al., 2019). Extra sounds include:

- **S3:** a sound in early diastole, just after S2, from rapid ventricular filling. It can be normal in young people and athletes (Warriner et al., 2019); a new S3 in an older adult is reported (Chapter 18).
- **S4:** a sound in late diastole, just before S1. It is always abnormal and is linked to cardiomyopathies or increased afterload (Warriner et al., 2019).
- **Murmur:** a sound made when smooth blood flow becomes turbulent. Murmurs are described by timing (systole or diastole), location, loudness and quality (Warriner et al., 2019). A new murmur is reported (Chapter 18).

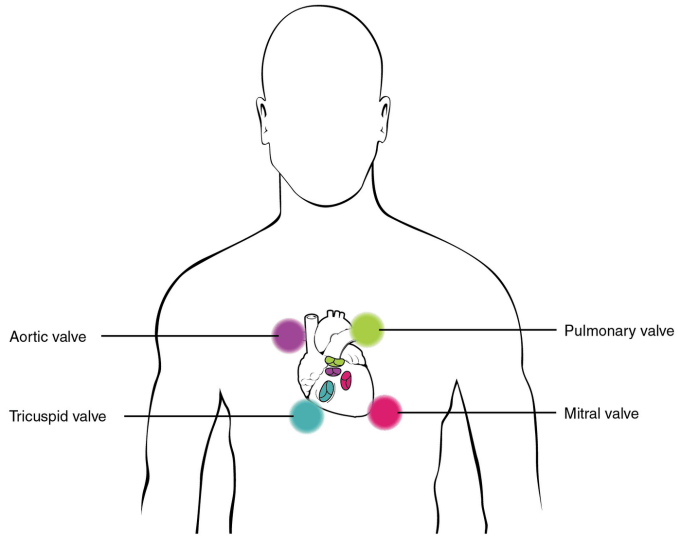

Figure 16.5 Where to listen to the heart: the aortic, pulmonic, tricuspid and mitral areas. (credit: "2030 Stethoscope Placement" by OpenStax College/Wikimedia Commons, CC BY 3.0)

Perfusion on a range of skin tones. Pallor and cyanosis are harder to see on darker skin, and visual assessment alone is unreliable (Pusey-Reid et al., 2023). The nurse looks where the skin is thin and blood vessels are close to the surface: the lips, tongue and inside of the mouth, the conjunctivae, the nail beds, palms and soles (Mukwende et al., 2020; Pusey-Reid et al., 2023). On dark skin, cyanosis may make the lips and tongue look grey or whitish, and pallor may make the skin look ashen grey; the conjunctivae look pale pink or white with pallor on any skin tone (Mukwende et al., 2020; Pusey-Reid et al., 2023). Natural light works best, and the nurse compares with an unaffected area (Pusey-Reid et al., 2023). Chapter 12 covers cyanosis and oximetry, and Chapter 6 covers mottling and other signs of shock.

Recognizing Deterioration

Low cardiac output shows up as poor perfusion: a rising heart rate, falling blood pressure, new restlessness or confusion, cool clammy skin, weak pulses, falling urine output and breathlessness. Together, these cues suggest cardiogenic shock (Chapter 6). Every nurse who notices deterioration stays with the patient, calls for help as the agency's rapid response criteria direct, and reports using SBAR (Situation, Background, Assessment, Recommendation; Chapter 6). The RPN consults the RN as the patient's needs change.

New chest pain, or symptoms that could stand in for it, are treated as an emergency until proven otherwise. The nurse stays with the patient, checks vital signs, obtains a 12-lead ECG as ordered or as agency policy directs (section 16.3), and notifies the prescriber or rapid response team (Chapter 6; acute coronary syndromes are covered in Chapter 17). Outside hospital, people with heart attack signs should call 9-1-1 at once (Heart and Stroke Foundation of Canada, n.d.-d).

LIFESPAN CONSIDERATIONS

Chest Pain and Heart Symptoms in Older Adults and Women

- **Older adults:** Heart disease is very common late in life. In 2012/13, diagnosed ischemic heart disease was recorded for 38.5% of women and 47.9% of men aged 85 and older in Canada (Public Health Agency of Canada [PHAC], 2017). Illness often shows up differently in older adults (Chapter 8), so the nurse treats new breathlessness, fatigue, confusion or a fall as a possible cardiac cue.
- **Age and sex together:** In one large registry, heart attacks without chest pain were more common in women than in men. The gap was widest in younger adults and had nearly closed in those aged 75 and older (Canto et al., 2012).
- **Women:** After a heart attack, women's risk of dying is on average 30% higher than men's. Subtler symptoms, more coexisting illnesses and delays in care help explain this gap (PHAC, 2017). Women with ST-elevation myocardial infarction (STEMI) are also slower to recognize their symptoms and to seek care (Mulvagh et al., 2024).
- **Nursing focus:** Ask about every symptom, use the patient's words, and never dismiss "indigestion", jaw pain or exhaustion without assessment.

16.3 Cardiac Tests

The 12-Lead ECG

The 12-lead ECG records the heart's electrical activity from 10 electrodes as 12 views, or leads: six limb leads (I, II, III, aVR, aVL and aVF) and six precordial (chest) leads, V1 to V6 (Kligfield et al., 2007; Figure 16.6). It shows the rhythm, conduction problems, ischemia or infarction (Chapter 17) and some electrolyte and drug effects (Chapter 3).

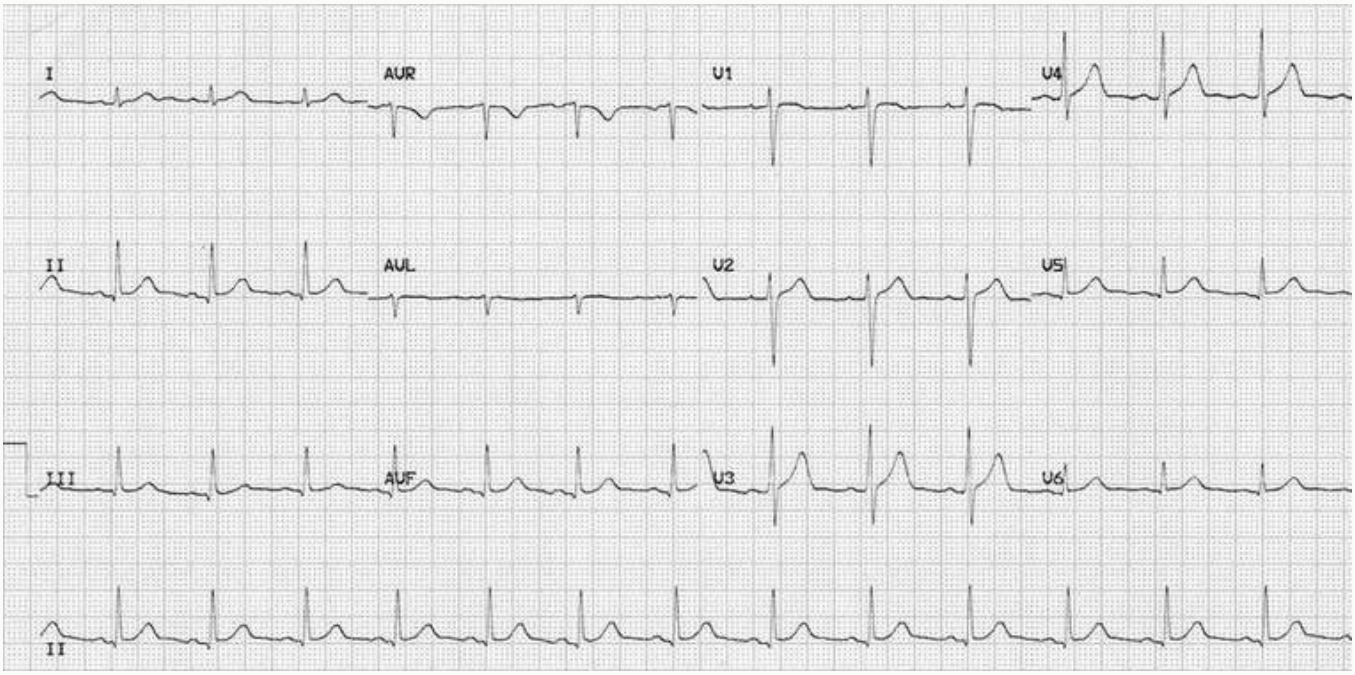

Figure 16.6 A 12-lead ECG in normal sinus rhythm. Each row shows four leads; the long strip along the bottom is lead II. (credit: "Normal sinus rhythm" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

Misplaced electrodes change the tracing, so placement must be exact (Figure 16.7) (Kligfield et al., 2007; Society for Cardiological Science and Technology [SCST], 2014):

- **Limb electrodes:** on the arms and legs, usually just above the wrists and ankles; for a diagnostic 12-lead, never on the torso;
- **V1:** right sternal border, fourth intercostal space;
- **V2:** left sternal border, fourth intercostal space;

- **V3:** midway between V2 and V4;
- **V4:** midclavicular line, fifth intercostal space;
- **V5:** anterior axillary line, level with V4;
- **V6:** midaxillary line, level with V4 and V5.

To find the fourth intercostal space, the nurse locates the sternal angle, moves to the second intercostal space beside it, and counts down. V1 and V2 are often placed too high, and V4 to V6 too low. When breast tissue covers the sites, V4 to V6 usually go under the breast, which the nurse lifts gently with the back of the hand (Kligfield et al., 2007; SCST, 2014).

The skin should be clean and dry. Mild soap, an alcohol wipe or very light abrasion helps, and chest hair is clipped only when needed and with the patient's agreement. The patient reclines at about 45 degrees with relaxed, supported limbs to limit muscle interference. The standard recording speed is 25 mm per second (Kligfield et al., 2007; SCST, 2014).

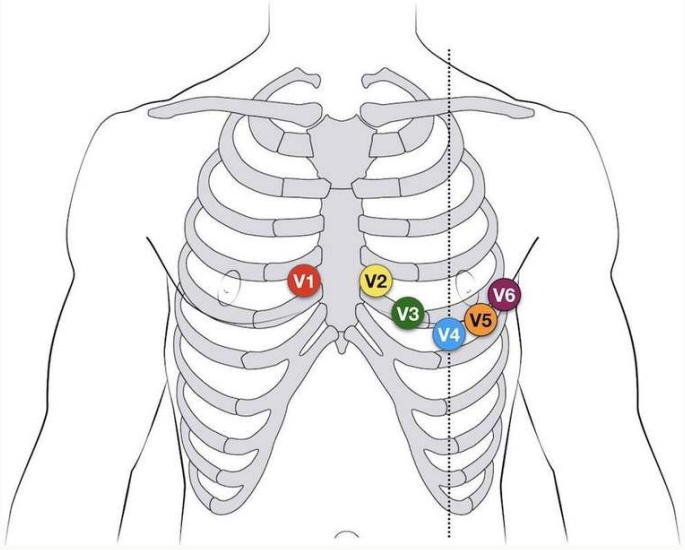

Figure 16.7 Placement of the six chest (precordial) electrodes, V1 to V6, for a 12-lead ECG. The dotted line marks the left midclavicular line. (credit: "ECG lead positioning" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

For acute chest pain, the 2021 American chest pain guideline from the American Heart Association, the American College of Cardiology and partner societies calls for an ECG to be recorded and read within 10 minutes of the patient's arrival, in any care setting (Gulati et al., 2021). The nurse obtains the ECG as ordered or as a medical directive allows, labels it with the time and the patient's symptoms, and shows it to the prescriber at once (Chapter 1, section 1.3).

Blood Tests

Troponins are heart muscle proteins that enter the blood when the cells are damaged. **High-sensitivity cardiac troponin** (hs-troponin) tests measure very low levels precisely (Reichlin et al., 2015). Myocardial injury is present when troponin is above the 99th percentile upper reference limit (the value below which 99% of healthy people fall), and a rise or fall on repeat samples shows that the injury is acute. Results are reported in nanograms per litre (ng/L) (Thygesen et al., 2018). Rapid pathways repeat the test after a short interval; one validated algorithm compares a sample at arrival with one taken 1 hour later (Reichlin et al., 2015), so the nurse draws each sample on time and records the exact time. Troponin can also rise without a heart attack, for example with tachydysrhythmias, myocarditis or pulmonary embolism (Reichlin et al., 2015).

Natriuretic peptides, B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP), are released by heart muscle mainly when wall stress increases. A low level makes heart failure an unlikely cause of acute breathlessness. Levels rise with age and kidney impairment and differ between assays (Felker et al., 2006; Chapter 18).

Potassium, magnesium and calcium affect how heart cells fire (Chapter 3). Reference ranges vary by laboratory (Table 16.1).

Table 16.1 Cardiac biomarkers and other key laboratory tests (Felker et al., 2006; Reichlin et al., 2015; Thygesen et al., 2018; original wording)

Test	What it shows	Notes for the nurse
High-sensitivity cardiac troponin	Injury to heart muscle cells; a rise or fall on repeat samples suggests acute injury	Reported in ng/L; draw repeat samples exactly on time per protocol; can rise without a heart attack; ranges vary by laboratory and assay
BNP or NT-proBNP	Wall stress in the heart; helps judge whether heart failure explains breathlessness	Higher with older age and kidney impairment, lower with obesity; assays are not interchangeable; see Chapter 18

Test	What it shows	Notes for the nurse
Potassium	Electrolyte that strongly affects heart cell excitability	High or low levels can cause dysrhythmias; avoid hemolysis when drawing; ranges vary by laboratory; see Chapter 3
Magnesium	Electrolyte linked to stable heart rhythm	Low levels can cause dysrhythmias and often occur with low potassium; ranges vary by laboratory; see Chapter 3
Calcium	Electrolyte needed for heart muscle contraction and conduction	Abnormal levels can change the ECG; ranges vary by laboratory; see Chapter 3
Complete blood count	Hemoglobin and other blood cells	Anemia reduces oxygen delivery to the heart; also checked before invasive tests; ranges vary by laboratory; see Chapter 20

Imaging and Invasive Tests

Echocardiography uses ultrasound to show the heart's structure and movement (Heart and Stroke Foundation of Canada, n.d.-e), usually with a probe on the chest. For a **transesophageal echocardiogram (TEE)**, often used to look for clots in the heart, a probe passes into the esophagus. The patient fasts for 4 to 6 hours, may receive a mild sedative, has the throat numbed with an anesthetic, and needs someone to drive them home (Heart and Stroke Foundation of Canada, n.d.-f). The nurse monitors sedation as policy directs and follows the agency's protocol on when eating can resume, because a numbed throat raises the risk of choking.

An **exercise stress test** records the heart's response as the patient walks on a treadmill or pedals, until the heart reaches the fastest safe rate or chest pain develops. Patients usually avoid food and smoking for at least 2 hours beforehand (Heart and Stroke Foundation of Canada, n.d.-b).

Cardiac catheterization threads a thin tube through a vessel in the groin or arm into the heart. In angiography, dye injected through it shows the coronary arteries on X-ray (Heart and Stroke Foundation of Canada, n.d.-a). Before the test, the nurse confirms consent and fasting, reviews anticoagulants, antiplatelets and the diabetes plan (Heart and Stroke Foundation of Canada, n.d.-a), asks about past reactions to contrast, and checks kidney function. Canadian radiology guidance states that kidney injury after contrast is a risk mainly for people with an estimated glomerular filtration rate (eGFR) of 30 mL/min/1.73 m² or less or with existing acute kidney injury. Needed contrast should not be withheld, and metformin is held only for those patients (Macdonald et al., 2022). Afterward, the nurse checks the access site for bleeding or swelling and the limb below it for pulse, colour, warmth and sensation (Chapter 17).

Holter monitors record the rhythm continuously for 24 hours or longer while the patient keeps a symptom diary. **Event monitors** record only when the patient triggers them during symptoms (Heart and Stroke Foundation of Canada, n.d.-c).

CANADIAN CONTEXT

Heart Disease Across Canada

- **Burden:** In 2024, diseases of the heart caused 17.7% of deaths in Canada, second to cancer (Statistics Canada, 2026). In 2012/13, about 2.4 million adults aged 20 and older (8.5%) were living with diagnosed ischemic heart disease (PHAC, 2017).
- **Women:** Heart and Stroke's 2018 report found that two-thirds of clinical research on heart disease still focused on men. It also reported that 78% of women had warning signs that went unrecognized before their heart attack, and that the exercise treadmill (stress) test is far less sensitive in women than in men (Heart and Stroke Foundation of Canada, 2018).
- **Indigenous women:** The same report described a 53% higher death rate from coronary heart disease among Indigenous women than non-Indigenous women. It also noted a lack of cardiac care in the remote and rural hospitals that serve women living on reserve (Heart and Stroke Foundation of Canada, 2018). This pan-Indigenous figure is not distinctions-based. The gap reflects colonialism, racism and unequal access to care, not biology (Chapter 2). OCAP® principles apply whenever First Nations data are used.
- **Rural access:** Distance from cardiac services shapes how fast patients reach an ECG, a catheterization laboratory or rehabilitation.

GOING DEEPER

Reading the 12-Lead ECG

Required for RN students; optional for PN students.

- **Leads as views:** Each lead looks at the heart's electrical activity from a different angle. The limb leads come from the arm and leg electrodes; the precordial leads, V1 to V6, cross the front and left side of the chest (Kligfield et al., 2007).
- **Contiguous leads:** Leads that look at neighbouring areas of the heart are read as groups: I and aVL; V1 to V6; and II, III and aVF, often called the inferior leads (Thygesen et al., 2018). ST-segment changes are judged significant when they appear in at least two contiguous leads.
- **Axis:** The axis is the overall direction of the ventricles' electrical activity, viewed by the limb leads. The ECG machine reports it in degrees; in adults, a normal axis lies between −30° and +90° (Surawicz et al., 2009). A value outside this range is called left or right axis deviation and can accompany conduction blocks or changes in the ventricles; a qualified clinician interprets it.
- **ST and T changes:** New ST elevation, measured at the J point, in two contiguous leads, new horizontal or downsloping ST depression, and new T-wave inversion can signal myocardial ischemia or injury. The thresholds vary with the lead, sex and age (Thygesen et al., 2018); Chapter 17 explains them.
- **QTc:** The QT interval spans the start of the QRS through the end of the T wave. Because it shortens as the heart speeds up, it is corrected for rate (QTc). The common Bazett formula (QT ÷ √R–R, with R–R in seconds) overestimates the QTc at fast rates. A QTc above 450 ms in males or 460 ms in females is prolonged. Above 500 ms, the risk of torsades de pointes, a dangerous ventricular tachycardia, rises; the prescriber is notified at once, and a drug causing the prolongation is generally stopped. Measure in the lead with the longest T wave, and do not compare monitor values with 12-lead values (Sandau et al., 2017).

16.4 Cardiac Monitoring and Reading a Rhythm Strip

Who Needs Monitoring

The American Heart Association's practice standards list common indications, with suggested durations (Sandau et al., 2017):

- intermediate- or high-risk acute coronary syndrome (at least 24 to 48 hours, or until it is ruled out), and at least 12 to 24 hours after a blocked coronary artery is reopened;
- fainting that may have a cardiac cause (at least 24 hours, and until the cause and treatment are identified);
- new or recurrent atrial fibrillation, until a treatment plan is set;
- symptomatic bradycardia, symptomatic second- or third-degree AV block, and some second- or third-degree blocks even without symptoms (section 16.7);
- moderate to severe potassium or magnesium imbalance, until corrected;
- drug overdose, until the drug's effects have resolved;
- the first 12 to 24 hours after a pacemaker is placed in a patient who depends on it.

A stable patient with long-standing atrial fibrillation admitted for an unrelated reason does not need monitoring. The need for monitoring should be reviewed no less often than every 24 to 48 hours (Sandau et al., 2017), and stopping it when it is no longer needed reduces alarms.

Telemetry sends the ECG from a small wireless transmitter to a central station, so patients can move about. Bedside monitors, common in critical care, display the rhythm in the room. A patient with a strong indication who leaves the unit is monitored with a portable monitor-defibrillator, accompanied by a provider skilled in its use and in reading the ECG (Sandau et al., 2017).

Lead Placement and Signal Quality

For monitoring, the limb electrodes are placed on the torso so patients can move freely with less artifact (Sandau et al., 2017). In a common 3-electrode system, the right arm electrode sits below the right clavicle, the left arm electrode below the left clavicle, and the left leg electrode on the lower left rib cage. A 5-electrode system adds a right leg electrode on the lower right rib cage and a chest electrode, usually in the V1 position (Sampson, 2018). V1 is often chosen because it helps tell ventricular tachycardia from other wide rhythms (Sandau et al., 2017). Colour codes differ between standards, so the nurse follows the labels on the lead wires. Because torso placement changes the waveforms, a monitor strip is never a substitute for a 12-lead ECG (Sampson, 2018).

The skin must be dry and free of oil, loose flakes and excess hair. The nurse washes with soap and water or uses an alcohol wipe, exfoliates gently with dry gauze, and clips hair if needed (Sampson, 2018). In a before-and-after study on one 36-bed adult cardiac telemetry unit, daily electrode changes were followed by a 74% drop in telemetry alarms (McGuffin & Ortiz, 2019).

An **artifact** is a signal on the monitor that does not come from the heart. Loose electrodes, dried gel, movement, shivering and tremor are common causes. Low-amplitude complexes can make the monitor miss beats, and artifact can mimic ventricular tachycardia (Drew et al., 2014).

Alarm Safety

Most monitor alarms need no action. In one study of intensive care units, audible alarms averaged 187 per bed per day, and 88.8% of the arrhythmia alarms reviewed were false (Drew et al., 2014). Other studies found 89% to 99% of ECG monitor alarms to be false or clinically insignificant (American Association of Critical-Care Nurses [AACN], 2018).

Alarm fatigue is the desensitization that follows: clinicians exposed to too many alarms respond more slowly or miss alarms, and deaths have been linked to it (AACN, 2018). Safer practice includes:

- monitoring only patients with an indication (Sandau et al., 2017);
- setting alarm limits to the patient's baseline and the purpose of monitoring, within agency policy (Sandau et al., 2017);
- preparing the skin and changing electrodes as policy directs (McGuffin & Ortiz, 2019);
- never permanently silencing alarms (Sampson, 2018) and always assessing the patient.

A Systematic Strip Analysis

ECG paper is a grid of small 1-mm boxes, with a heavier line every five boxes. At the standard speed of 25 mm per second (Kligfield et al., 2007; SCST, 2014), each small box equals 0.04 seconds (1 mm ÷ 25 mm per second) and each large box 0.20 seconds. Thirty large boxes equal 6 seconds. Two quick rate methods follow:

- **6-second method:** count the QRS complexes in a 6-second strip and multiply by 10. It works for regular and irregular rhythms.
- **Large-box method:** for a regular rhythm only, divide 300 by the number of large boxes between two R waves.

The nurse then works through the same steps every time (Table 16.2).

Normal sinus rhythm meets all of these criteria: a regular rhythm at 60 to 100 bpm; an upright P wave before every QRS; a PR interval of 0.12 to 0.20 seconds (3 to 5 small boxes); and a QRS narrower than 0.12 seconds (fewer than 3 small boxes) (Sampson, 2016; Sampson & McGrath, 2015). In adults, a QRS of 0.12 seconds or more is wide, as in complete bundle branch block (Surawicz et al., 2009). The 60 to 100 bpm range is the traditional one. The 2018 American College of Cardiology, American Heart Association and Heart Rhythm Society (ACC/AHA/HRS) bradycardia guideline defines sinus bradycardia as a sinus rate below 50 bpm (Kusumoto et al., 2019), so by that definition a sinus rate of 50 to 59 bpm is not called bradycardia (section 16.5).

The strip never replaces the patient. A chaotic tracing in a patient who is chatting and brushing their teeth is almost certainly artifact. A flat line in a patient who is awake points to a loose lead. An organized rhythm in a patient with no pulse is a cardiac arrest (section 16.5). The nurse looks at the patient, checks responsiveness and pulse, and only then interprets the screen.

Table 16.2 Steps of rhythm strip analysis (Kusumoto et al., 2019; Sampson, 2016; Sampson & McGrath, 2015; Sandau et al., 2017; Surawicz et al., 2009; original wording)

Step	What to look at	Normal finding	What an abnormal finding may mean
Rate	Count QRS complexes (6-second method) or use 300 divided by large boxes between R waves	60 to 100 bpm for a sinus rhythm (traditional range; one guideline defines sinus bradycardia as under 50 bpm)	Slower suggests bradycardia; faster suggests tachycardia (section 16.5)
Regularity	Measure the R–R intervals across the strip with calipers or paper	R–R intervals about equal	Irregular spacing suggests early beats, atrial fibrillation or some heart blocks
P waves	Look for one upright, similar P wave before each QRS	One P wave before every QRS	Missing, extra, inverted or chaotic P waves suggest a rhythm starting outside the SA node or a block
PR interval	Measure from the start of the P wave to the start of the QRS	0.12 to 0.20 seconds (3 to 5 small boxes), the same each beat	Longer, lengthening or varying PR intervals suggest AV block (section 16.7)

Step	What to look at	Normal finding	What an abnormal finding may mean
QRS duration	Measure from the start to the end of the QRS	Less than 0.12 seconds (fewer than 3 small boxes)	A QRS of 0.12 seconds or more suggests a bundle branch block or a beat that starts in the ventricles
QT and QTc	Measure from QRS onset through the end of the T wave, in the lead with the longest T wave; correct for rate	QTc 450 ms or less in males and 460 ms or less in females	A prolonged QTc raises the risk of torsades de pointes; over 500 ms is high risk

CLINICAL SAFETY

Monitor Alarms

- Go to the patient for every alarm. Look, check responsiveness and breathing, and feel for a pulse before deciding the alarm is false.
- Never turn alarms off or permanently silence them. If a pause is needed during care, use the agency's temporary pause and stay with the patient.
- Set alarm limits to the patient's own baseline, following policy and the prescriber's orders, and review them at every handover.
- Prepare the skin, place electrodes correctly, and change them as policy directs. Most false alarms come from poor signal, not from the heart.
- Ask each day whether the patient still needs monitoring. Unneeded monitoring adds alarms and burden.
- Report repeated false alarms and device problems through the agency's safety reporting system.
- Remember why this matters: in one study, most arrhythmia alarms were false, yet the true alarms still included ventricular tachycardia (Drew et al., 2014).

16.5 Common Dysrhythmias and How to Respond

A **dysrhythmia** is any rhythm other than normal sinus rhythm: one that is too fast, too slow, irregular or started from the wrong place. Section 16.4 set out a step-by-step way to read a rhythm strip. This section applies that method to common rhythms and to what the nurse does next. Table 16.3 brings the key points together.

Responding by Stability

The response to a new rhythm begins with the patient, not the monitor. An alarm or an odd-looking strip sends the nurse to the bedside to check responsiveness, breathing and a pulse, and to rule out artifact from movement or loose electrodes (section 16.4). The same rhythm can be harmless in one person and dangerous in another, so the deciding question is whether the rhythm is causing poor perfusion.

The Heart and Stroke Foundation of Canada, a member of the International Liaison Committee on Resuscitation (ILCOR), publishes a Canadian edition of the highlights of the 2025 American Heart Association (AHA) resuscitation guidelines, adapted to Canadian systems, practices and drugs (Heart and Stroke Foundation of Canada, 2025). Because Canadian guidance follows this science, this chapter cites the AHA guidelines where the Canadian edition follows them. That guidance treats a fast rhythm as unstable when it comes with **hypotension**, a sudden change in mental status, signs of shock, chest pain or acute heart failure (Wigginton et al., 2025). A slow rhythm is judged the same way: dizziness, confusion, chest discomfort, fainting, low blood pressure or new heart failure signs show that the slow rate is harming perfusion. Pallor and cyanosis can be harder to see on darker skin, so the nurse also checks the lips, oral mucosa, nail beds and conjunctivae (Chapter 12).

When the patient is unstable, the nurse stays at the bedside and calls for help at once through the rapid response or code system (Chapter 6). While help comes, the nurse supports airway and breathing, gives oxygen if saturation is below the target (Chapter 12), keeps the patient on the monitor, confirms intravenous (IV) access and, if the patient's condition allows, records a 12-lead ECG, which shows the rhythm in more detail than a monitor strip. In a stable patient there is time to look for causes. Many dysrhythmias have a correctable trigger: low or high potassium or low magnesium (Chapter 3, sections 3.5–3.6), hypoxemia (Chapter 12), drugs

that slow or speed the heart, stimulant use (Chapter 11), pain, fever, low blood volume and myocardial ischemia (Chapter 17). The AHA notes that a slow rhythm may not resolve until its cause is treated (Wigginton et al., 2025).

Sinus Rhythms

In **sinus bradycardia**, the sinus node fires in the normal way but slowly (Figure 16.8). The 2018 American College of Cardiology (ACC), AHA and Heart Rhythm Society (HRS) guideline defines it as a sinus rate below 50 per minute, lower than the 60 per minute used in the past (Kusumoto et al., 2019; Wigginton et al., 2025). A slow rate is normal for many fit adults and during sleep. Causes include high vagal tone, rate-slowing drugs, hypothyroidism, hypothermia, hypoxemia and ischemia (Kusumoto et al., 2019). The rhythm matters when it causes symptoms. For bradycardia with poor perfusion, the guidance supports atropine; if atropine does not work, an infusion of an adrenergic drug such as epinephrine or dopamine, or transcutaneous pacing, may be used while transvenous pacing is arranged (Wigginton et al., 2025; section 16.7).

Sinus tachycardia is a sinus rhythm faster than 100 per minute (Page et al., 2016; Figure 16.9). It is usually the body's response to something else: fever, pain, anxiety, bleeding or low blood volume, anemia, hypoxemia, sepsis (Chapter 4), stimulants or pulmonary embolism (Chapter 15). The fast rate is often keeping cardiac output up, so the goal is to treat the cause, not to slow the heart with a drug. The nurse checks temperature, pain, fluid balance, signs of bleeding, oxygen saturation and any new breathlessness or chest pain, and reports the likely cause.

Supraventricular Tachycardia

In this chapter, **supraventricular tachycardia (SVT)** means a regular, narrow-complex tachycardia that starts above the ventricles, often from a short-circuit loop that runs through the AV node. The rate is fast and steady, and P waves are hard to see because they are hidden in or just after each QRS complex. Patients often describe a sudden racing or pounding heartbeat, light-headedness or chest discomfort.

For a stable adult with a regular narrow-complex tachycardia, the AHA recommends **vagal manoeuvres** first and adenosine next (Wigginton et al., 2025). A standard Valsalva manoeuvre, in which the patient strains against a closed airway, ends about 20% to 30% of episodes. Modified methods raise success to about half: for example, the patient strains while semi-reclined and is then laid flat with the legs raised right away, or strains by blowing into a syringe connected to a pressure gauge. Carotid sinus massage carries a risk of stroke in people with carotid artery disease (Wigginton et al., 2025).

Adenosine briefly blocks conduction through the AV node. Its Canadian monograph states that it must be given only with cardiac monitoring and with resuscitation equipment at hand, because short or longer pauses, including asystole, can occur (Fresenius Kabi Canada, 2016). Before the dose, the nurse warns the patient that flushing, shortness of breath or chest pressure may start right away and usually passes in under a minute. Caffeine and theophylline can block its effect, it is avoided in asthma and chronic obstructive pulmonary disease, and it does not convert atrial fibrillation, atrial flutter or ventricular tachycardia (Fresenius Kabi Canada, 2016). An unstable patient with SVT needs synchronized cardioversion, which is also used when vagal manoeuvres and drugs fail (Wigginton et al., 2025; section 16.7).

Premature Beats

A **premature atrial contraction (PAC)** is an early beat from a site in the atria. The strip shows an early P wave, often shaped differently, followed by a normal narrow QRS. A **premature ventricular contraction (PVC)** is an early beat that starts in the ventricles: a wide, oddly shaped QRS with no P wave before it, usually followed by a pause. Nearly everyone has some PVCs, and in a person with a normal heart and few PVCs they usually need no treatment beyond avoiding triggers such as caffeine, stimulants and stress (Cantillon, 2013; Figure 16.10).

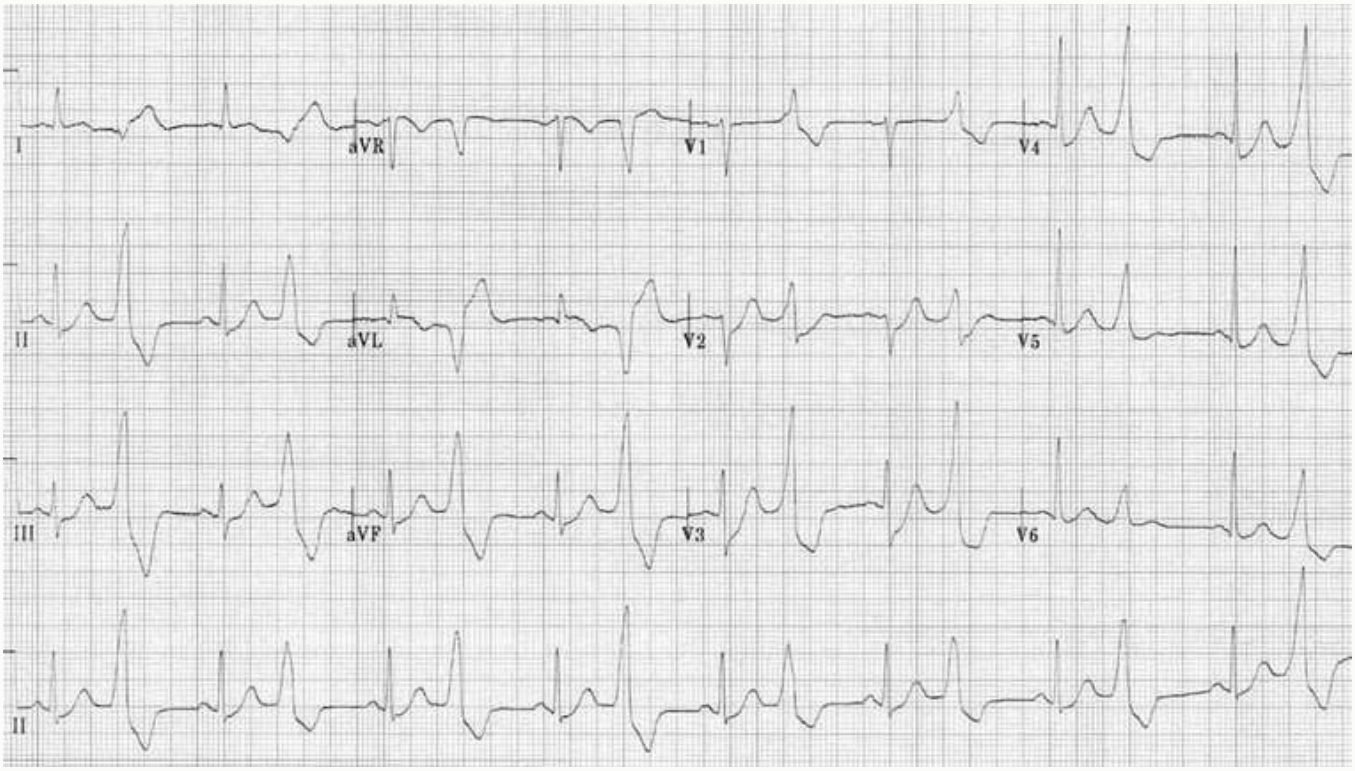

Figure 16.10 A 12-lead ECG showing ventricular bigeminy: a wide, early premature ventricular contraction (PVC) after every normal beat. (credit: "ECG Premature Ventricular Complex (PVC) Bigeminy" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

PVCs need closer attention in four situations:

- **Frequent PVCs:** a high share of PVCs among all beats, or short runs of ventricular tachycardia, can weaken the left ventricle over time (Cantillon, 2013).
- **Heart disease or ischemia:** PVCs in a person with structural heart disease warrant cardiology assessment, and new frequent PVCs in a patient with chest pain call for a 12-lead ECG and escalation (Cantillon, 2013; Chapter 17).
- **Electrolytes and drugs:** low potassium or magnesium (Chapter 3) and digoxin toxicity, in which PVCs, often in a pattern of every second or third beat, are the most common rhythm problem (Pharmascience, 2022).
- **Early timing:** a PVC that falls on the T wave of the beat before it (the "R-on-T" pattern) is reported promptly, especially in a patient with ischemia, low potassium or magnesium, or a long QT interval.

Ventricular Tachycardia, Ventricular Fibrillation, Asystole and PEA

Ventricular tachycardia (VT) is a fast rhythm from the ventricles with wide QRS complexes (Figure 16.11). In monomorphic VT the complexes look alike; in polymorphic VT their shape keeps changing. VT may or may not produce a pulse, so the nurse checks the patient. A stable patient in VT with a pulse needs urgent help, a 12-lead ECG and expert care; IV amiodarone or procainamide, or synchronized cardioversion, may follow. An unstable patient with a pulse needs urgent synchronized cardioversion. Polymorphic VT cannot be reliably synchronized and is treated with an unsynchronized shock (Wigginton et al., 2025). VT without a pulse is cardiac arrest.

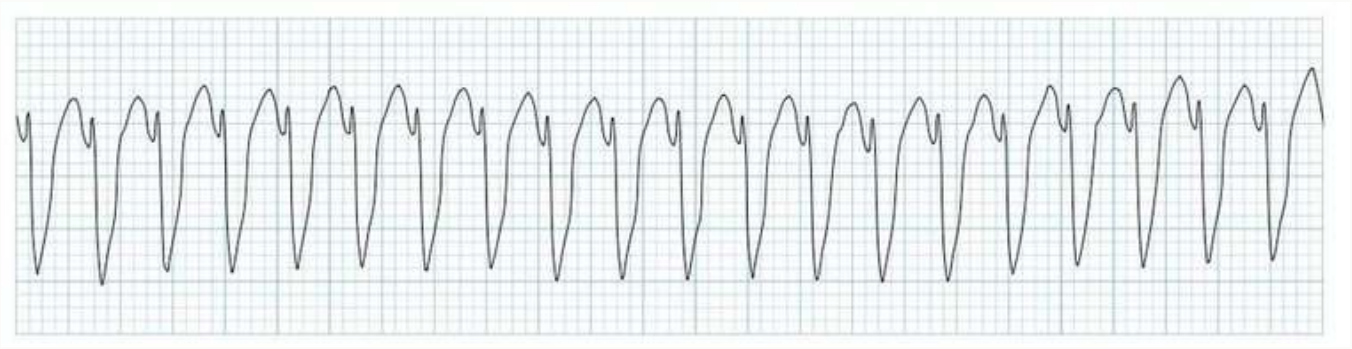

Figure 16.11 Rhythm strip of monomorphic ventricular tachycardia: a fast, regular rhythm of wide QRS complexes that look alike. (credit: "Monomorphic ventricular tachycardia" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

Ventricular fibrillation (VF) is chaotic electrical activity in the ventricles, with no organized QRS complexes and no cardiac output (Figure 16.12). The patient collapses and is unresponsive, without normal breathing or a pulse. The emergency response follows Heart and Stroke Foundation of Canada guidance (Heart and Stroke Foundation of Canada, 2025; Wigginton et al., 2025):

- **Recognize:** the patient is unresponsive, not breathing normally and pulseless.
- **Call:** activate the code system and bring the defibrillator.
- **Compress:** start high-quality cardiopulmonary resuscitation (CPR) at once.
- **Shock:** defibrillate VF and pulseless VT as soon as the defibrillator is ready, one shock at a time, then resume CPR for about 2 minutes before the next rhythm check.
- **Drugs:** for these shockable rhythms, epinephrine is given after the first shocks have failed and repeated during the arrest; amiodarone or lidocaine may be considered when VF or pulseless VT continues despite shocks.

Figure 16.12 Rhythm strip of ventricular fibrillation: chaotic, irregular waves with no identifiable P waves, QRS complexes or T waves. (credit: "VF rhythm strip" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

Asystole is the absence of electrical activity in the ventricles (Figure 16.13), seen as a flat line once the nurse has confirmed that the electrodes are attached and the patient has no pulse. **Pulseless electrical activity (PEA)** is an organized rhythm on the monitor without a palpable pulse. Neither is shockable. The team gives CPR and epinephrine as soon as feasible, and pacing is not used during an established arrest (Wigginton et al., 2025). The team also hunts for reversible causes, listed in the AHA algorithm as the Hs (hypovolemia, hypoxia, hydrogen ion or acidosis, low or high potassium, hypothermia) and the Ts (tension pneumothorax, cardiac tamponade, toxins, pulmonary thrombosis and coronary thrombosis) (American Heart Association, 2025). The nurse helps by reporting recent laboratory values, medications and events before the arrest.

When a pulse returns, post-arrest care begins. Canadian guidance includes keeping the mean arterial pressure at 65 mm Hg or higher, keeping oxygen saturation between 90% and 98%, recording an early 12-lead ECG and controlling temperature (between 32 °C and 37.5 °C) for at least 36 hours in patients who do not follow commands, and coronary angiography before discharge for survivors when a cardiac cause is suspected (Heart and Stroke Foundation of Canada, 2025). The family needs updates and support throughout.

Table 16.3 Common dysrhythmias: recognition, causes and first nursing actions (Kusumoto et al., 2019; Andrade et al., 2020; Wigginton et al., 2025)

Rhythm	Key features on the strip	Common causes	First nursing actions
Sinus bradycardia	Regular; a P wave before every QRS; sinus rate below 50 per minute	High vagal tone, sleep, fitness, rate-slowing drugs, hypothyroidism, hypothermia, hypoxemia, ischemia	Assess perfusion and symptoms; review drugs; report; if unstable, call for help and prepare for atropine and pacing as ordered
Sinus tachycardia	Regular; normal P waves; rate above 100 per minute	Fever, pain, anxiety, bleeding, low volume, hypoxemia, sepsis, pulmonary embolism, stimulants	Find and treat the cause: temperature, pain, fluid balance, bleeding, oxygen saturation; report
Supraventricular tachycardia	Fast, regular, narrow QRS; P waves hard to see	Re-entry loop involving the AV node; triggers such as stimulants	Assess stability; 12-lead ECG; coach a vagal manoeuvre as ordered; prepare adenosine with monitoring; if unstable, call for help for synchronized cardioversion
Premature ventricular contractions	Early, wide, oddly shaped QRS with no P wave before it, then a pause	Stimulants, ischemia, low potassium or magnesium, digoxin toxicity, structural heart disease	Assess the patient; count frequency; check electrolytes and drug levels as ordered; report new or frequent PVCs, especially with chest pain
Atrial fibrillation	Irregularly irregular; no clear P waves; wavy baseline; QRS usually narrow	Age, hypertension, heart failure, valve disease, thyroid disease, sleep apnea, alcohol, surgery, acute illness	Check stability and apical-radial pulses; 12-lead ECG; report; ask about onset time and anticoagulation (section 16.6)
Ventricular tachycardia	Fast, wide QRS complexes; regular if monomorphic	Ischemia or scarred myocardium, heart failure, electrolyte imbalance, drug effects	Check for a pulse; if pulseless, start the cardiac arrest response; if a pulse is present, call for urgent help and a 12-lead ECG
Ventricular fibrillation	Chaotic baseline with no recognizable QRS complexes	Ischemia, cardiomyopathy, electrolyte imbalance, untreated VT	Call a code; start CPR; defibrillate as soon as possible
Asystole	Flat line once leads and gain are checked	End stage of untreated arrest; reversible causes (Hs and Ts)	Call a code; start CPR; no shock; epinephrine as soon as feasible as ordered; search for reversible causes
Pulseless electrical activity	Organized rhythm on the monitor but no pulse	Hypovolemia, hypoxia, tamponade, tension pneumothorax, pulmonary embolism and other Hs and Ts	Call a code; start CPR; no shock; search for and correct reversible causes

PRACTICE STORY

The Artifact That Wasn't

Names and details are fictional; this is a composite story.

Nurse: Samuel Boateng, RN. Years in practice: 6. Setting: telemetry unit, community hospital, Ontario.

It was just after 0700 and I was halfway through report when the central station alarmed for Mr. Kovac in room 12. He was 74, admitted two days earlier with heart failure, and his potassium had been low the evening before. The strip showed a run of wide, fast complexes. My colleague at the desk glanced at it and said, "He's brushing his teeth; it's probably artifact. He did that yesterday too."

She might have been right. Movement can make a strip look terrible. But in nursing school I learned that the screen is a clue, not an answer, so I walked to his room. Mr. Kovac was sitting on the edge of the bed, grey, sweaty and confused, with the toothbrush still in his hand. His radial pulse was fast and thready. The monitor beside him showed the same wide-complex rhythm, and it was not changing with his movement.

I pressed the call bell for help, laid him down and asked the RPN who came in to call the rapid response team. His blood pressure was 78/50 mm Hg. The team arrived within minutes. Just as the physician confirmed ventricular tachycardia and the team prepared for synchronized cardioversion, he became unresponsive and lost his pulse. We started CPR, and he was defibrillated within a minute of losing his pulse. He had a pulse again after the first shock.

Later his potassium came back low again, and his medications were reviewed. He went home a week later with a cardiology appointment booked to discuss whether he needed an ICD.

I still think about how easy it would have been to silence that alarm. Since then, our unit has changed its practice: any wide-complex alarm gets a bedside check, every time, before anyone calls it artifact.

Reflect: What cues at the bedside helped Daniel tell a real rhythm from artifact? If the RPN had reached the room first, what actions would fall within the RPN's authority, competence and context, and how should the RPN and RN share the response?

16.6 Atrial Fibrillation and Flutter

What Happens

In **atrial fibrillation (AF)**, many disorganized electrical wavelets activate the atria instead of the sinus node, so the atria quiver rather than contract. The AV node receives far more impulses than it can conduct and lets them through at random. The strip shows an **irregularly irregular** rhythm with no clear P waves, a wavy baseline and usually narrow QRS complexes (section 16.4; Figure 16.14). **Atrial flutter** comes from a single, organized loop of electrical activity in the atrium. It produces regular **flutter waves** with a sawtooth look (Figure 16.15), and the ventricular rhythm is often regular because the AV node passes a fixed share of the flutter waves.

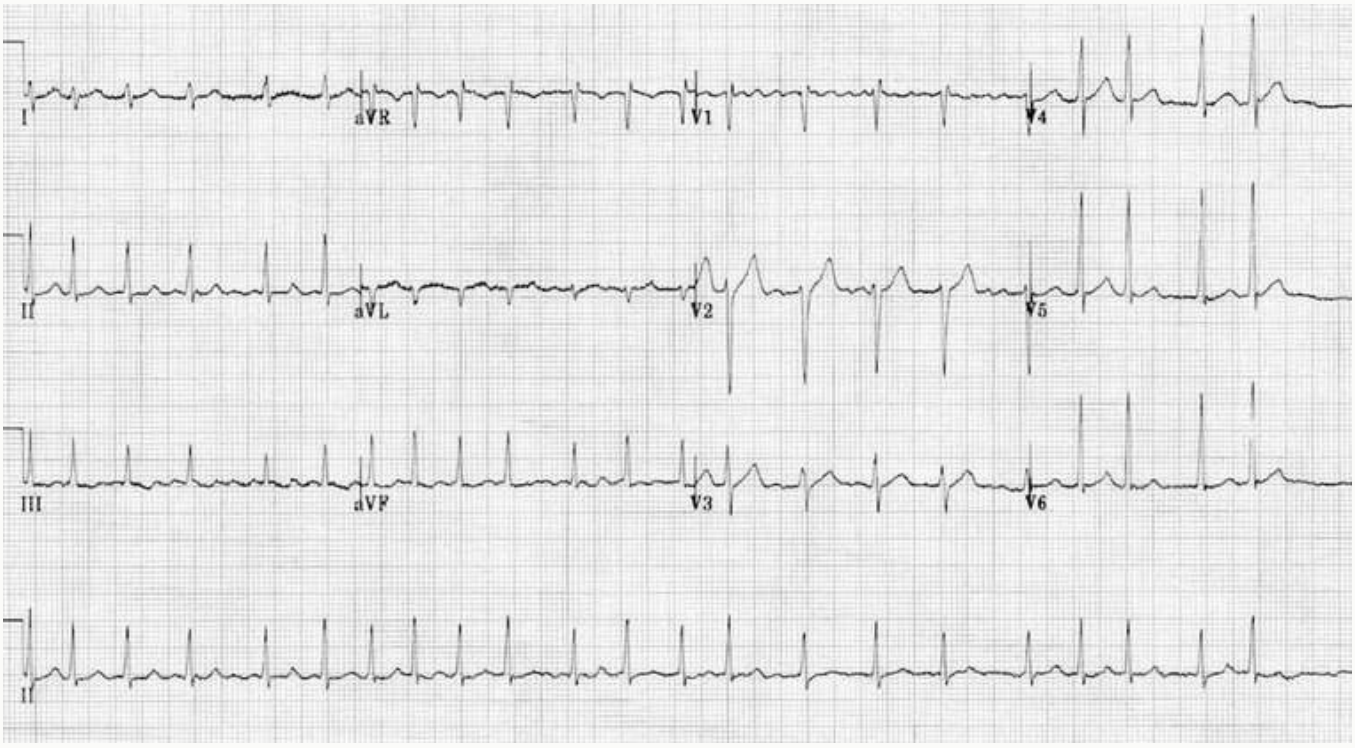

Figure 16.14 A 12-lead ECG showing atrial fibrillation with a rapid ventricular response: an irregularly irregular rhythm with no clear P waves. (credit: "AF with rapid ventricular response" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

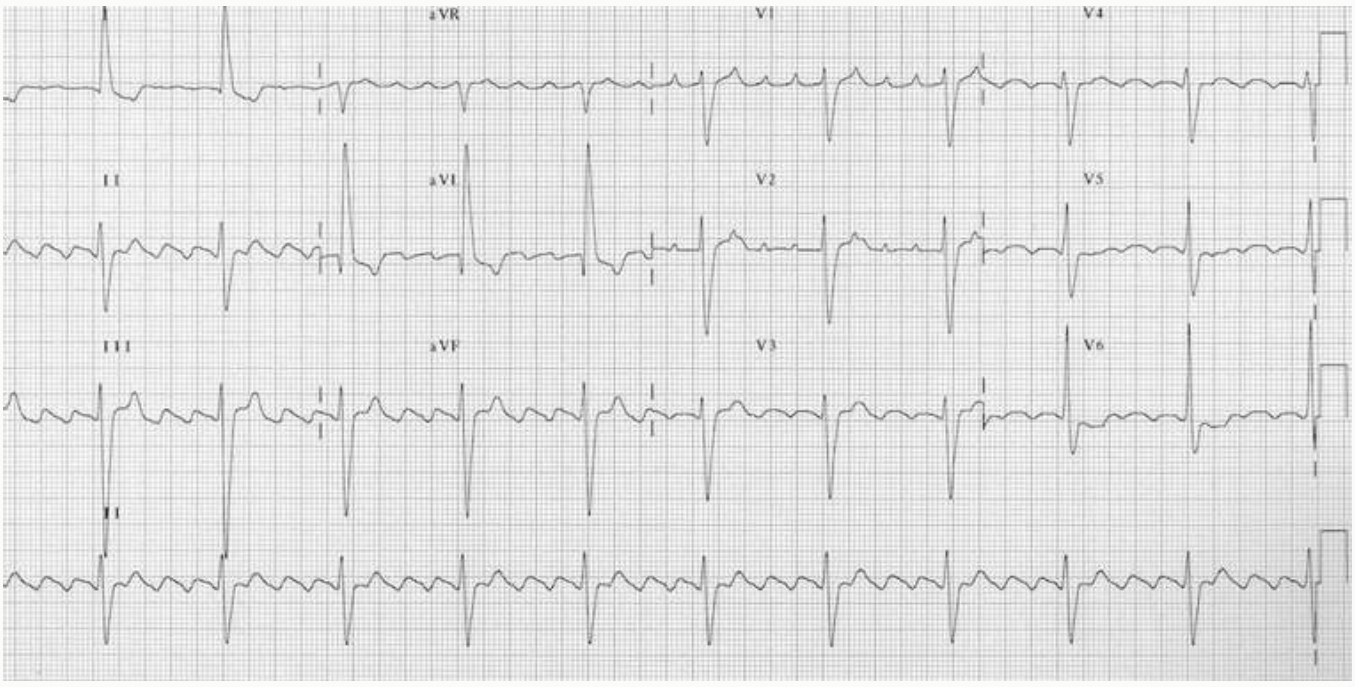

Figure 16.15 A 12-lead ECG showing atrial flutter with 4:1 block: sawtooth flutter waves, with one QRS complex for every four flutter waves. (credit: "Atrial flutter with 4:1 block" by LITFL/Life in the Fast Lane, CC BY-NC-SA 4.0)

AF harms the patient in three ways. First, losing the **atrial kick**, the atrial contraction that tops up ventricular filling, lowers stroke volume. Second, a **rapid ventricular response (RVR)**, a ventricular rate above 100 per minute in AF, shortens filling time even further and can cause hypotension, heart failure or ischemia; a fast rate that lasts for weeks can weaken the ventricle (tachycardia-mediated cardiomyopathy) (Andrade et al., 2020). Third, blood pools in the quivering atria, especially in the left atrial appendage,

where clots can form and travel to the brain. AF-related strokes tend to be the most severe (Canadian Cardiovascular Society [CCS], n.d.). Weak beats may not reach the wrist, so the radial pulse can be lower than the apical pulse (section 16.2).

AF in Canada

The 2020 Canadian Cardiovascular Society and Canadian Heart Rhythm Society (CCS/CHRS) guidelines describe AF as the most common sustained dysrhythmia. They estimate that 1% to 2% of the general population has AF, rising to about 4% at age 65 and about 12% at age 80 or older. When people with paroxysmal and silent AF are counted, the estimated number of Canadians with AF rises from 500,000 to nearly 1 million. In 2007–2008, AF accounted for 76,964 emergency department visits and 64,214 acute care admissions in Canada (Andrade et al., 2020).

Established risk factors include older age, male sex, hypertension, heart failure with reduced ejection fraction, valve disease, overt thyroid disease, obstructive sleep apnea, obesity, heavy alcohol use and congenital heart disease. Emerging risk factors include diabetes, chronic kidney disease, coronary artery disease and tobacco use (Andrade et al., 2020). Many can be changed, so AF care includes managing them.

Stroke Prevention

The CCS uses a decision tool, the **CHADS-65** algorithm (the "CCS algorithm"), to decide who needs an anticoagulant (Andrade et al., 2020):

- **Step 1:** If the person is 65 years or older, oral anticoagulation (OAC) is recommended.
- **Step 2:** If the person is younger than 65 but has at least one CHADS2 risk factor (congestive heart failure, hypertension, diabetes, or a previous stroke or transient ischemic attack), OAC is recommended.
- **Step 3:** If the person is younger than 65, has no CHADS2 risk factor but has coronary or peripheral arterial disease, a single antiplatelet drug such as acetylsalicylic acid (ASA) is suggested instead of OAC.
- **Step 4:** If none of these applies, no routine antithrombotic drug is suggested.

For most patients with AF who need OAC, the CCS recommends a direct oral anticoagulant (DOAC), such as apixaban, dabigatran, edoxaban or rivaroxaban, over warfarin. Warfarin remains the drug for people with a mechanical heart valve or moderate to severe mitral stenosis (Andrade et al., 2020). Bleeding risk, drug interactions, adherence and kidney function are reassessed regularly, and bleeding risks are reduced by controlling blood pressure, avoiding nonsteroidal anti-inflammatory drugs (NSAIDs) and preventing falls (Andrade et al., 2020). Chapter 19 covers anticoagulants in full.

Rate and Rhythm Control

Rate control slows the ventricular response. When the left ventricular ejection fraction (LVEF) is above 40%, the CCS lists beta-blockers or the nondihydropyridine calcium channel blockers diltiazem and verapamil as first-line choices. When the LVEF is 40% or less, beta-blockers such as bisoprolol, carvedilol or metoprolol come first, and IV calcium channel blockers are used with caution because they can worsen heart failure. Digoxin or amiodarone may be used when heart failure is decompensated or blood pressure is low; digoxin can also be added to other drugs or used alone in older or less active people with permanent AF. The long-term target is a resting heart rate under 100 per minute (Andrade et al., 2020).
